for compositionality in language**
O. ĩrsoy and C. Cardie

**AtomNet: a deep convolutional neural network
for bioactivity prediction in structure-based
drug discovery**
I. Wallach et al.

CNNs can leverage molecule shapes (on a 3-dimensional grid) for drug discovery.

Unsupervised representation learning with deep convolutional generative adversarial networks
A. Radford et al. (2016)

- Replace pooling layers with strided convolutions (discriminator) or fractionally strided convolutions (generator);
- Remove fully-connected layers;
- Use batch normalization;
- Use ReLU (generator), tanh (generator output) and leaky ReLU (discriminator).

Convolutional networks on graphs for learning molecular fingerprints
D. Duvenaud et al.

To fingerprint molecules (or graphs), for each node, compute a hash of its neighbours, then a hash of the neighbours' hashes, and so on (circular fingerprints). Alternatively, use a graph convnet with large random weights and tanh activations.

Geometric deep learning on graphs and manifolds using mixture model CNNs
F. Monti et al.

CNNs can be defined on arbitrary graphs or manifolds, not just lattices in Euclidian space. For instance, for each vertex x , and each neighbouring vertex $y \in \mathcal{N}(x)$, define pseudo coordinates $\mathbf{u}(x, y)$ (e.g., geodesic polar coordinates (ρ, θ) on a surface, or the degree on a graph), apply a weight function $\mathbf{w}(\mathbf{u}(x, y))$ (e.g., a Gaussian or triangular kernel, possibly with a learnable parameter) and set

$$D_j(x)f = \sum_{y \in \mathcal{N}(x)} \mathbf{w}(\mathbf{u}(x, y))f(y).$$

Graph stream algorithms: a survey
A. McGregor

Many graph problems can be solved, at least approximately, with streaming data, *i.e.*, without storing the whole graph in memory (but you still need $\Omega(\#V)$ storage):

- Test connectivity by building a spanning forest (a set of edges): add the next edge $\{u, v\}$ if there is currently no path from u to v ;
- Approximate distances by building a subgraph: add the next edge $\{u, v\}$ if the current $d(u, v)$ is above some threshold (*i.e.*, if the new edge closes a small loop);
- Minimum spanning tree (MST);
- Approximately count triangles by considering the vectors with coordinates $x_T = \# \text{edges in } T$ where $T \in \mathcal{P}_3(V)$;
- Greedy matching;
- Random walks (\sqrt{t} passes on the data suffice: stitch \sqrt{t} walks of length \sqrt{t}).

Many streaming algorithms use a *linear sketch*, *i.e.*, a random projection (of the adjacency or some related

matrix). Algorithms for sliding window graphs (the last w edges in an infinite stream) often keep the k most recent edges satisfying some property.

Darwini: generating realistic large-scale social graphs
S. Edunov et al.

To generate a (large) graph with prescribed degree and clustering coefficient distributions (conditional on degree):

- Assign a target degree and clustering coefficient to each node;
- Group the nodes in clusters, according to $cd(d-1)$;
- Build an Erdős-Rényi graph on each cluster, choosing the probability (and cluster size) to get the desired expected clustering coefficient (and a degree inferior to the target);
- Add edges between clusters to get the desired degree distribution [tricky for large-degree nodes], trying to keep the joint degree distribution.

How to partition a billion-node graph
L. Wang et al. (2014)

To partition a graph (for distributed processing, or sparse matrix ordering):

- Coarsen it by finding a maximum match (a set of edges sharing no vertices) and collapsing its edges, until the graph is sufficiently small;
- Assign a unique label to each vertex; set the label of each vertex to the majority label in its neighbourhood;
- If there are too many labels, collapse vertices with the same label, and propagate labels anew.

Graphons, mergeons and so on
J. Eldridge et al. (2016)

A **graphon** is a symmetric measurable function $w : [0, 1]^2 \rightarrow [0, 1]$. It can be seen as a weighted graph on the uncountable vertex set $[0, 1]$. It defines a sequence of random graphs (graph-valued random variable) $(G_n)_n$, where G_n samples n points x_i uniformly in $[0, 1]$ and then an edge $i-j$ with probability $w(x_i, x_j)$. It is *consistent* (the random graph obtained by removing the $(n+1)$ st vertex from G_{n+1} has the same distribution as G_n) and *local* (if $S, T \subset [n]$ are disjoint, then $G_n|_S \perp\!\!\!\perp G_n|_T$); these properties characterize graphons. A subset $A \subset [0, 1]$ is *disconnected* at level λ if there exists $S \subset A$ such that $0 < \mu(S) < \mu(A)$ and $w < \lambda$ on $S \times (A \setminus S)$. Define an equivalence relation \sim on the set \mathcal{A}_λ of λ -connected subsets by $A_1 \sim A_2$ iff $\exists A \in \mathcal{A}_\lambda \quad A \supset A_1 \cup A_2$. The clusters at level λ are the (essential) largest elements in each equivalence class. A **mergeon** describes how clusters merge as λ decreases: it is a graphon M such that

$$M^{-1}[\lambda, 1] = \bigcup_{C \text{ } \lambda\text{-cluster}} C \times C.$$

GraphChi-DB: simple design for a scalable graph database system – on just a PC

A. Kyrola and C. Guestrin

Adapt the *log-structured merge tree* (LSM tree) to store edges: partition them on the destination vertex, but sort each partition along the source vertex.

Time series analysis of the S&P 500 index: a horizontal visibility graph approach

M.D. Vamvakaris et al. (2017)

The *horizontal visibility graph* is a variant of the visibility graph:

- Fit the degree distribution with a power law: if the exponent is greater than $\log 3/2$, the time series is auto-correlated; if it is less, it is chaotic;
- The *Hellinger distance* between the in- and out-degree distributions measures irreversibility.

Process systems engineering as a modeling paradigm for analyzing systemic risk in financial networks

R. Bookstaber et al. (2015)

The financial system can be modeled as a *signed-directed graph* (SDG): the directed arcs represent causal relations, and the sign of $x \rightarrow y$ is that of $\partial y / \partial x$. *Process hazard analysis* can help identify feedback loops, which amplify shocks – many agents act in a locally stabilizing but globally destabilizing way.

Diffusion-convolutional neural networks

J. Atwood and D. Towsley (2016)

On a graph, one can forecast node labels Y from node features X by using the $A^n X$ as predictors, where A is the adjacency matrix. Averaging over the nodes, this can be generalized to edge or graph labels.

A machine learning perspective on predictive coding with PAQ

B. Knoll and N. de Freitas (2011)

Prediction by partial matching (PPM) is a lossless compression algorithm well-suited to text:

- Start with a prior probability distribution on the letters;
- Encode the first character with the Huffman code or the arithmetic code for this distribution;
- Somehow update the probability distribution; iterate.

For instance, one could use an n -gram model, *i.e.*, keep track of all the substrings seen so far, and use

the longest matches to predict (the probability) of the next letter. With noisy inputs, approximate matching helps. For images, scan by row or column, or along a space-filling curve (Hilbert) – you can beat JPEG but not JPEG2000.

PAQ8 uses 500 such models, for bit-level predictions, ensembled with a *mixture of experts* (implemented as a neural net).

Compression can be used to define distances

$$d_C(x, y) = \frac{C(x|y) + C(y|x)}{C(xy)}$$

$$d_{\text{CDM}}(x, y) = \frac{C(xy)}{C(x) + C(y)}$$

$$d_e(x, y) = \frac{1}{2} [E[x|y] + E[y|x]]$$

$$d_{\text{NDM}}(x, y) = \frac{C(x, y) - \text{Min}\{C(x), C(y)\}}{\text{Max}\{C(x), C(y)\}}$$

where $C(x)$ is the compressed size of x (approximation of its Kolmogorov complexity), $C(x|y)$ is the compressed size of x if the compressor is trained on y , $E[x|y]$ is the corresponding cross-entropy of x .

Arithmetic coding encodes a text given a sequence of probability distributions on letters, as a single rational number: divide the interval $[0, 1]$ into segments, one for each possible letter, of length their probabilities; pick the segment corresponding to the current letter; repeat the process on that segment, with the next letter; iterate and return any rational number in the final segment.

A brief review of the ChaLearn AutoML challenge

I. Guyon et al. (2016)

AutoML is a competition for automated (black-box, with no human intervention) supervised learning, combining the following ideas:

- Decision trees, k -NN, naive Bayes, neural nets;
- Uniformize, replace missing values, group modalities of categorical variables, feature selection, dimension reduction (PCA, kPCA, ICA, MDS, LLE, Laplacian eigenmaps), clustering (k -means)
- Hyperparameter tuning (SMAC, hyperopt)
- Model selection (k -fold cross-validation, l.o.o, o.o.b., bilevel optimization).

Structure discovery in nonparametric regression through compositional kernel search

D. Duvenaud et al. (2013)

The “automated statistician” performs a search in a space of kernel structures, built from sums and products of linear, square exponential, periodic, etc. bricks, in a Gaussian process.

**Machine learning techniques: reductions
between prediction quality metrics**
A. Beygelzimmer et al.

Reduction is the set of techniques converting a loss-minimization problem into a well-studied machine-learning one, typically binary classification or regression. Examples include:

- Importance-weighted classification (different cost for false positives and negatives) by reweighting the training set;
- Multiclass classification with one-against-all (inconsistent), error correcting codes (ECOC, inconsistent), probabilistic ECOC, all-pairs;
- Cost-sensitive multiclass classification, with weighted all-pairs;
- Quantile regression with importance weighted classification;
- Ranking (of binary data).

Multi-view machines
B. Cao et al.

Sparse variant of factorization machines.

**FastDBT: A speed-optimized
and cache-friendly implementation
of stochastic gradient-boosted decision trees
for multivariate classification**
T. Keck

May be faster than XGBoost. Also check LightGBM and CatBoost.

**Coresets for scalable
Bayesian logistic regression**
J.H. Higgins et al. (2016)

Replace large datasets with a *coreset*, i.e., a weighted (smaller) subset (obtained, e.g., from an approximate streaming clustering algorithm) to approximate Bayesian posterior likelihood (for logistic regression).

**Domain-adversarial training
of neural networks**
Y. Ganin et al. (2016)

Domain adaptation (DA) is the transfer of a model from one domain to another, sometimes by a mapping (alignment) between the two domains.

One can also use an adversarial approach to build domain-invariant features.

Progressive neural networks
A.A. Rusu et al.

To learn a task related to an already-learned one, consider a new neural net, parallel to the first one, initialized with random weights, with lateral connections. To keep the model scalable (task $n + 1$ has connections from tasks $1, 2, \dots, n$), use dimension reduction (single-layer network) for those lateral connections.

**Net2Net: accelerating learning
via knowledge transfer**
T. Chen et al. (2016)

Transform an already trained network into a deeper one by inserting a layer initialized as the identity function, or into a wider one by duplicating some of the nodes (keep their input weights and halve their output weights).

Sampling generative networks
T. White (2016)

In high dimensions, linear interpolation goes through atypical points (too close to the origin): prefer *spherical interpolation*.

To study analogies, e.g., king – man + woman, generate images in a grid having those three points as corners.

In the latent space, find the directions corresponding to “smile”, “open mouth”, “gender” or even “blurry” and generate a 1- or 2-dimensional grid of images by moving along those directions.

**Efficient convolutional auto-encoding
via random verification
and frequency-domain minimization**
M.C. Oventneke et al. (2016)

Use random projections for the non-linear encoding part of the auto-encoders, and only learn the (linear) decoding part. [cf echo networks, reservoir learning]

Universal adversarial perturbations
S.M. Moosavi-Dezfooli et al.

There exist almost universal adversarial perturbations: a small perturbation which, when added to almost any image, tricks a neural network into misclassifying it.

Matrix neural networks
J. Gao et al. (2016)

If your neural network has matrices as input (instead of vectors), try *bilinear layers*: $Y = \sigma(UXV' + B)$ (U , V and B are matrices).

**FastText.zip:
compressing text classification models**
A. Joulin et al.

Product quantization decomposes the space into k orthogonal subspaces $\mathbf{R}^n = \bigoplus_{i=1}^k V_i$, computes 2^b (with $b = 8$) k -means centroids in each of them, and approximates points as sums of those centroids $x \approx \sum q_i(x)$.

Use when you want to approximate scalar products – e.g., for vector embeddings.

Tensorizing neural networks
A. Novikov et al.

Dimension reduction (TensorTrain) for dense weight matrices (of fully-connected layers).

**Neural network based clustering
using pairwise constraints**
Y.C. Hsu and Z. Kira (2016)

Cluster data by training a (softmax) network on similar and dissimilar *pairs*.

**Composing graphical models
with neural networks for structured
representations and fast inference**
M.J. Johnson et al.

Use neural nets to add non-linear transformations to your graphical models; inference is tricky: SVAE (structural variational encoders) use stochastic gradients of a variational approximation.

**mgm: Structure estimation
for time-varying mixed graphical models
in high-dimensional data**
J.M.B. Haslbeck and L.J. Waldorp

To estimate a Gaussian graphical model, identify the neighbourhood of each node with a lasso regression. For mixed data (exponential family), use GLMs. For time-varying models, use (Gaussian) weights.

**Inference compilation
and universal probabilistic programming**
T.A. Le et al.

Neural networks can be trained to provide better proposal distributions for sequential importance sampling (SIS).

Memory efficient kernel approximation
S. Si et al. (2014)

Approximate large kernel matrices as a direct sum of low-rank matrices, where the blocks correspond to clusters.

**Multi-class generative adversarial networks
with the L^2 loss function**
X. Mao et al.

Replace the sigmoid cross-entropy loss in the discriminator with an L^2 loss.

**GANs for sequences of discrete elements
with Gumbel-softmax distribution**
M. Kusner and J.M. Hernández-Lobato

The Gumbel softmax distribution is the distribution of

$$y = \text{softmax} \frac{1}{\tau(h + g)}$$

where $g_i \stackrel{\text{iid}}{\sim} \text{Gumbel}(0, 1)$. When $\tau \rightarrow 0$, this becomes the one-hot encoding of $h_i + g_i$, i.e., $y \sim \text{Multinomial}(p)$, where $p = \text{softmax } h$, i.e., $p_i \propto \exp h_i$. It can be used as a differentiable approximation of the multinomial distribution, e.g., in GANs.

**Augmenting supervised neural networks
with unsupervised objectives
for large-scale image classification**
Y. Zhang et al. (2016)

Augment supervised networks with autoencoder losses.

Infinite-dimensional word embedding
E.T. Nalisnick and S. Ravi (2016)

Make word embeddings “infinite dimensional” by initializing them with high-dimensional (not really infinite) vectors, using only the first z components, with a penalty for z , and a sparsity penalty on the vectors [unrelated to Dirichlet processes, iHMM and other finite-dimensional models].

Pointer networks
O. Vinyals et al.

Attention-based networks for TSP, convex hull, Delaunay triangulation.

Structured prediction energy networks
D. Belanger and A. McCallum (2016)

Structured prediction can be performed indirectly, by learning an energy function and minimizing it.

For instance, the model could use a 2-layer neural net to compute features and combine them, linearly and bilinearly, with the label. The problem can be relaxed from $y \in \{0, 1\}^n$ to $y \in [0, 1]^n$.

To learn the model, notice that we want $\forall y E(x_i, y) \geq E(x_i, y_i)$, with a larger difference if y and y_i are far apart, e.g., $\forall y E(x_i, y) - E(x_i, y_i) \geq d(y, y_i) \geq 0$. This suggests minimizing a *structured SVM* (SSVM) loss

$$\sum_i \text{Max}_y [d(y, y_i) - E(x_i, y) + E(x_i, y_i)]_+.$$

Machine learning techniques for Stackelberg security games: a survey
G. De Nittis and F. Trovò (2016)

In the Stackelberg security game (SSG), a defender protects T targets from an attacker, by allocating resources $R < T$. The strategies are $\{x \in \mathbf{R}^T : 0 \leq x \leq 1, x' \mathbf{1} \leq R\}$. If the adversary attacks t , both receive a penalty and a reward:

$$\begin{aligned} \text{Attacker} &: x_t P_t^a + (1 - x_t) R_t^a \\ \text{Defender} &: (1 - x_t) P_t^d + x_t R_t^d \end{aligned}$$

Boundedly rational adversaries attack a target at random, with a probability depending on their (potentially incorrect) subjective utility. The subjective utility function can be estimated from data (poaching and illegal fishing provide real-world data). The defender's strategy should be robust to suboptimal adversaries.

Apprenticeship learning using inverse reinforcement learning and gradient methods
G. Neu et al. (2007)

Inverse reinforcement learning (IRL) learns a policy (a map from state features to actions) from an expert's observed behaviour. Instead, one can learn the

reward function for which the optimal policy is as close to the expert's as possible.

Dueling network architectures for deep reinforcement learning
Z. Wang et al.

In deep reinforcement learning, separately learn the state value function and the state-dependent action advantage function.

Deep successor reinforcement learning
T.D. Kulkarni et al.

Successor reinforcement learning learns the value function as the inner product between a reward predictor and a successor map.

Convexified convolutional neural networks
Y. Zhang et al. (2016)

Training a 1-hidden-layer CNN with linear activations is an optimization problem with a low-rank constraint (corresponding to weight sharing) which can be relaxed into a nuclear norm constraint. For non-linear activations, use a kernel (RKHS). For deeper networks, this no longer works, but greedy layer-wise training seems a good heuristic.

End-to-end kernel learning with supervised convolutional kernel networks
J. Mairal (2016)

A *convolutional kernel network* uses the kernel trick to increase the dimension and add non-linearities

$$\mathbf{R}^n \xrightarrow{\phi} \mathbf{R}^N \xrightarrow{\text{projection}} \mathbf{R}^m, \quad N \gg n, m$$

without explicitly computing the high-dimensional coordinates. The kernel parameters can be learnt as usual.

Network in network
M. Lin et al.

CNNs slide simple masks over an image, to detect features. Instead, one could slide slightly deeper networks ("micro-networks").

Towards a mathematical theory of super-resolution
E.J. Candès and C. Fernandez-Granda (2012)

It is possible to recover a spike train (*i.e.*, a discrete complex measure, $x = \sum_i a_i \delta_{t_i}$) from low-resolution measurements or, equivalently, from a truncated Fourier transform $\hat{x} = \mathcal{F}_n x$, by solving a convex problem

$$\begin{aligned} \text{Find} & \quad y, \text{ a complex measure} \\ \text{To minimize} & \quad \|y\|_{\text{TV}} \\ \text{Such that} & \quad \mathcal{F}_n y = \hat{x} \end{aligned}$$

provided the spikes are sufficiently separated, where the total variance of a measure μ on $[0, 1]$ is a continuous analogue of the ℓ^1 norm:

$$\|\mu\|_{TV} := |\mu|([0, 1]).$$

Multiscale Retinex
A.B. Petro et al. (2014)

The *retinex* algorithm is a local contrast enhancement algorithm. Consider random walks from a point, x_0, x_1, \dots, x_n ; compute

$$L = \sum \delta \left(\log \frac{I(x_k)}{I(x_{k+1})} \right),$$

where $\delta(u) = u \mathbf{1}_{|u| \geq t}$ is a thresholding function, and use $\langle L \rangle$ as the new luminance.

Alternatively, use the ratio of a pixel value to the average of its neighbours (with Gaussian weights); repeat for several scales ($\sigma = 15, 80, 250$), and average. Restore the colours to their original range, or apply the algorithm to the intensity channel only.

A point set generation network for 3D object reconstruction from a single image
H. Fan et al.

To reconstruct a 3D scene as a cloud of points (union of balls – this eliminates overlap and connectivity problems), learn a neural net consuming an image and random data. The resulting shape sampler also accounts for ground truth ambiguity.

Spatial transformer networks
M. Jaderberg et al.

Add a transformation layer, to help align images – it is differentiable, so it will go through gradient descent.

StackGAN: text to photorealistic image synthesis with stacked generative adversarial networks
H. Zhang et al.

Stack several GANs, generating images of increasing resolution.

The more you know: using knowledge graphs for image classification
K. Marino et al.

LSTMs can be generalized to arbitrary DAGs (instead of time, $\bullet \rightarrow \bullet \rightarrow \bullet \rightarrow \bullet \rightarrow \bullet$).

Propagating over the “promising” subset of the graph may be sufficient.

A deep and autoregressive approach for topic modeling of multimodal data
Y. Zheng et al. (2016)

Represent images as bags of visual words (e.g., SIFT features) to use topic models (LDA, DocNADE).

v_1, \dots, v_d words

$p(\mathbf{v}) = \prod p(v_i | \mathbf{v}_{<i})$ or a balanced binary tree

$$\mathbf{h}_i(\mathbf{v}_{<i}) = g \left(c + \sum_{k < i} W_{\bullet, v_k} \right)$$

$$p(v_i = w | \mathbf{v}_{<i}) \propto \exp(b_w + V_{w, \bullet} \mathbf{h}_i(\mathbf{v}_{<i}))$$

Simplicial mixtures of Markov chains: distributed modelling of dynamic user profiles
M. Girolami and A. Kabán

Variant of latent Dirichlet allocation (LDA: a document is a mixture of topics, a topic is a distribution on words) for mixtures of Markov chains: user activity is a mixture of behaviours, a behaviour is a distribution on sequences (Markov chains).

Solving heterogeneous estimating equations with gradient forests
S. Athey et al. (2016)

Random forests are (high-dimensional) adaptive nearest neighbour functions: they can be used as an alternative to kernel-based weighting, where the weight of an observation is the proportion of trees in which it is in the same leaf as the point of interest. The choice of the splits can be tailored to the model (quantile regression, etc.) by minimizing the after-cut squared error, or some gradient-based approximation.

Implementation in `gradientForest`, `ranger`.

bartMachine: machine learning with Bayesian additive regression trees
A. Kapelner and J. Bleich

Forests of regression (not classification) trees, with a prior on tree structure and leaf parameters:

- Nodes at depth d are non-terminal with probability $\alpha(1+d)^{-\beta}$, $\alpha = .95$, $\beta = 2$,
- Splitting variables are selected uniformly at random,
- Splitting values are sampled from the multiset of values taken,
- The parameters are Gaussian,
- The noise is inverse Gamma,

estimated with Metropolis-within-Gibbs sampling (Metropolis for the tree structure, Gibbs for the rest), in Java.

On the generalized ratio of uniforms as a combination of transformed rejection and extended inverse of density sampling
L. Martino et al.

Let p be a monotonic probability density (e.g., a half-Gaussian) and

$$\mathcal{A} = \left\{ (u, v) \in \mathbf{R}^2 : 0 \leq u \leq \sqrt{p(v/u)} \right\},$$

If $(U, V) \sim \text{Unif } \mathcal{A}$, then $V/U \sim p$.

This can be generalized: let $g : \mathbf{R}_+ \rightarrow \mathbf{R}$, \mathcal{C}^1 , strictly increasing, $g(0) = 0$,

$$\mathcal{A}_g = \left\{ (u, v) \in \mathbf{R}^2 : 0 \leq u \leq g^{-1} \left[c \cdot p \left(\frac{v}{g(u)} \right) \right] \right\},$$

if $(U, V) \sim \text{Unif } \mathcal{A}_g$, then $V/g(U) \sim p$.

Inverse of density sampling, for monotonic probability density functions, uses

$$(X, Y) \sim \text{Unif} \{ (x, y) : 0 \leq y \leq p(x) \}$$

or, if it is easier to sample from p^{-1} ,

$$Y \sim p^{-1}, \quad X \sim \text{Unif}[0, p^{-1}Y].$$

In both cases, $X \sim p$.

For non-monotonic densities, decompose them into intervals on which they are either increasing or decreasing.

Pareto smoothed importance sampling
A. Vehtari et al. (2016)

Importance sampling estimates

$$\int f dP = \int f \frac{dP}{dQ} dQ \approx \frac{1}{N} \sum f(x_i) \frac{p(x_i)}{q(x_i)},$$

where $x_i \sim Q$, when it is easier to sample from Q than P . If p is only known up to a normalization factor,

$$\int f dP \approx \frac{\sum f(x_i) \frac{p(x_i)}{q(x_i)}}{\sum \frac{p(x_i)}{q(x_i)}}.$$

To stabilize this ratio estimate, one can truncate the weights $w_i = p(x_i)/q(x_i)$, but this introduces bias. Alternatively, one can fit a Pareto distribution to their tail and replace the tail values with the corresponding Pareto quantiles.

Constrained maximum correntropy adaptive filtering
S. Peng et al. (2016)

Maximum correntropy estimators use a kernel as a loss function, e.g.,

$$\begin{aligned} \text{Loss}(\hat{y}, y) &= - \sum \kappa(\hat{y}, y) \\ \kappa(x, y) &= \exp - \frac{1}{2} \left(\frac{x - y}{\sigma} \right)^2 \end{aligned}$$

Learning design patterns with Bayesian grammar induction
J.O Talton et al. (2012)

It is not possible to learn a (deterministic) grammar from positive examples, but it is possible for probabilistic languages (grammar induction). A Bayesian approach would be:

- Build a grammar that recognizes all exemplars and nothing else;
- Modify it (MCMC), to reduce its length while keeping the likelihood high.

A case for robust Bayesian priors with applications to binary clinical trials
J.A. Fúquene et al.

Conjugate Bayesian analysis is not robust to the prior. The Cauchy prior (for the normal log-odds model, or the binomial model for binary data) is robust but does not lead to a closed form posterior. *Berger's prior* (a continuous mixture of Gaussians) is also robust and does.

RUSBoost: a hybrid approach to alleviating class imbalance
C. Seiffert et al. (2010)

Class imbalance can be addressed by:

- Adding more samples to the minority class: over-sampling, boosting, extrapolating (SMOTE);
- Removing samples from the majority class: under-sampling (RUS).

Those methods can be combined.

Orthant probabilities for robust correlation and structural performance enhancement
M. Anderson et al. (2015)

To capture non-linear effects with correlations, notice that if (X, Y) is Gaussian

$$\begin{aligned} P_{ij} &= P[(-1)^i X > 0 \wedge (-1)^j Y > 0] \quad i, j \in \{0, 1\} \\ &= \frac{1}{4} + \frac{(-1)^{i+j}}{2\pi} \arcsin \rho \end{aligned}$$

and convert those orthant probabilities into 4 **quadrant correlations**.

Efficient thresholded correlation using truncated singular value decomposition
J. Baglama et al. (2016)

To find all pairs of variables (X_i, X_j) with correlation above a threshold $0 < t < 1$ without examining them all, notice that, if $\forall i \|x_i\| = 1$,

$$\|x_i - x_j\|^2 > 2(1 - t) \implies \text{Cor}(x_i, x_j) < t$$

and $\|Px_i - Px_j\| \leq \|x_i - x_j\|$ if P is a projection. Only examine pairs of vectors whose projections on the first few singular vectors are sufficiently close.

A survey of discretization techniques: taxonomy and empirical analysis in supervised learning
S. García et al. (2013)

Comparison of 80 discretization algorithms (equal width, equal frequency, χ^2 , etc.), without any detail.

Efficient thresholded correlation using truncated singular value decomposition
J. Baglama et al. (2016)

To find the most correlated (*i.e.*, the closest) pairs of unit vectors, project them on the first singular value dimensions.

Model selection for Gaussian process regression by approximation set coding
B. Fischer et al.

Approximation set coding (ASC) is a model selection procedure maximizing the posterior agreement η_θ

$$\begin{aligned}\theta &: \text{hyperparameters} \\ \alpha &: \text{parameters} \\ p_\theta(\alpha) &: \text{prior} \\ D &= D_1 \sqcup D_2 \text{ random partition of the data} \\ \eta_\theta &= \int p_\theta(\alpha|D_1)p_\theta(\alpha|D_2)p_\theta(\alpha)d\alpha.\end{aligned}$$

The likelihood can be:

$$\begin{aligned}p(\alpha|D) &\propto p_\theta(D|\alpha)p_\theta(\alpha) && \text{Bayesian} \\ (\alpha|D) &\propto p_\theta(D|\alpha)^\beta && \text{Entropy } (\beta = 1).\end{aligned}$$

It can be used to select the kernel of a Gaussian process: square exponential e^{-x^2} , rational quadratic $(1+x^2)^{-\alpha}$, exponential $e^{-|x|}$, periodic $e^{-\sin^2 x}$.

Counterfactual prediction with deep instrumental variable networks
J. Hartford et al.

Instrumental variables can be added to deep neural networks.

Doubly stochastic neighbor embedding on spheres
Y. Lu et al.

Normalizing the t-SNE similarity matrix to make it doubly stochastic limits the crowding around the origin. The resulting approximately spherical embedding can be plotted on \mathbf{S}^2 .

Causal inference and the data-fusion problem
E. Bareinboim and J. Pearl (2016)

The rules of *do-calculus* (for causal inference) can be expressed in terms of conditional independence and graphical models.

Principled detection of out-of-distribution examples in neural networks
S. Liang et al.

To help detect out-of-distribution observations, increase the temperature of the softmax

$$p_i(x) \propto \exp \frac{f_i(x)}{T}$$

and add noise $x \leftarrow x - \varepsilon \cdot \text{sign} - \nabla_x \log p_{\hat{y}}(x)$.

HiCS: high contrast subspaces for density-based outlier ranking
F. Keller et al.

Outlier detection algorithms often compare the density of a point with that of its neighbours – they suffer from the curse of dimensionality. Instead, compute the LOF (local outlier factor) for high-contrast subspaces, defined as axis-aligned subspaces on which the conditional distributions $Y|X = x$ (estimated on slices $Y|x_1 \leq Xx_2$) and the marginal distribution Y are significantly different, as measured by a Welsh test (T test with unequal variances) or a Kolmogorov-Smirnov test.

Programming with models: writing statistical algorithms for general model structures with Nimble
P. de Valpine et al.

Nimble lets you describe a computational graph in R, and compiles it into C++, for use in Bugs; it also lets you change how the data is sampled (importance sampling, Metropolis Hastings).

sgof: an R package for multiple testing problems
O. Castro-Conde and J. de Uña-Álvarez

For a large number of tests, SGoF (sequential goodness of fit, which compares $\#\{p : p < \gamma\}$ with its expected value γ under H_0) is more powerful than FDR or FWER approaches. Also check: `qvalue` (the q-value is the proportion of false positives), `HybridMTest`, `multtest`, `mutoss`, `multcomp`, `stats::p.adjust`.

conting: an R package for Bayesian analysis of complete and incomplete contingency tables
A.M. Overstall and R. King (2014)

Log-linear models, for contingency tables, are of the form

$$\begin{aligned}y_1 &\sim \text{Poisson } \mu_i \\ \mu_i &= x'_i \theta\end{aligned}$$

where i is a multiindex and \mathbf{x} a design matrix describing which interactions the model allows. For instance, $\mu_{ijk} = a + b + i + c_j + d_k$ or $\mu_{ijk} = a + b + i + c_j + d_k + e_{ij} + f_{ik} + g_{jk}$. In a Bayesian context, the model \mathbf{x} is also unknown. The *generalized hyper-g-prior* for $\theta|x$ is the posterior from a locally uniform prior and an imaginary sample of size $1/\sigma^2$.

**Counterfactual:
an R package for counterfactual analysis**
M. Chen et al.

Given two populations 0 and 1 (e.g., men and women), counterfactual analysis tests if the differences in the distributions of the same variable y (e.g., salary) comes from different characteristics x (are the marginal distributions x the same?) or a different treatment (are the conditional distributions $y|x$ the same?).

$$F_{\langle ij \rangle}(y) = \int_{\mathcal{X}_j} F_{Y_i|X_j}(y|x) dF_{X_j}(x), \quad i, j \in \{0, 1\}$$

$$F_{\langle 11 \rangle}^{-1} - F_{\langle 00 \rangle}^{-1} = (F_{\langle 11 \rangle}^{-1} - F_{\langle 01 \rangle}^{-1}) + (F_{\langle 01 \rangle}^{-1} - F_{\langle 00 \rangle}^{-1})$$

Multilabel classification with R package mlr
P. Probst et al.

Multiple label classification assigns several labels (or “tags”) to each observation. One could train a classifier for each label, sepeartely, but this assumes they are independent. Instead, one can add all or some of the labels, either the true or forecasted values, to the predictors.

**coxphMIC: an R package for sparse
estimation of Cox proportional hazards models
via approximate information criteria**
R. Nabi and X. Su

Best subset selection models add a penalty of the form $\lambda \sum \mathbf{1}_{\beta_i \neq 0}$, with $\lambda = 2$ (AIC) or $\lambda = \log n$ (BIC). It can be relaxed by replacing $\mathbf{1}_{\beta \neq 0}$ with $\tanh \beta^2$ (or $\tanh(a\beta^2)$), but since it is smooth in 0, it does not give sparse solutions. Instead, replace $\beta = \beta \mathbf{1}_{\beta \neq 0}$ with $\beta = \gamma \tanh \gamma^2$ and use $\tanh^2 \gamma$ as a penalty.

**GsymPoint: an R package to estimate
the generalized symmetry point,
an optimal cut-off point
for binary classification
in continuous diagnostic tests**
M. López-Ratón et al.

To find the best cutoff point on a ROC curve, one can use the *symmetric point*, i.e., the intersection with the diagonal $y = 1 - x$, if the costs of false positives and negatives are the same or, more generally, the solution of $\rho(1 - \text{specificity}) = 1 - \text{sensitivity}$, where

$$\rho = \frac{\text{cost FP}}{\text{cost FN}},$$

which corresponds to $E[\text{cost FP}] = E[\text{cost FN}]$. If the scores are Gaussian,

$$Y_{\text{healthy}} \sim N(\mu_0, \sigma_0)$$

$$Y_{\text{diseased}} \sim N(\mu_1, \sigma_1),$$

then $\text{ROC}(x) = \Phi(a + b\Phi^{-1}(x))$, $a = (\mu_1 - \mu_0)/\sigma_1 > 0$, $b = \sigma_0/\sigma_1$. If there is uncertainty on μ_i , σ_i , ρ , one can also compute confidence intervals for the generalized ($\rho \neq 1$) symmetry point.

**spcadjust: an R package for adjusting
for estimation error in control charts**
A. Gandy and T. Kvaløy

Use the bootstrap to estimate the threshold to use in *control charts* to spot a move from $N(\mu, \sigma^2)$ to $N(\mu + \Delta, \sigma^2)$.

$$\text{Shewhart} \quad S_t = \frac{X_t - \hat{\mu}}{\hat{\sigma}}$$

$$\text{CUSUM} \quad S_t = \text{Max} \left\{ 0, S_{t-1} + \frac{X_t - \mu - \frac{1}{2}\Delta}{\sigma} \right\}$$

**Weighted effect coding
for observational data with wev**
R. Nieuwenhuis et al.

With unbalanced classes, consider *weighted effects* to put categorical variables into the design matrix.

**IsoGeneGUI: multiple approaches
for dose-response analysis
of microarray data using R**
M. Otava et al.

Isotonic regression estimates means μ_1, \dots, μ_n under a monotonicity constraint. The corresponding test is $H_0: \forall i \neq j \mu_i = \mu_j$ versus $H_1: \forall i < j \mu_i \leq \mu_j$ or $H_1: \forall i < j \mu_i \geq \mu_j$. The constraint can also be applied to clustering (e.g., by using the isotonic means instead of the raw data).

**milr: multiple-instance logistic regression
with Lasso penalty**
P.Y. Chen et al.

Multiple instance learning considers bags of observations rather than observations:

$$i : \text{bag of instances}$$

$$(i, j) : \text{instance}$$

$$x_{ij} : \text{covariates}$$

$$p_{ij} = g(x'_{ij}\beta) \text{ defect rate of instance } (i, j)$$

$$Y_{ij} \sim \text{Bernoulli}(p_{ij})$$

$$\pi_i : \text{defect rate of bag } i$$

$$\pi_i \propto \sum_j p_{ij} e^{ap_{ij}} \text{ or } 1 - \prod_j (1 - p_{ij})$$

$$\text{or } h\left(\sum h(Y_{ij} = 1)\right).$$

***phtt: Panel data analysis
with heterogeneous time trends in R***
O. Baba and D. Liebl (2014)

Panel models are usually of the form

$$y_{it} = \sum_j x_{ijt} \beta_j + \nu_t + \varepsilon_{it}.$$

Big data allows the time-varying component ν_t to be subject-specific and described by a factor model

$$y_{it} = \sum_j x_{ijt} \beta_j + \nu_{it} + \varepsilon_{it}$$

$$\nu_{it} = \sum_\ell \lambda_{i\ell} f_{\ell t};$$

neither λ nor f is observed, the $f_{\bullet t}$ are orthonormal, so are the $\lambda_{i\bullet}$. The factors can be assumed to be smooth (splines, KSS) or ARIMA (Eup)

***Bayesian state-space modelling
on high-performance hardware using LibBi***
L.M. Murray

LibBi is a BUGS-like language for parallel (multicore CPU, GPU) Bayesian estimation of state space models, using particle filters (sequential Monte Carlo, SMC) instead of Gibbs sampling (as Jags) or Hamiltonian Monte Carlo (HMC, as Stan).

***GPflow: a Gaussian process library
using TensorFlow***
A.G.G. Matthews et al.

Also check: GPy (Python), GPML (Matlab), GPstuff (Matlab).

***Visualizing dependence
in high-dimensional data:
an application to S&P 500 constituent data***
M. Hofert and W. Oldford (2016)

Scatterplot matrices contain each plot twice; it is possible to show each plot only once, while ensuring that each plot shares its vertical (resp. horizontal) axis with a neighbour. This is implemented in the `zenplot` package.

Given a measure of interestingness, one can reduce the number of plots further, and arrange them along an *Eulerian path* (PairViz package).

This can be applied to stock returns, de-GARCHed (ARMA-GARCH residuals, from `qrmtools::fit_ARMA_GARCH`, `rugarch::ugarchfit`) and their tail dependence indices (`copula::fitCopula(tCopula..., method="itau.mpl")`).

***Probabilistic data analysis
with probabilistic programming***
F. Saad and V. Mansinghka

Composable generative population models (CGPM) are a generalization of CrossCat for probabilistic modeling in BayesDB (and its Bayesian query language,

BQL); they can be written VentureScript (a probabilistic programming language) or even Stan.

***Edward: a library for probabilistic modeling,
inference and criticism***
D. Tran et al. (2016)

Edward is a Python probabilistic programming library, built on TensorFlow, based on *variational inference*: describe the model, the priors, a family of posterior approximations, and find the posterior approximation minimizing the KL divergence with the true posterior – this also includes MAP (the posterior approximation of a point mass) and MCMC (an empirical distribution).

***RankPL: a qualitative
probabilistic programming language***
T. Rienstra

Spohn's δ rank theory is a qualitative alternative to probability theory, replacing probabilities with degrees of surprise (ranks). A ranking function $\kappa : \Omega \rightarrow \mathbf{N} \cup \{\infty\}$ is extended to $\mathcal{P}(\Omega)$ as $\kappa(A) = \text{Min}\{\kappa(a), a \in A\}$. (One usually assumes $\kappa(\Omega) = 0$: replace κ with $A \mapsto \kappa(A) - \kappa(\Omega)$ if needed.) The conditional rank is $\kappa(A|B) = \kappa(A \cap B) - \kappa(B)$ if $\kappa(B) \neq \infty$. There is a formal similarity:

Probability	0	1	+	/	×
Rank	∞	0	Min	–	+

TRX: A formally verified parser interpreter
A. Koprowski and H. Binsztok (2010)

PEGs (parsing expression grammars) are very similar to *context-free grammars* (CFG) but

- The choice operator $e_1|e_2$ is prioritized: e_2 is only tried if e_1 fails;
- The repetition operators e^* and e^+ are greedy;
- (There are also predicates, $\&e$ and $!e$, which do not consume any input, and provide unlimited look-ahead and limited backtracking).

PEGs are unambiguous; they formalize what *recursive descent parsers* do (*packrat parsers* are recursive descent parsers with memoization).

Is there an optimal forecast combination?
C. Hsiao and S.K. Wan (2011)

There are many ways of combining forecasts f_{1t}, \dots, f_{nt} of a time series y_t into $\beta' f_t$.

With a small sample, the (unweighted) *simple average* \bar{y}_t works well. With more data, one can correct the bias $\mu + y_t$, or both bias and scale $\mu + c\bar{y}_t$.

Minimizing the mean square error

$$\begin{aligned} \phi(\beta) &= E[(\beta'x - y)^2] \\ &= E[\beta'x\beta'x] - 2E[\beta'xy] + E[y^2] \\ &= E[\beta'xx'\beta] - 2E[\beta'xy] + E[y^2] \\ &= \beta'E[xx']\beta - 2\beta'E[xy] + E[y^2] \end{aligned}$$

$$\phi(\beta + h) = \phi(\beta) + 2h'(E[xx']\beta - E[xy]) + O(\|h\|^2)$$

gives $\beta = E[xx']^{-1}E[xy]$. There are many variants:

- Linear regression;
- Linear regression with no intercept;
- Constrained linear regression, imposing $\beta' \mathbf{1} = 1$, *i.e.*, a convex combination of the forecasts;
- Inverse-mean-square combination (Bates-Granger), *i.e.*, using a diagonal estimator of $E[xx']$;
- Best subset regression, using the AIC, AICC or BIC to select the subset of forecasts to use;
- Bayesian model averaging, *i.e.*, $w_i \propto \exp -\frac{1}{2}\Delta\text{BIC}_i$, where ΔBIC_i is the difference between in BIC between model i and the best model.

One can try to replace the constraint $\beta' \mathbf{1} = 1$ with $\|\beta\|_2 = 1$. This gives the eigenvector e_i for the smallest eigenvalue λ_i , but it has to be rescaled to give an unbiased estimate: $e_i/e'_i \mathbf{1}$. The paper suggests to use the eigenvector minimizing $\lambda_i/(e'_i \mathbf{1})^2$ instead of the first. It is possible to improve the resulting estimator by estimating and correcting for the bias, and by discarding the worst performing forecasts (half of them, if the performance looks stable, or just a quarter), based on their variance or their mean square error.

Prediction with expert advice

N. Cesa-Bianchi and G. Lugosi (2006)

1. *Sequence prediction* tries to forecast the future values of a sequence without any underlying stochastic model: the sequence could be deterministic, stochastic, or even devised by an adversary, dynamically adapting to our behaviour.

Consider the following setup.

- N : number of experts
- n : number of observations
- i : expert
- t : time
- y_t : time series to forecast
- f_{it} : forecast of y_t by expert i
- \hat{p}_t : combination of the experts' forecasts
- $\ell(f_{it}, y_t)$: loss for expert i
- $\ell(\hat{p}_t, y_t)$: loss for the forecaster
- $h(f, y)$: payoff, $-\ell(f, y)$

The regret of not having followed expert i is

$$r_{it} = \ell(\hat{p}_t, y_t) - \ell(f_{it}, y_t)$$

$$R_{in} = \sum_{t=1}^n r_{it} \quad (\text{cumulated regret}).$$

We want to minimize the *cumulated regret* wrt the best expert,

$$\hat{L}_n = \min_{1 \leq i \leq N} L_{in}.$$

2. Here are a few weighted average predictors,

$$\hat{p}_t \propto \sum_{i=1}^N w_{i,t-1} f_{it}.$$

Polynomial	$w_{it} \propto (R_{it})_+^{p-1}$
Exponential	$w_{it} \propto \exp \eta R_{it} \propto \exp -\eta L_{it}$ $\eta = \sqrt{8 \log N/n}$
Gradient	$w_{it} \propto \exp -\eta \sum_{s < t} \nabla_{\hat{p}_s} \ell(\hat{p}_s, y_s) \cdot f_{is}$
Multilinear	$w_{it} \leftarrow (1 + \eta \cdot h(f_{it}, y_t)) \cdot w_{i,t-1}$

The polynomial and exponential predictors can be written $w_{it} \propto \nabla \Phi(R_{it})_i$, for some potential $\Phi(u) = \psi(\sum \phi(u_i))$ or, equivalently, $w_{it} \propto \phi'(R_{i,t-1})$. (While ψ does not affect the weights, different choices lead to different inequalities.)

The multilinear predictor increases or decreases the weights depending on the sign of the payoff.

Methods for pastcasting, nowcasting and forecasting using Factor-MIDAS, with an application to Korean GDP **H.H. Kim and N.R. Swanson (2016)**

Given two (or more) time series with different frequencies, Y (slow) and X (fast), the **MIDAS** model is a regression

$$Y_{y+k} = \beta_0 + \sum_{i=0}^{\ell} \beta_i X_{t-i} + \text{noise}$$

where the β_i have a sparse parametrization, *e.g.*, the *exponential Almon lag model* $\beta_i \propto \exp[\theta_1 i + \theta_2 i^2]$.

Given a large number of time series, “diffusion indices” are latent factors. To estimate them (by PCA), the time series have to be aligned, *e.g.*, by AR interpolation – other methods are available (and preferable): EM, state space model, etc.

A *factor-MIDAS* model is a MIDAS model with those latent factors as predictors.

The many revisions the data undergoes (the preliminary GDP is revised several times, often drastically) complicate the picture – each value has two timestamps: when it was published, and the period it refers to.

Deep symbolic representation learning for heterogeneous time series classification **S. Zhang et al.**

To classify heterogeneous (continuous and categorical) time series, discretize them, consider the values at a point in time as a word, and learn (end-to-end) word embeddings – or character embeddings, representing words as the direct sums of their characters.

PSF: introduction to R package for pattern sequence based forecasting algorithm **N. Bokde et al.**

The pattern sequence-based forecasting (PSF) algorithm forecasts time series by clustering (k -means) historical data into “patterns”. Only use if patterns are actually present (weather, energy, etc.).

***Interpreting finite automata
for sequential data***
C.A. Hammerschmidt et al. (2016)

Finite automata can model sequence data (model each word with an automaton; progressively merge them, selecting the “best” merge each time; stop when no good merge can be found); even large ones may be interpretable (use some graph layout algorithm and domain knowledge to interpret the clusters, bridges, etc.).

***Comparison of pattern detection methods
in microarray time series
of the segmentation clock***
M.L. Dequéant et al. (2008)

To detect patterns: uniformize the data and compute

- $\sigma/(\sigma_1 + \dots + \sigma_4)$, where σ_i is the standard deviation of the i th quarter of the data;
- The number (or proportion) of permutations with the same total variation;
- The persistence diagram of the sublevel sets $[x \leq a]$, for $0 \leq a \leq 1$.

***Detecting periodic patterns
in unevenly spaced gene expression time series
using Lomb-Scargle periodograms***
E.F. Glynn et al. (2005)

The **Lomb-Scargle periodogram** generalizes the discrete Fourier transform to unevenly spaced observations.

$$2\sigma^2 P(\omega) = \frac{\sum (y_i - \bar{y}) \cos^2(\omega(t_i - \tau))}{\sum \cos^2(\omega(t_i - \tau))} + \frac{\sum (y_i - \bar{y}) \sin^2(\omega(t_i - \tau))}{\sum \sin^2(\omega(t_i - \tau))}$$

$$\tau = \frac{1}{2\omega} \arctan \frac{\sum \sin 2\omega t_i}{\sum \cos 2\omega t_i}$$

$$H_0 : P(\omega) \sim \text{Exp}$$

***The cyclohedron test for finding periodic genes
in time course expression studies***
J. Morton et al. (2007)

The *cyclohedron test* tests if a time series (v_1, \dots, v_n) looks cyclic by computing its *signature* $\{\sigma_1, \dots, \sigma_{n-1}\}$

$$\sigma_1 = \{\text{index of the largest element}\}$$

$$\sigma_i = \{\text{index of the } i\text{th largest element}\} \cup \sigma_{k_{\text{left}}} \cup \sigma_{k_{\text{right}}}$$

where $\sigma_{k_{\text{left}}}$ is the latest σ_k containing $\delta_i - 1 \pmod{n}$. The test statistic is the *permutation count*, the number of permutations with the same signature.

***Factor models for matrix-valued
high-dimensional time series***
D. Wang et al. (2016)

Time series of matrices X_t (e.g., country \times variable \times time) can be described by a factor model $X_t = RF_tC' +$

E_t (it is not identifiable, but the column spaces of R and C are).

***On the relation between Gaussian process
quadratures and sigma-point methods***
S. Särkkä et al.

Sigma-point quadrature approximates integrals as

$$\int g(x)p(x)dx \approx w_i g(x_i),$$

where the w_i are predefined (from p) and the x_i 's are chosen according to some criterion, e.g., giving exact results on low-degree polynomials or minimizing the error on some class of functions. They are used in non-linear Kalman filters and can be interpreted as Gaussian process (GP) quadratures.

Lattice methods for multiple integration
I.H. Sloan and S. Joe (1994)

The *Fibonacci rule* estimates a 2-dimensional integral by evaluating it on a lattice

$$\iint_{[0,1]^2} f(x,y) dx dy \approx \frac{1}{F_k} \sum_{j=0}^{F_k-1} f\left(\left\{\frac{j}{F_k}(1, F_{k-1})\right\}\right)$$

where F_n is the n th Fibonacci number and $\{x\}$ is the fractional part of x . In dimension 2, they are the lattices with the best convergence rate.

***Monte Carlo
with determinantal point processes***
R. Bardenet and A. Hardy (2016)

Determinantal point processes (DPP) can be used to build repulsive particle systems, and give an alternative to quasi-Monte-Carlo integration or *scrambled sets* (randomized QMC). A *point process* is a random variable S whose values are finite subsets $[-1, 1]^d$. It may have an *n-correlation function* ρ_n , such that for all bounded measurable $\phi : [-1, 1]^d \rightarrow \mathbf{R}$,

$$E \left[\sum_{\substack{x_1, \dots, x_n \in S \\ \text{all different}}} \phi(x_1, \dots, x_n) \right] = \int_{[-1, 1]^d} \phi(x_1, \dots, x_n) \rho_n(x_1, \dots, x_n) \mu(dx_1) \cdots \mu(dx_n).$$

It is *determinantal* if the n -correlation functions exist and are given by a kernel,

$$\rho_n(x_1, \dots, x_n) = \det k(x_i, x_j)_{1 \leq i, j \leq n}.$$

For the orthogonal polynomial (OP) ensemble, the kernel is given by

$$k_N(x, y) = \sum_{k=0}^{N-1} \phi_k(x) \phi_k(y),$$

where the ϕ_k are the Gram-Schmidt orthonormalization of $x_1^{\alpha_1} \dots x_d^{\alpha_d}$, where the monomials are in the sup-graded lexicographic order.

$$\int f d\mu = E \left[\sum_{i=1}^N \frac{f(x_i)}{k_N(x_i, x_i)} \right]$$

(However, as N increases, the ϕ_k become difficult to compute and sampling from the DPP time-consuming.)

Why interval arithmetic is so useful
Y. Hijazi et al.

Affine arithmetic is a generalization of interval arithmetic.

$$\begin{array}{ccc} a \leq x \leq b & \text{vs} & a \leq \alpha x + \beta y \leq b \\ c \leq y \leq d & & c \leq \gamma x + \delta y \leq d \end{array}$$

Applications in computational geometry include computing surface intersections (ensuring that no bit of the intersection is lost), ray tracing, implicitly-defined surfaces.

A comparison of three high-precision quadrature schemes
D.H. Bailey et al. (2005)

The author's ARPEC C++/F90 multiprecision library also contains an implementation of PSLQ and quadrature schemes, $\int_{-1}^1 f \approx \sum w_j f(x_j)$:

Gauss : $x_j = \text{Roots of Legendre polynomials}$

$$w_j = \frac{-2}{(n+1)P'_n(x_j)P_{n+1}(x_j)}$$

Erf : $x_j = \text{erf}(hj)$

$$w_j = \frac{2}{\sqrt{\pi}} e^{-h^2 j^2}$$

Tanh-Sinh : $x_j = \tanh u_2$

$$w_j = \frac{u_1}{\cosh^2 u_2}$$

$$u_1 = \frac{\pi}{2} \cosh(hj)$$

$$u_2 = \frac{\pi}{2} \sinh(hj)$$

Dynamic trading with predictable returns and transaction costs
N. Gârleanu and L.H. Pedersen (2013)

In presence of transaction costs:

- Do not rebalance all the way to the target portfolio;
- The target portfolio is not the current optimal portfolio, but that in a few periods: the weights of all assets are shrunk, with that of those present because of fast signals shrinking faster.

The dynamic optimization problem can be solved exactly (Bellman equation).

Weighted elastic net penalized mean-variance portfolio design and computation
M. Ho et al. (2015)

Add an elastic net penalty to portfolio optimization problems to control overfitting and portfolio size.

Portfolio optimization based on stochastic dominance and empirical likelihood
T. Post and S. Karabati (2017)

The **empirical likelihood** (EL) tweaks the empirical distribution (from uniform on the sample to multinomial) to ensure some known properties of the population not satisfied by the sample (moment conditions) or add some prior information.

$$\begin{array}{ll} \text{Find} & \pi_1, \dots, \pi_n \\ \text{To maximize} & \sum \log \pi_i \quad (\text{MaxEnt}) \\ \text{Such that} & \sum \pi_i = 1 \\ & \forall j \sum_i \pi_i g_j(x_i) = 0 \quad (\text{Moments}) \end{array}$$

The moment conditions can also be inequalities; the maximum entropy objective is the multinomial log-likelihood. It is often used in econometrics, as an alternative to the generalized method of moments, when the moment conditions depend on a parameter θ , to be estimated with the π_i 's.

To account for dynamic patterns (ARMA, GARCH), blockwise empirical likelihood (BEL) uses overlapping data blocks instead of individual observations.

The resulting distribution can be used for second-order stochastic dominance portfolio optimization (a big linear problem). For instance, one can build a sector rotation strategy, maximizing the expected returns, using the 12-month momentum as an estimate of future returns, and moment conditions truncating the Fama-French-Cahart factors to their long-term 25%–75% quantiles.

All that glitters is not gold: comparing backtest and out-of-sample performance on a large cohort of trading algorithms
T. Wiecki et al.

The in-sample information ratio (IR) of a maximim IR strategy is not a good predictor of the out-of-sample IR, but other measures of performance fare better (volatility, maximum drawdown).

Instead of using the in-sample IR as an estimate, let machine learning build one, using a long list of performance and risk measures as features.

Dynamic quantile models of rational behavior
L. de Castro and A.F. Galvao (2017)

Instead of *expected* utility, maximize *quantile* utility.

The capacity of trading strategies

A. Landier et al. (2015)

Using the Garleanu-Pedersen model, *i.e.*, an AR(1) investment signal with persistence parameter ϕ ,

$$\begin{aligned}\Delta s_{t+1} &= -\phi s_t + \varepsilon_{t+1} \\ s_{t+1} &= (1 - \phi)s_t + \varepsilon_{t+1}\end{aligned}$$

with quadratic transaction costs $\frac{1}{2}\lambda(\Delta w)'\Sigma(\Delta w)$ and trading rate τ

$$x_t = (1 - \tau)x_t + \tau x_t^*$$

and with a few approximations, one can compute the relation between portfolio size and Sharpe ratio

$$\text{Size} = \frac{\text{SR}}{\lambda\phi^2} \left[\left(\frac{\text{SR}^*}{\text{SR}} \right)^{2/3} - 1 \right]^2.$$

For instance, if you are willing to accept a 30% drop in the Sharpe ratio, *i.e.*, $\text{SR} = 0.7 \times \text{SR}^*$, $\text{Size} = \text{SR}^*/10\lambda\phi^2$.

A Sharpe ratio neutral prior for Bayesian portfolio selection

R. Croessmann

In Bayesian portfolio selection,

$$\text{Maximize}_w \mathbb{E}_{X \sim N(\mu, \Sigma)} [U(w'X)],$$

$(\mu, \Sigma) \sim \text{Prior}$

the uninformative (improper) Jeffrey prior $p(\mu, \Sigma) \propto |\Sigma|^{-(N+1)/2}$ does not account for known information:

- Very high Sharpe ratios are unlikely, while Jeffrey's prior gives

$$\begin{aligned}\text{SR}_{\max} &= \sqrt{\mu'\Sigma^{-1}\mu} \\ p(\text{SR}_{\max}) &\propto \text{SR}_{\max}^{N-1}\end{aligned}$$

- High returns are a compensation for higher risks, while the prior assumes $\mu \perp \Sigma$.

Instead, use

$$\begin{aligned}X &\sim N(\beta\lambda, \beta\beta' + \Sigma) \\ \Sigma &= \text{diag}(\tau) \Omega \text{diag}(\tau) \\ p[\Omega] &\propto |\Omega|^{N(N-1)/2} \prod_i |\Omega_{-i, -i}|^{-(N+1)/2} \\ \beta, \lambda, \tau &\text{ flat;}\end{aligned}$$

this gives uniform marginal posteriors for $\text{Cor}(X_i, X_j)$.

Optimal selection of large portfolios: aggregation is better than ignoring the return constraint

G.Y. Ban and C. Chen

The out-of-sample Sharpe ratio deteriorates as the number of assets increases. Instead of optimizing a portfolio with all assets, group them, randomly, into

“super-assets”; replace each group with the equal-weighted portfolio of its constituents; optimize.

Instead of randomly grouping the assets, group them in pairs with high correlation (or low covariance) and put the elements of each pair in separate super-assets.

Optimizing optimal portfolio choice

Y. Jin (2017)

Instead of looking for better estimates of Σ , Σ^{-1} , or μ , one can directly look for better estimates of the optimal (unconstrained) weights, $\Sigma^{-1}\mu$. Since they can be defined by an optimization problem, $\text{Argmin}_w \|\Sigma w - \mu\|_2^2$, one can add an L^1 penalty to get a sparse portfolio,

$$\hat{w} = \text{Argmin}_w \frac{1}{2} \left\| \hat{\Sigma} w - \hat{\mu} \right\|_2^2 + \lambda \|w\|_1.$$

Under reasonable assumptions (e.g., a shrinkage estimator for $\hat{\Sigma}$, $\|\hat{w} - w^*\| = O_p(\sqrt{S \log(N)/T})$, where $S = \text{Min}\{T, N\}$ and $O_p(\cdot)$ means $O(\cdot)$ with high probability – the best possible bound is $O(\sqrt{S \log(N)/T})$.

Bayesian emulation for multi-step portfolio decisions

K. Irie and M. West (2016)

Optimization problems can often be recast as estimation problems, by interpreting the loss function as a log-likelihood and the penalties as priors. For instance, multi-period optimization problems become state space models, which can be estimated with a “forward filtering backward smoothing” (FFBS) algorithm (e.g., Kalman filter, Viterbi algorithm).

Portfolio construction by mitigating error amplification: the bounded-noise portfolio

L. Zhao et al.

Eigenvectors can only be reliably estimated if their eigenvalues are isolated (*eigengap*): this is only the case for large eigenvalues.

The minimum variance portfolio is a linear combination of that for large eigenvalues (“signal”) and that for small ones (“noise”), $w = \alpha w_S + (1 - \alpha)w_N$. The noise portfolio can be replaced with a robust alternative, minimizing an upper bound on volatility. The resulting optimization problem has the usual form, with the variance Σ replaced with $\Sigma + mNN'$, where the columns of N are the noise eigenvectors (the number of noise eigenvectors is estimated by bootstrap).

Dynamical system theory of periodically collapsing bubbles

V.I. Yukalov et al.

Interactions between a stock and a bond can be modeled as

$$\begin{aligned}\dot{x} &= x - x^2 e^{-bxz} \\ \dot{z} &= z - z^2 e^{-ax},\end{aligned}$$

with $a \in [-.5, .5]$, $b \in [0, 1]$. The presence of bifurcations explains periodically exploding bubbles.

Measuring uncertainty
K. Jurado et al. (2015)

Measure the uncertainty of a macroeconomic series as the standard deviation of the forecasted error,

$$Y_t \sim \sum_i X_{it} \quad \text{factors}$$

$$X_{it} \sim \text{Time series model} \quad \text{factor evolution}$$

and use a stochastic volatility model for the innovations in both models. Finally, aggregate (weighted average) the uncertainties of several series.

Multivariate geometric expectiles
K. Herrmann et al. (2017)

Univariate quantiles can be defined from an asymmetric absolute value loss; they generalize the median.

$$\rho_\alpha(t) = \begin{cases} \alpha t & \text{if } t \geq 0 \\ (1 - \alpha)t & \text{if } t \leq 0 \end{cases}$$

$$F^{-1}(\alpha) = \underset{c \in \mathbf{R}}{\text{Argmin}} E\rho_\alpha(X - c).$$

The univariate **expectiles** are defined from an asymmetric square loss; they generalize the mean.

$$\lambda_\alpha(t) = \begin{cases} \alpha t^2 & \text{if } t \geq 0 \\ (1 - \alpha)t^2 & \text{if } t \leq 0 \end{cases}$$

$$E(\alpha) = \underset{c \in \mathbf{R}}{\text{Argmin}} E\lambda_\alpha(X - c).$$

In higher dimensions (implementation in **qrmtools**):

$$\Phi_u(t) = \|t\|_2 + \langle u, t \rangle \quad u \in B(0, 1)$$

$$\text{VaR}_\alpha X = \underset{c \in \mathbf{R}^d}{\text{Argmin}} E\Phi_\alpha(X - c)$$

$$\Lambda_u(t) = \|t\|_2 (\|t\|_2 + \langle u, t \rangle)$$

$$e_\alpha(X) = \underset{c \in \mathbf{R}^d}{\text{Argmin}} E\Lambda_\alpha(X - c).$$

A generalized contagion process with an application to credit risk
A. Dassios and H. Zhao (2016)

A **Cox process** (doubly stochastic model) is a Poisson process in which the intensity $\lambda(t)$ is itself stochastic. A *dynamic contagion process with diffusion* (DCPD) is a Hawkes process $(T_i)_{i \geq 0}$ with both self-excited and external jumps, with noise.

$$\lambda(t) = a \quad \text{mean-reverting level}$$

$$+ \sum_{T_i < t} Y_i e^{-\delta(t-T_i)} \quad \text{internal jumps}$$

$$+ \sum_{S_i < t} X_i e^{-\delta(t-S_i)} \quad \text{external jumps}$$

$$+ \sigma \int_0^t e^{-\delta(t-s)} \sqrt{\lambda(s)} dW_s \quad \text{noise}$$

Data-driven partition-of-unity copulas with applications to risk management
D. Pfeifer et al. (2017)

The following procedure defines a bivariate density:

- Take two 1-parameter families ϕ, ψ of (discrete) distributions on \mathbf{N} , indexed by $[0, 1]$, e.g., negative binomial or Poisson;
 - Take a discrete distribution on $\mathbf{N} \times \mathbf{N}$ whose marginals are the averages of ϕ and ψ :
- $$p_{i,\cdot} = \int_0^1 \phi_i(u) du \quad p_{\cdot,j} = \int_0^1 \psi_j(v) dv;$$
- Set $c(u, v) = \sum_{ij} p_{ij} \frac{\phi_i(u)}{p_{i,\cdot}} \frac{\psi_j(v)}{p_{\cdot,j}}$.

Robust return risk measures
F. Bellini et al. (2016)

The *Orlicz premium* of a positive random variable X is the only solution $H_\Phi(X)$ of

$$E \left[\Phi \left(\frac{X}{H_\Phi(X)} \right) \right] = 1,$$

where $\Phi : [0, +\infty) \rightarrow [0, +\infty)$ is convex, $\Phi(0) = 0$, $\Phi(1) = 1$, $\Phi(\infty) = \infty$.

The utility-based *shortfall risk* of a real random variable Y is $\rho_\ell(Y) = \inf\{m : E[\ell(Y - m)] \leq 0\}$ where $\ell : \mathbf{R} \rightarrow \mathbf{R}$ is non-decreasing and $\ell(-\infty) < 0 < \ell(+\infty)$. These notions are related:

$$\Phi(x) = 1 + \ell(\log x)$$

$$H_\Phi(X) = \exp(\rho_\ell(\log X))$$

$$\rho_\ell(Y) = \log(H_\Phi(\exp Y)).$$

They can be robustified, e.g., by replacing $E[\cdot]$ with $\sup_{Q \in \mathcal{S}} E_Q[\cdot]$ (one can also consider a set of Young functions Φ).

The *Hazendonck-Goovaert risk measure* is

$$\Pi_\Phi(X) = \inf_{x \in \mathbf{R}} x + H_\Phi((X - x)_+).$$

Multifactor risk models and heterotic CAPM
Z. Kakushadze and W. Yu (2016)

Build your own risk model:

- Separately model variances and correlations;
- Use a factor model for the correlation;
- Use (6-digit) industries as factors, but estimate the model in a russian-dolls fashion.

Multiportfolio time consistency for set-valued convex and coherent risk measures
Z. Feinstein and B. Rudloff

Intuitively, a *set-valued risk measure* is a collection of portfolios covering the risk of the asset of interest. A risk measure is *time-consistent* if a portfolio covering the risk at time t also covers the risk at any earlier time $s < t$.

***Latent common return volatility factors:
capturing elusive predictive accuracy gains
when forecasting volatility***
M. Cheng et al. (2017)

Stock volatility forecasts are usually computed independently for each stock, ignoring dependencies. Instead:

- Compute the realized volatility (RV: multipower, multiscale, etc.) of each stock;
- Use the lasso to find stocks whose RV is close to that of the target;
- Compute a sparse PCA on them, to extract “volatility factors” (or just use a factor model);
- Fit a heteroskedastic autoregressive (HAR) model $y_{[t,t+1]} \sim y_{[t-1,t]} + y_{[t-4,t]} + y_{[t-21,t]}$ to the RV of the stock of interest, with the factors as exogenous variables.

***Introduction to noise-reduced correlations
using singular spectrum analysis***
J.W. Dash et al. (2017)

The signal-to-noise ratio of a correlation matrix can be defined as

$$\text{SNR} = \frac{\sum_{i < i_c} \lambda_i}{\sum_{i \geq i_c} \lambda_i}$$

where the cutoff i_c is determined by finite (not asymptotic) random matrix theory (RMT).

To estimate a correlation matrix, start with log-prices, normalize them, smooth them with singular spectrum analysis (SSA), compute the returns, and then the correlations.

***The 7 reasons
most machine learning funds fail***
M. López de Prado (2017)

Do not compute returns by differentiating prices: *fractional differentiation* ($\alpha = .5$) is sufficient to yield a stationary process.

Do not use clock time but market time (subordinated process using, not time, but volume or dollar bars).

Do not forecast “up” or “down” for a fixed horizon, but use *three barriers*: up and down thresholds, and a time limit; the labels to forecast may overlap: weigh them accordingly.

To avoid overfitting, make sure there is no overlap between training and test sets, and use the *deflated Sharpe ratio*.

***A tug of war:
overnight versus intraday expected returns***
D. Lou et al. (2014)

Some investment signals realize their profits overnight (momentum, reversal), some intraday (the rest).

101 formulaic alphas
Z. Kakushadze (2015)

101 technical indicators.

***Extracting consumer demand:
credit card spending and post-earnings returns***
S. Agarwal et al. (2017)

Consumer spending (credit card data, email invoice data (Slice)) and spending surprises predict future earnings, sales surprises and future returns

***What makes stock prices move?
Fundamentals vs investor recognition***
S. Richardson et al. (2012)

Stocks with low investor recognition (number of institutional shareholders) have a lower price and higher expected returns; realized returns as higher when they gain more recognition.

Facts about formulaic value investing
U.W. Kok et al. (2017)

Formulaic value investing (P/E and other financial ratios) only highlights companies with temporarily high inflated earnings.

A framework for value investing
S. Chee et al. (2013)

The discounted dividend model computes an intrinsic value from dividend forecasts and an “appropriate discount rate”. Instead, the Ohlson model estimates this discount rate (prospective yield) so that the value equals the current market price,

$$P = \sum_{t \geq 1} \frac{E[\text{Div}_t]}{(1+y)^t}.$$

Estimating the dividends as $\text{Div}_t = \text{Earnings}_t - \Delta \text{BV}_t$,

$$y \approx \left[\frac{E[Z_T]}{P} + 1 \right]^{1/T} - 1$$

where Z_T is the expected aggregate cum-dividend earnings for the next T periods.

Accounting anomalies, risk and return
S.H. Penman and J. Zhu (2011)

Cash accounting recognizes revenue when it is actually received.

Accrual accounting recognizes revenue when it becomes certain.

One could go one step further and recognize revenue when it can be forecasted: this explains many accounting “anomalies” – higher returns are a compensation for the uncertainty of future profits.

***A dynamic model of characteristic-based
return predictability***
A. Alti and S. Titman (2017)

Model firms as a combination of assets and projects, each project yielding a deterministic cash flow from inception to termination and liquidation cash flows (salvage value), with younger firms having more, and more profitable projects.

$$\begin{aligned} z_i &\in \{\text{early, mature, dying, dead}\} && \text{state} \\ dk_{it} &= k_{z_i}(1 - \lambda)(dt + dM_t) && \text{capital} \\ df_{it} &= (a_{z_i}k_{z_i} - \lambda f_{it})(dt + dM_t) && \text{profitability} \\ dM_t &= \mu_t dt + \sigma_M d\omega_t^M && \text{systematic disruption} \\ d\mu_t &= -\rho\mu_t dt + \sigma d\omega_t^\mu && \text{disruption climate (hidden)} \\ ds_t &= \eta d\omega_t^M + \sqrt{1 - \eta^2} d\omega_t^s && \text{soft interaction signal} \end{aligned}$$

Investors' overconfidence on the precision of their estimates creates mispricing.

Having a model of the economy (knowing the soft information s instead of just the performance of the sorted portfolios) helps (it doubles the information ratio).

***Structure in the Tweet haystack: uncovering
the link between text-based sentiment signals
and financial markets***
A. Groß-Klußmann et al. (2015)

Manually identify 200 "expert" Twitter users (from web pages: "top 50 Twitter influencers", "who to follow", etc.); measure tweet sentiment using the Harvard general inquirer and Loughran-McDonald lists (in the latter, adapted to finance, "tax" is no longer negative), without stemming (this can mix up some positive and negative words). Sentiment and sentiment disagreement have some predictive power on market returns and volatility.

***Stock return predictability:
consider your open options***
F. Farazmand and A. de Souza (2017)

The put-call open interest ratio (aggregated put open interest, divided by aggregated call open interest, for liquid options, *i.e.*, $K/S \in [.8, 1.2]$ and maturity $\in [30d, 90d]$), for high-volatility (arbitrage-constrained) stocks is a good predictor of future market returns. This can be explained by investors' limited attention.

Beta dispersion and market timing
L.C. Kuntz (2016)

After an exogenous shock to the market, stocks with a high beta are in trouble; if there are many of them, *i.e.*, in markets with high beta dispersion (measured by the 10%-90% interquantile range), this could trigger a second, endogenous shock.

***Investor attention and sentiment:
risk or anomaly?***
M.C. Bucher (2017)

Google searches to measure investor attention (index, stock tickers) and sentiment (panic words, Fears index).

***Algorithmic differentiation in finance
explained***
M. Henrard (2017)

R in Finance 2017

1. GAS (generalized autoregressive score) models generalize GARCH models (a Gaussian GAS is a GARCH) but can be made less sensitive to outliers, leading to better VaR estimation.

Markov switching GARCH models (implemented in MSGARCH) give better VaR forecasts than single-regime ones. Prefer GJR, with skewed Student innovations; prefer MCMC to MLE to account for parameter uncertainty.

Continuous GARCH models (**COGARCH**) generalize GARCH models to non-regularly-spaced observations. In high dimensions, they can be combined with ICA (independent component analysis).

The yuima package estimates and simulates SDEs; it now has an HTML GUI.

Two time series X, Y are **partially cointegrated** if some linear combination $Y - \beta X$ is partially autoregressive, *i.e.*, the sum of a random walk and an AR process.

For many multivariate diffusions, an arbitrarily close approximation (in terms of Hermite polynomials) of the transition function is known in closed form: the MLE is easy to compute. (If not all components are observed, further approximations are available.) The MLEMVD package implements this for many for many 1- or 2-dimensional diffusions

$$\begin{aligned} dX_t &= \mu(X_t)dt + \Sigma(X_t)dW_t \\ \mu : \mathbf{R}^m &\rightarrow \mathbf{R}^n \\ \Sigma : \mathbf{R}^n &\rightarrow \mathbf{R}^{n \times n} \end{aligned}$$

2. The standard error of performance measures T (Sharpe, Sortino, etc.) can be estimated from the sample cumulative distribution function F_n by bootstrap (or **block bootstrap**, in presence of serial correlation) or with **influence functions**

$$\text{IF}(r, T, F_n) = \frac{d}{d\gamma} T((1 - \gamma)F_n + \gamma\delta_r) \Big|_{\gamma=0}$$

(for many performance measures, they can be explicitly computed) since the asymptotic variance is

$$\text{Var}[T(F_n)] \underset{n \rightarrow \infty}{\sim} E[\text{IF}(r_1, T, F)]^2.$$

With serial correlation,

$$\begin{aligned}\text{Var}[T(F_n)] &= \sum_{\ell \in \mathbf{Z}} E[\text{IF}(r_1, T, F_n) \text{IF}(r(1 + \ell), T, F_n)] \\ &= \sum_{\ell \in \mathbf{Z}} C(\ell) \quad \text{autocovariance density} \\ &= S(0) \quad \text{spectral density}\end{aligned}$$

and $S(0)$ can be estimated from a polynomial fit to the periodogram of the IF time series $\text{IF}(r_t, T, F_n)$.

Whenever possible, use the *two-scale estimator* (TSRV) of volatility.

The (block) rearrangement algorithm (BRA) takes a matrix and reorders the elements within each column to minimize the variance of row sums. It can be used to estimate the worst-case portfolio VaR when only the asset return distributions are known (and not their copula). When applied to $(X_1, \dots, X_n, -S)$, where $S = X_1 + \dots + X_n$, it gives a dependence structure close to the maximum entropy one (the correlation matrix of the reordered (X_1, \dots, X_n) has maximum determinant), *i.e.*, answers the question: “if we know the marginal distribution of X_1, \dots, X_n and S , what is the most likely dependence structure?”

When estimating sample comoment tensors, do not re-compute entries already computed (the tensors are symmetric), and use shrinkage, towards a factor model

$$\begin{aligned}X &= BF + \varepsilon \\ \Sigma &= B\Sigma_F B' + \Delta \\ \Phi &= B\Phi_F(B \otimes B)' + \Omega \\ \Psi &= B\Psi_F(B \otimes B \otimes B)' + \Gamma.\end{aligned}$$

Covariance matrix estimators can be more or less structured:

$$\begin{aligned}(1) \quad R_t &\sim N(0, \Sigma_t) & (3) \quad R_t &= F_t \beta'_t + \varepsilon_t \\ & & \beta_t &= \beta_{t-1} + \eta_t \\ (2) \quad R_t &= F_t \beta'_t + \varepsilon_t & \varepsilon_t &\sim N(0, \Sigma_t) \\ \varepsilon_t &\sim N(0, \Sigma_t) & \varepsilon_t &\sim N(0, \Gamma_t)\end{aligned}$$

3. Do not just prefer the “best” strategy: also look at its *sensitivity* to parameter estimation. This is the usual bias-variance tradeoff: you may prefer a slightly worse performance if it is more certain.

It is difficult to select a good manager, especially if there are many of them and/or there is not enough history. Prefer *ensemble methods*: instead of selecting a single manager, select several.

The following stochastic, continuous-time model of **private equity** cash flow and value, which can accommodate fees, should replace the Yale model (deter-

ministic, with no fees).

$$\begin{aligned}dV &= V(\mu dt + \beta \sigma dB + \sigma dB) + dD - dR & \text{Value} \\ dD &= \delta(I - D)dt & \text{Cumulative drawdowns} \\ dR &= vV dt & \text{Cumulative distributions} \\ \delta &= \delta_0 + \sigma B & \text{Drawdown rate} \\ v &= v_0 t + \sigma B & \text{Distribution rate} \\ B & & \text{Different Brownian motions} \\ \sigma & & \text{Different volatilities} \\ dC &= Cr dt - dD + R dt & \text{Cash flow}\end{aligned}$$

This leads to several measures of risk:

– Market: $\text{VaR}[\text{P\&L}]$, where

$$\text{P\&L}_{[t, t+h]} = d_{[t, t+h]} P_{t+h} - P_t,$$

d is the discount factor and $P = V + C$;

– Liquidity: VaR of the liquidity-adjusted P&L,

$$(1 - \pi_{t+h})V_{t+h} + C_{t+h} - P_t,$$

where $d\pi = \kappa(\theta - \pi) + \sigma dB$ is the secondary market discount rate;

– Cash flow: $\text{VaR}[C_{t+h} - C_t]$.

4. For a sparse solution to your portfolio optimization problems, add an L^1 constraint; this also improves performance and can be generalized to structured sparsity.

Risk parity can be generalized to higher moments. The **mrpc** package minimizes the discrepancy between the contribution to second-, third- or fourth-order risk or the assets, or some linear combination of those discrepancies.

$$\begin{aligned}v &= E(r_p - \mu_p)^2 \\ &= E[r_p - \mu_p \otimes (r_p - \mu_p)] \\ &= E\left[\sum w_i(r_i - \mu_i) \otimes (r_p - \mu_p)\right] \\ s &= E\left[\sum w_i(r_i - \mu_i) \otimes (r_p - \mu_p)^{\otimes 2}\right] \\ \kappa &= E\left[\sum w_i(r_i - \mu_i) \otimes (r_p - \mu_p)^{\otimes 3}\right]\end{aligned}$$

$$\frac{\partial v}{\partial w} = 2M_2 w, \quad \frac{\partial s}{\partial w} = 3M_3(w \otimes w), \quad \frac{\partial \kappa}{\partial w} = 4M_4(w \otimes w \otimes w)$$

$$M_i = E[(r - \mu)^{\otimes i}]$$

Find

w

To minimize $\lambda_1 \text{Var } w \otimes \frac{\partial v}{\partial w} + \lambda_2 \text{Var } w \otimes \frac{\partial s}{\partial w} +$

$$\lambda_3 \text{Var } w \otimes \frac{\partial \kappa}{\partial w}$$

Such that $w' \mathbf{1} = 1, \quad w \geq 0$

PortfolioAnalytics can optimize (small) portfolios and generate random portfolios.

5. The score difference, in a soccer match, can be modeled as a difference of Poisson processes (a **Skel-lam process**) and calibrated using the odds provided by the bookie (dynamically); one can also define an “implied volatility” $\sqrt{\lambda_t^A + \lambda_t^B} \sqrt{1 - t}$, $t \in [0, 1]$.

Ratings (credit ratings, Morning Star stars, etc.) are often estimated independently in different categories, on a curve (*i.e.*, not calibrated) and therefore not comparable. Yet, people compare them.

The overnight gap on ex-div date is different from the dividend, because of taxes.

The `obmodeling` package models the order book (VPIN, etc.).

Not all brokers are liquidity providers; high-frequency traders seem to be liquidity-takers.

6. The `sn` package provides a skew-T distribution.

The risk-neutral density can be modeled as a piecewise constant function, generating the correct call and put prices (minimizing the squared relative error).

7. `MXNet` is available from R; it also works on Windows and can leverage your GPU.

Email length, and perhaps also sentiment was a better predictor of future returns than new sentiment in the two years leading to Enron's demise. **Topic analysis** (LDA) may also be interesting.

The `mlr` package now provides the same interface for machine learning (regression, etc.) and time series forecasting (ARIMA, GARCH, etc.)

Several talks compared ML algorithms (Adaboost, MARS, Neural networks and error correcting models (ECM) are very similar – prefer Adaboost and MARS).

Projection methods turn big data into data. A random orthogonal projection on a 1-dimensional subspace gives a lower bound for pairwise distances; **random projections** can be used to find the most correlated columns in a large matrix (`tcors`). Sparse SVD (`irlba`) can help compute the most central nodes of a large graph or bicluster large matrices (`s4vd`).

8. If the prior is not a single distribution but a family of distribution, then so is the posterior: it is a *regularization path*, and can be used to choose the “best” prior and also for prior sensitivity analysis.

To model the time evolution of multivariate yield curves $y_{\text{market},t}$ (tenor), write them as linear combinations of a few “principal” yield curves, modeled with splines, with weights changing as random walks. This is implemented in the `FDLM` package [but this could probably be implemented in Stan, and HMC should be better than Gibbs sampling].

9. Microsoft R server lets you expose your code as an API (not unlike OpenCPU). You can also put your R code in a stored procedure (as with Postgres).

The `roll` package provides a few (fast, parallelized with `RcppParallel`) rolling statistics: regression, PCA, correlation matrices, etc.

`ztsdb` is a time series database (C++, either file-based or client-server), append-optimized, with an R interface, and an R-like language.

Syberia is a workflow framework for data science in R.

The `rTRNG` package provides random numbers for parallel MCMC computations

You do not have big data. If you want speed, try `VowpalWabbit` and `xgboost`. If you really want something distributed, try `H2O` (it often turns out to be faster than `Spark`).

10. Some of the presentations showcased analyses with `plotly`, `shiny`, `flexdashboard`, `dygraph`, `rnaturalearth`, etc.

The tidyverse assumes data is in dataframes, while financial data tends to be in xts objects. The `tidyquant` package provides a “tidy” interface to manipulate data in xts objects.

Five stages of accepting constructive mathematics A. Brauer (2016)

1. **Constructive mathematics** is mathematics without the law of the excluded middle (and, therefore, without the axiom of choice):

- There are still proofs by negation ($P \Rightarrow \perp$ is the definition of $\neg P$), but no proofs by contradiction (proving $\neg P \Rightarrow \perp$ only gives $\neg\neg P$, not $\neg P$).
- The notions of non-empty set ($A \neq \emptyset$) and inhabited set ($\exists x \in A$) are different.

2. Since we have removed an axiom, we can add more, which sometimes leads to surprising consequences, e.g.,

- All functions are continuous;
- Subsets of finite sets need not be finite (*i.e.*, in bijection with some $\llbracket 1, n \rrbracket$);
- There is an injection $\mathbf{N}^{\mathbf{N}} \hookrightarrow \mathbf{N}$;
- There is an unbounded continuous map $[0, 1] \rightarrow \mathbf{R}$;
- \mathbf{R} has zero measure;
- There is an unbounded, increasing sequence without an accumulation point.

3. Models of constructive mathematics include:

- Classical mathematics;
- Computer programs (realizability);
- Sheaves on a topological space X (the truth values are the open sets of X), a topos;
- *Locales* (partially-ordered sets with properties similar to those of the open sets of a topological space; points are not needed: the regular open subsets of \mathbf{R} , *i.e.*, subsets U such that $U = \overset{\circ}{\bar{U}}$, is a sublocale of \mathbf{R} with no points).

4. Some results need to be adapted (e.g., the intermediate value theorem remains true with altered conclusions or additional assumptions, e.g., an approximate solution, a monotonic function, or isolated roots) and new objects can be defined: for instance, the set of random reals of \mathbf{R} minus all subsets of measure zero – it has full measure, but no points.

*What is the best fractional derivative
to fit data?*
R. Almeida

Phenomena traditionally modeled by differential equations such as

$$y' = k, \quad y' = ky, \quad y' = k(y - a), \quad y' = f(t)$$

may be more accurately described by fractional differential equations

$$D^\alpha y = k, \quad D^\alpha y = ky, \quad D^\alpha y = k(y - a), \quad D^\alpha y = f(t)$$

for some $\alpha \in (0, 1)$. The fractional differential and integral are, for $\alpha \in (n - 1, n)$,

$$D^\alpha f(x) = \frac{1}{\Gamma(n - \alpha)} \int_a^x (x - t)^{n - \alpha - 1} f^{(n)}(t) dt$$

$$D^{\alpha, \psi} f(x) = \frac{1}{\Gamma(n - \alpha)} \times \int_a^x \psi'(t) (\psi(x) - \psi(t))^{n - \alpha - 1} \left(\frac{1}{\psi'(t)} \frac{d}{dt} \right)^n f(t) dt$$

$$I^{\alpha, \psi} f(x) = \frac{1}{\Gamma(\alpha)} \int_a^x \psi'(t) (\psi(x) - \psi(t))^{\alpha - 1} f(t) dt.$$

Bayesian inference of log determinants

J. Fitzsimons et al.

To compute log-determinants of large kernel matrices as a Bayesian inference problem, use

$$\log \det A = \text{tr} \log A$$

$$\log(I - A) = \sum_{k \geq 1} A^k$$

$$\text{tr} A = \mathbb{E}_{\mathbf{r} \sim N(0, 1)} \mathbf{r}' A \mathbf{r}$$

and use probabilistic numerics for the *stochastic trace estimation*.

Exploiting gradients and Hessians in Bayesian optimization and Bayesian quadrature

A. Wu et al.

In Bayesian optimization, if the gradient or the Hessian is readily available, use it: the joint process $(f, \nabla f)$ is still Gaussian, with covariance function

$$\begin{pmatrix} k(x, y) & \nabla_x k(x, y) \\ \nabla_y k(x, y) & \nabla_x \nabla_y k(x, y) \end{pmatrix}.$$

The algorithms do not change, they no not use directly the derivatives, but conditioning on this additional information helps.

The kernel becomes ill-conditioned much more quickly: if the bandwidth is small, rescaling can help; if it is large, try moving to the spectral domain:

$$f \sim \text{GP} \implies \mathcal{F}f \sim \text{GP}.$$

On the construction of probabilistic Newton-type algorithms

A.G. Wills and T.B. Schön

Model the Hessian as a Gaussian process, updated with 1-dimensional information at each step (quasi-Newton), and use this expectation for the Newton step in optimization problems.

No spurious local minima in nonconvex low rank problems: a unified geometric analysis

R. Ge et al.

Many nonconvex optimization problems (even asymmetric ones) have a well-behaved loss landscape: local minima are also global (and saddle points have at least one negative eigenvalue in their Hessian).

A probabilistic linear genetic programming with stochastic context-free grammar for solving symbolic regression problems

L.F. Dal Piccol Sotto and V.V. de Melo

Use a stochastic grammar as prior for symbolic regression.

Structural change in (economic) time series

C. Kleiber (2016)

To test for the presence of structural change

$$\begin{array}{ll} \text{Univariate signal} & y_t = \mu_t + \varepsilon_t \quad \mu_t = \text{constant?} \\ \text{Regression} & y_t = x_t' \beta_t + \varepsilon_t \quad \beta_t = \text{constant?} \end{array}$$

one can look at the cumulated residuals (**empirical fluctuation process**, EFP, Rec-CUMSUM)

$$\hat{\mu}_k = \frac{1}{k} \sum_1^k y_t$$

$$e_t = y_t - \hat{\mu}_{t-1}$$

$$S_T = \frac{1}{\hat{\sigma} \sqrt{T}} \sum e_t$$

which can be approximated by a Brownian motion, and look for excessive fluctuations (crossing certain boundaries).

Instead, one can look at the OLS-CUMSUM process

$$e_t = y_t - \hat{\mu}_T$$

$$S_k = \frac{1}{\hat{\sigma} \sqrt{T}} \sum_1^k e_t$$

which can be approximated by a Brownian bridge; fluctuations can be identified by looking at $\text{Max}_t |S_t|$.

The location of the breakpoints can be estimated by minimizing the sum of squared residuals, with dynamic programming; the BIC can help choose the number of breakpoints.

In R, check the **strucchange**, **ecp** and **wbs** packages.

A nonparametric approach for multiple changepoint analysis of multivariate data
D.S. Matteson and N.A. James (2013)

To detect a changepoint in a multivariate time series $X_{1:n}$, compute

$$\operatorname{Argmax}_k \frac{k(n-k)}{n} \mathcal{E}(X_{1:n}, X_{k+1:n})$$

where

$$\mathcal{E}(X, Y) = 2E|X - Y|^\alpha - E|X - X'|^\alpha - E|Y - Y'|^\alpha$$

is the distance correlation (which can be seen as a divergence between characteristic functions).

In presence of multiple changepoints, prefer

$$\operatorname{Argmax}_{k,\ell} \frac{k\ell}{k+\ell} \mathcal{E}(X_{1:k}, X_{k+1:k+\ell})$$

and proceed recursively. In R: `ecp::e.divisive`.

Use permutation tests to assess the significance of the breakpoints and decide when to stop.

The agglomerative variant of the algorithm, merging the adjacent clusters minimizing

$$\frac{|C_i| |C_{i+1}|}{|C_i| + |C_{i+1}|} \mathcal{E}(C_i, C_{i+1}),$$

is faster.

Wild binary segmentation for multiple change-point detection
P. Fryzlewicz (2014)

Binary segmentation splits a time series at the point maximizing the CUSUM statistic (equivalently, it fits a piecewise constant function with exactly one jump to the data), and proceeds recursively to find more changepoints. It does not work well in presence of several breakpoints.

Wild binary segmentation is similar, but works on randomly-selected subsequences, of various lengths. R implementation in `wbs`.

Optimal detection of changepoints with a linear computational cost
R. Killick et al. (2012)

Optimal partitioning uses dynamic programming to find the breakpoints minimizing some criterion, with a penalty β to control this number

$$\begin{aligned} F(s) &= \min_{\substack{\tau \text{ partition} \\ \text{of } 1:s}} \sum_i \operatorname{Cost}(y_{\tau_i+1:\tau_{i+1}}) + \beta \\ &= \min_{t < s} F(t) + \operatorname{Cost}(y_{t+1:s}) + \beta. \end{aligned}$$

The computations can be pruned (pruned exact linear time, PELT) using the fact that, under reasonable assumptions, if $F(t) + \operatorname{Cost}(y_{t+1:s}) + k \geq F(s)$, then t cannot be the last optimal changepoint for any $T > s$.

Local extremes, runs, strings and multiresolution
P.L. Davies and A. Kovac (2001)

After smoothing a time series, one expects the residuals to be similar to white noise; in particular, their signs should not present long *runs*.

To detect extrema in a noisy time series (to approximate a time series with a function with few extrema), one can try to minimize the number of extrema among approximations of the time series for which the maximum length of the runs is below some threshold. This can be generalized to a multiresolution condition, where 2^k consecutive residuals are aggregated, for all k .

Given upper and lower bounds on the unknown values of a time series observed with noise, the *taut string method* looks for the shortest curve between those bounds (it can be computed in linear time, see `fntnonpar::mintvnorm(..., method=1)`).

Dynamic Bayesian combination of multiple imperfect classifiers
E. Simpson et al. (2012)

Consider k judges inferring the labels of N objects:

- κ : label distribution (multinomial)
- t_i : label of object i
- c_{ik} : label assigned to object i by judge k
- $\pi_{k\ell j} : P[\text{judge } k \text{ says } \ell \text{ when the true label is } j]$
- α : Dirichlet prior on π
- ν : Dirichlet prior on κ

The **IBCC** (independent Bayesian combination of classifiers) model can be estimated by MAP (maximum a posteriori), Gibbs sampling or, better, variational Bayes (VB).

Bayesian classifier combination
H.C. Kim and Z. Ghahramani (2012)

Contrary to IBCC, Bayesian model averaging (BMA) assumes the classifiers are somewhat correct (unbiased).

Stacking is an alternative to ensembling in which we do not simply average the classifiers, but learn how to combine them – for IBCC, the combiner is a graphical model.

***Correlation and
large-scale simultaneous significance testing***
B. Efron

Multiple testing procedures assume the tests are independent: if not, they can be too conservative or liberal.

- Convert the test statistic to z scores;
- Fit a Gaussian to the middle of the distribution;
- Use this empirical null distribution instead of $N(0, 1)$ to compute the p -values.

In R, check the `locfdr` package.

***Homotopy parametric simplex method
for sparse learning***
H. Pang et al. (2017)

Many sparse learning problems,

$$\underset{\theta}{\operatorname{Argmin}} L(\theta) + \lambda \|\theta\|_1$$

or $\underset{\theta}{\operatorname{Argmin}} \|\theta\|_1 \text{ st } \|\nabla L(\theta)\|_\infty \leq \lambda$

(Dantzig selector, sparse regression, etc.) can be formulated as linear optimization problems. The *parametric simplex method* (PSM, or homotopy optimization) generalizes the simplex algorithm to solve those problem, while keeping the regularization parameter λ unspecified – the result is not a single solution, but a whole regularization path.

Voronoi treemaps
M. Balzer and O. Deussen (2005)

In a *centroidal Voronoi tessellation* (CVT), the generators are the centers of mass of their Voronoi cells. The “distances”

$$d(p_i, q) = \|p_i - q\| - w_i$$

$$d(p_i, q) = \|p_i - q\|^2 - w_i$$

define weighted Voronoi tessellations; the latter (power-weighted Voronoi diagram) has straight boundaries. To build a *Voronoi tree map*, start with a CVT (replace each generator with the center of mass of its cell and iterate a few times), adjust the weights in the direction suggested by the desired and current areas, and iterate.

Computing Voronoi treemaps
A. Nocaj and U. Brandes (2012)

The power (weighted Voronoi) diagram can be computed using a 3-dimensional convex hull algorithm.

***Certification of approximate roots of exact
polynomial systems***
A. Szanto (2016)

Bertini (non-free, but Bertini2, in development, will be GPL) solves large systems of algebraic equations (numerical algebraic geometry). An approximate zero z of

f is a point such that Newton’s iteration started at z converges to a root $\xi \in \mathbf{C}^n$ of f , with an upper bound R on $\|z - \xi\|$ and the guarantee that there is no other root in $B(z, R)$.

As an application, one can prove that, in \mathbf{R}^3 , seven (infinite) cylinders can touch each other.

Level set method
T.H. Colding and W.P Minicozzi (2016)

If the level sets of $v : \mathbf{R}^2 \rightarrow \mathbf{R}$ flow by mean curvature, then

$$v_t = |\nabla v| \operatorname{div} \left(\frac{\nabla v}{\|\nabla v\|} \right).$$

Hodge theory of matroids
K. Adiprasito et al. (2016)

The coefficients of the chromatic polynomial of a graph $\chi_G(q)$ (number of proper colourings of G using q colours form a log-concave sequence

$$a_i^2 \geq a_{i-1} a_{i+1}.$$

More generally, the number f_i of independent subsets of size i in a matroid is log-concave – this can be proved by defining a Hodge theory for matroids.

***TimescaleDB:
SQL made scalable for time series***

Postgres extension to store time series as tables (time, id₁, ..., id_n, v₁, ..., v_m), partitioned on (time, id).

***Implementing operational calculus
on programming spaces
for differentiable computing***
Ž. Sajovic (2017)

Automatic differentiation (AD) in C++, using templates.

High-dimensional discriminant analysis
C. Bouveyron et al.

Quadratic discriminant analysis (QDA) requires estimates of the variance matrix for each class: in high dimension, use regularized estimators, or make further assumptions, e.g., that the variance matrix only has two distinct eigenvalues.

Persistent topology of syntax
A. Port et al. (2015)

Application of TDA to language classification.

***Spin glass models of syntax
and language evolution***
K. Siva et al. (2015)

Modeling language interactions (from the number of bilingual editors for each pair of languages) using a *spin glass model* (aka *Potts model*, i.e., the *Ising model* with more than two states).

***Prevalance and recoverability of syntactic
parameters in sparse distributed memories***
J.J. Park et al. (2015)

Features to classify human languages (e.g., SVO order) can be found in:

- SSWL: syntactic structures of the world’s language;
- WAL: world atlas of language structures.

***Manopt, a matlab toolbox
for optimization on manifolds***
N. Boumal et al. (2014)

Describe the manifold (from a few predefined ones and a few operations: projection, quotient, product); provide the (Euclidean) derivatives; choose the method (trust region or conjugate gradient).

***Langevin and Hamiltonian based sequential
MCMC for efficient Bayesian filtering
in high-dimensional spaces***
F. Septier and G.W. Peters (2015)

Sequential Monte Carlo (SMC, particle filters) does not work well in high dimensions: instead of using importance weights, apply a few MCMC moves after each step.

***Information-geometric
Markov chain Monte Carlo methods
using diffusions***
S. Livingstone and M. Girolami (2014)

The Metropolis adjusted Langevin algorithm (MALA) can be generalized to Riemannian manifolds.

***Fast Langevin based algorithm
for MCMC in high dimension***
A. Durmus et al. (2016)

Other discretizations of the Langevin diffusion (SDE) give variants of MALA (Metropolis-adjusted Langevin algorithm) with faster convergence in higher dimensions.

Langevin-Euler moves

If $\pi(x) \propto \exp -U(x)$ then the solution of the Langevin diffusion SDE

$$dx = -\frac{1}{2} \frac{\partial U}{\partial x} dt + dW$$

follows the target distribution π .

PyCaMa: Python for cash management
F. Salas-Molina et al. (2017)

Given a set of bank accounts, desired transactions (from customers to suppliers), and transaction costs ($A \rightarrow B \rightarrow C$ may be cheaper than $A \rightarrow C$), finding the cheapest path is a linear problem.

***Downside risks
and the cross-section of asset returns***
A. Farago and R. Tédongap (2017)

The cross-section of returns can be explained with the covariance between stock returns and: market returns, change in market volatility, down times (boolean variable indicating either a fall in price or a rise in volatility), market returns $\times \mathbf{1}_{\text{down}}$, change in market volatility $\times \mathbf{1}_{\text{down}}$. Contrary to the Fama-French-Cahart model (which works better for stocks), this applies to all asset classes, including options and currencies.

Systematic tail risk
R.D.F. Harris et al. (2017)

The beta $\beta = \text{Cov}(R, R_m) / \text{Var } R_m$ and the correlation $\text{Cor}(R, R_m)$ can be turned into downside risk measures by conditioning on $R_m \leq \mu_m$, or replacing market returns R_m with their below-average part $\text{Min}\{R_m - \mu_m, 0\}$, or by replacing both asset and market returns with their below-average parts.

The extreme downside betas (EDB) and correlation (EDC) are obtained by replacing the means μ, μ_m with the 5% quantile. The extreme downside hedge (EDH) is the sensitivity of the forthcoming change in market value at risk, $\beta(R_t \sim \Delta \text{VaR}_{t \rightarrow t+1}^{\text{market}, 5\%})$, estimated from an AR(1)-GJR-GARCH(1,1) model with skewed Student innovations, on a 5-year moving window. There is a tail risk premium, visible if you compare the returns in $[t, t+1]$ and the risk estimated at time $t+1$, but it is not investible.

***Conditional asset pricing
in international equity markets***
T. Huynh (2017)

The returns of an equal-weighted momentum-value portfolio can be explained using the “lagged component” betas as instrumental variables.

The time-varying betas of a portfolio (on a moving window) can be estimated directly, by considering the portfolio as a single asset (“lagged portfolio” betas) or as a portfolio-weighted average of stock-level betas (“lagged component” betas).

***Contagion in financial systems:
a Bayesian network approach***
C. Chong and C. Klüppelberg (2017)

Tightly interconnected firms are robust to small shocks, but the network amplifies large ones (phase

transition, non-monotonic effect). Model firms as:

$$\begin{aligned} X_i &\sim N(\mu_i, \sigma^2) && \text{assets} \\ L_{ij} &&& \text{liabilities} \\ E_i &= X_i + \sum_{j \text{ survives}} L_{ij} - \sum_j L_{ji} && \text{equity.} \end{aligned}$$

If the redemption graph has no cycles, the defaulting and surviving firms are well-defined but, if not, there are multiple solutions with non-zero probability. For instance, with

both survive if netting is possible, but both default if not.

Two solutions are obtained by progressively building the list of defaulting (resp. surviving) firms. Using those rules, one can extend the redemption graph into a directed acyclic graph (DAG), by creating N copies of each vertex, corresponding to the iterations of the algorithm. Bayesian network tools are then available: independence detection, systemic impact measures, default probabilities, etc.

Instrumented principal component analysis **B. Kelly et al. (2017)**

Factor models combine stock-specific but constant loadings β with common, dynamic factors f :

$$y_{nt} = \sum_k \beta_{nk} f_{kt} + \varepsilon_{nt}.$$

Dynamic factor models usually assume a simple model for the changes of β , e.g., a random walk:

$$y_{nt} = \sum_k \beta_{nk} f_{kt} + \varepsilon_{nt}$$

$$\beta_{n,k,t} = \beta_{n,k,t-1} + \eta_{n,k,t}$$

Instead, one can use additional data (time-changing, stock-specific “instrumental” variables Z) to predict β :

$$y_{nt} = \sum_k \beta_{nk} f_{kt} + \varepsilon_{nt}$$

$$\beta_{n,k,t} = \sum_\ell Z_{k\ell,t} \Gamma_{\ell,k} + \eta_{n,k,t}.$$

The model can be estimated as follows:

- Orthonormalize the instruments so that, for each t , $N^{-1} Z_t' Z_t = I_L$;
- Set $x_{\ell,t} = N^{-1} \sum_n Z_{n,\ell,t-1} y_{n,t}$;
- Let $\Gamma_{\cdot,1}, \dots, \Gamma_{\cdot,k}$ be the k eigenvectors of $N^{-1} X' X$ for the K largest eigenvalues, normalized ($\Gamma' \Gamma = I_K$) and signed (so that the first non-zero entry of each column be positive);
- Set $f_{k,t} = \sum_\ell \Gamma_{\ell,k} x_{\ell,t}$.

If $y_{n,t}$ are stock returns and $z_{n,\ell,t}$ stock characteristics, then $x_{\ell,t}$ are the returns of portfolios defined using the (raw) instrumental variables Z as weights – factor-mimicking portfolios usually discretize them first.

Second-order optimization over the multivariate Gaussian distribution **L. Malagò and G. Pistone (2016)**

On a Riemannian manifold, the gradient and the Hessian, used in first- and second-order optimization algorithms (e.g., gradient descent, Newton) become the *natural gradient* and the *Riemannian Hessian*. For statistical manifolds and their three connections (Levi-Civita, exponential, mixture), there are actually three Hessians.

Stochastic relaxation replaces

$$x^* = \underset{x \in \mathbf{R}^n}{\text{Argmin}} f(x)$$

with

$$(x^*, 0) = \underset{\mu, V}{\text{Argmin}} \mathbb{E}_{X \sim N(\mu, V)} [f(X)].$$

The landscape of empirical risk for non-convex losses **S. Mei et al. (2016)**

Given enough observations ($\Omega(d \log d)$ in dimension d), non-convex loss functions, e.g.,

$$\frac{1}{n} \sum (y_i - \sigma \langle w, x_i \rangle)^2$$

for binary classification, have a unique minimizer.

Information geometry of neural networks **S.I. Amari**

Natural gradient descent, for neural nets, with an approximation of the Riemannian metric, avoids plateaus.

Hyperparameter optimization with approximate gradient **F. Pedregosa (2016)**

Hyperparameter optimization is a bilevel optimization problem

$$\begin{aligned} \text{Find} & \quad \lambda, \beta^* \\ \text{To minimize} & \quad f(\lambda) = g(\beta^*, \lambda) \\ \text{Such that} & \quad \beta^* = \underset{\beta}{\text{Argmin}} h(\beta, \lambda) \end{aligned}$$

where

λ : hyperparameters
 β : parameters
 h : loss
 g : cross-validation loss.

It can be reformulated as a constrained optimization

$$\begin{array}{ll} \text{Find} & \lambda, \beta \\ \text{To minimize} & f(\lambda) = g(\beta, \lambda) \\ \text{Such that} & \nabla_{\beta} h(\beta, \lambda) = 0. \end{array}$$

The gradient can be computed:

$$\begin{aligned} \frac{df}{d\lambda} &= \frac{\partial \beta}{\partial \lambda} \frac{\partial g}{\partial \beta} + \frac{\partial g}{\partial \lambda} \\ \frac{\partial}{\partial \beta} [\nabla_{\beta} h(\beta, \lambda)] &= 0 \\ \nabla f &= \nabla_{\lambda} g - (\nabla_{\beta, \lambda} g)' (\nabla_{\beta, \beta} g)^{-1} \nabla_{\beta} g. \end{aligned}$$

Approximations for β^* , ∇g and $\nabla^2 g$ are good enough.

**Mapping estimation
for discrete optimal transport**
M. Perrot et al. (2016)

Optimal transport, in particular the *Wasserstein distance*, is used in machine learning, as a divergence to compare distributions, to interpolate between distributions, to compute means, barycenters or PCA in spaces of probabilities.

Given probability spaces (X, μ) and (Y, ν) and a cost function $c : X \times Y \rightarrow \mathbf{R}$, the **Monge problem** asks for a function $T : X \rightarrow Y$ such that $T_{\#}\mu = \nu$ ($T_{\#}$ is the push-forward) minimizing $\int_X c(x, T(x)) d\mu(x)$. The **Kantorovitch** relaxation asks instead for a probability distribution γ on $X \times Y$ with marginals μ and ν minimizing $\int_{X \times Y} c(x, y) d\gamma(x, y)$. For discrete distributions, in particular, for empirical distributions, this is a linear program.

Jointly learn the *probabilistic coupling* γ (from the empirical distributions) and the *barycentric mapping* T (in a limited set of functions, e.g., linear, or using some kernel) with a penalty (e.g., to ensure T is close to the identity).

While transfer learning transforms a model $X \rightarrow Y$ into a model $X \rightarrow Y'$ with a new target (codomain), **domain adaptation** transforms it to a model $X' \rightarrow Y$ with a different source space (domain).

In image processing, before inpainting (Poisson image editing), one can force the gradient distribution of the source image to match that of the target image (using a random sample of 500 gradients on each side).

**Learning to learn, from transfer learning
to domain adaptation: a unifying perspective**
N. Patricia and B. Caputo

Supervised word mover's distance
G. Huang et al. (2016)

Combine the word mover's distance (the distance between two documents is the cost of the optimal transport between their (vector-embedded) bags of words) with metric learning (use the distance minimizing the

leave-out-one (LOO) k -nearest neighbour error when predicting document labels).

**SAGA: a fast incremental gradient method
with support for non-strongly convex
composite objectives**
A. Defazio et al. (2014)

To minimize a smooth convex function $f(x) = \frac{1}{n} \sum_i f_i(x)$, *variance-reduced stochastic gradient descent* uses updates of the form

$$x \leftarrow x - \gamma \frac{1}{n} \left[f'_i(x) - f'_i(x^*) + \sum_j f'_j(x^*) \right] \quad (\text{SAG})$$

$$\text{or } x \leftarrow x - \gamma \left[f'_i(x) - f'_i(x^*) + \frac{1}{n} \sum_j f'_j(x^*) \right] \quad (\text{SVRG})$$

where x^* and $\sum f'_i(x^*)$ are updated once in a while.

SAGA keeps track of n points $(x_i)_{1 \leq i \leq n}$ and the derivatives of the corresponding terms:

$$x \leftarrow x - \gamma \left[f'_i(x) - f'_i(x^*) + \frac{1}{n} \sum_j f'_j(x_j) \right];$$

one of them is updated at each step with the current value of x .

**Accelerating stochastic gradient descent
using predictive variance reduction**
R. Johnson and T. Zhang (2013)

To reduce variance in stochastic gradient descent (SVRG), approximate the gradient of $f = \sum f_i$ as

$$\nabla f(x) \approx \nabla f(x^*) - \nabla f_i(x^*) + \nabla f_i(x).$$

Faster asynchronous SGD
A. Odena

Distributed stochastic gradient descent (SGD) ignores synchronization problems, but keeps track of gradient staleness, either with the number of updates skipped, or with the difference between the gradient computed and the gradient that would have been computed (on the same minibatch) with the latest parameters, and uses it to fine-tune the learning rate (not unlike RMS-prop).

Fast and provably good seedings for k-means
O. Bachem et al. (2016)

Kmeans++ seeding does not scale to large datasets. Instead of sampling each point exactly from $p(x) \propto d(x, C)^2$, use MCMC, with the exact distribution after the first point (mixed with the uniform distribution) as proposal distribution, instead of a uniform distribution.

**Phased LSTM: accelerating recurrent network
training for long or event-based sequences**
A. Neil et al. (2016)

By allowing neurons to update at different frequencies (by adding a “time gate”), LSTMs can deal with irregularly-spaced signals, e.g., event streams.

Sequential neural models with stochastic layers
M. Fraccaro et al. (2016)

Recurrent neural nets (RNN) and state space models (SSM) are eerily similar.

Stochastic RNNs stack them – not unlike a variational auto-encoder (VAE) at each step.

Improved techniques for training GANs
T. Salimans et al. (2016)

Training a GAN is a Nash equilibrium problem

$$\theta_D \in \text{Argmin } J_D(\theta_D, \theta_G)$$

$$\theta_G \in \text{Argmin } J_G(\theta_D, \theta_G) :$$

gradient descent can fail to converge.

- To prevent the generator from overfitting the discriminator, have the generator generate data whose statistics match those of the real data, e.g., the expected values of the features on an intermediate layer of the discriminator (feature matching);
- Include a term for historical averaging

$$\left\| \theta - \frac{1}{t} \sum_{1 \leq i \leq t} \theta_i \right\|^2 ;$$

- To prevent the generator from always emitting the same point, allow the discriminator to look at several examples (minibatch discrimination);
- Replace the 0 and 1 targets with smoothed values (label smoothing);
- Batch normalize using the statistics of a fixed reference batch (virtual batch renormalization).

DeepMath – deep sequence models for premise selection
A.A. Alemi et al. (2016)

Using the Mizar mathematical library (the library is free, the theorem prover is not) of formal proofs (of real-world theorems: Hahn-Banach, Brouwer, Borsuk-Ulam, Gödel, etc.), train a RNN and/or a CNN, with LSTM/GRU, from character or word embeddings, to select which axioms will be useful in proving a given conjecture, to guide automated theorem provers.

Learning to pivot with adversarial networks
G. Louppe et al.

To make a model f of $Y \sim X$ robust to a latent parameter Z (e.g., model specification),

$$\begin{array}{ll} \text{Find} & f \\ \text{Such that} & Y \approx f(X) \\ \text{and} & f(X) \perp\!\!\!\perp Z \end{array}$$

using an adversarial network:

- Learn f so that $y \approx f(x)$ and g performs poorly;
- Learn g to predict z from $f(x)$.

Deep networks with stochastic depth
G. Huang et al. (2016)

During training, randomly drop a subset of layers.

Exponential family embeddings
M. Rudolph et al. (2016)

Dimension reduction with word vector embedding looks for a map $f : \text{Words} \rightarrow \mathbf{R}^n$ minimizing $\text{Loss}(f(\text{word}), f(\text{surrounding words}))$. One can replace the word and the surrounding words, and their discrete distributions, with exponential distributions conditioned on a “context”, for instance:

- A Gaussian embedding can be used to model neuron activity, conditioned on the activity of nearby neurons;
- A *Poisson embedding* can model items conditioned on other items from the same shopping basket.

On the expressive power of deep neural networks
R. Raghu et al.

To measure the expressivity of a neural net, check how the length of a 1-dimensional trajectory in the input space changes as it propagates through the network; for instance, for the output node, look at the number of sign changes.

The regimes in which the neurons are (ReLU have two regimes, zero and linear; hard-tanh have three, linear and saturated at ± 1) define the “activation patterns” of a network (binary strings, for ReLUs). For ReLU networks, the activation patterns subdivide the input space into convex polytopes.

Matrix factorization using window sampling and negative sampling for improved word representations

A. Salle et al.

Let M_{wc} be the cooccurrence matrix between words w and context words c ,

$$\text{PMI}_{wc} = \log \frac{M_{mw} M_{\cdot, \cdot}}{M_{w, \cdot} M_{\cdot, c}}$$

the pointwise mutual information matrix and PPMI the positive semidefinite matrix obtained by zeroing out negative eigenvalues. These matrices have been used to define word embeddings as follows:

- PPMI-SVD factorizes $\text{PPMI}_{wc} \approx W_w W'_c$ using a truncated SVD, $\text{PPMI} = U \Sigma V'$, $W = U \Sigma^{1/2}$;
- GloVe factorizes $\log M$ by minimizing

$$\sum_{w,c} f(M_{wc})(W_w W'_c + b_w + \tilde{b}_c - \log M_{wc})^2;$$

where the weights are

$$f(x) = \begin{cases} (x/x_{\max})^\beta & \text{if } x \leq x_{\max} \\ 1 & \text{otherwise;} \end{cases}$$

- Skipgram with negative sampling factorizes PMI by minimizing

$$\sum_{w,c} (W_w W'_c - \text{PMI}_{wc})^2 - E_{w'} (W_w W'_{w'} - \text{PMI}_{ww'})^2;$$

- LexVec is similar but factors PPMI.

On multiplicative integration with recurrent neural networks

Y. Wu et al.

Replace the computational blocks $\phi(Wx + Uz + b)$ with $\phi(Wx \odot Uz + b)$. [This is one of the ideas behind LSTMs, but it can be used separately.]

Tagger: deep unsupervised perceptual grouping

K. Greff et al.

To segment an image, look for groupings of pixels for which denoising autoencoders easily reconstruct the image withing each group.

Neural networks with differentiable structure

T. Miconi

To select network structure via gradient descent, make it differentiable by multiplying the output of each neuron with a scalar factor (e.g., one for each layer), and add an L^1 penalty for those new parameters to encourage sparsity.

Progressive neural networks

A.A. Rusu et al.

To learn a task related to an already-learned one, consider a new neural net, parallel to the first one, randomly initialized, with lateral connections. To keep the model scalable (task $n + 1$ has connections from tasks 1 through n), use dimension reduction (single-layer network) for those lateral connections.

Visualizing deep convolutional neural networks using natural pre-images

A. Mahendran and A. Vedaldi (2016)

To understand what a neural network (CMM for computer vision or image recognition) sees:

- Compute the inverse of a representation, i.e., look at images sharing the same representation;
- Maximize a certain component (cf. the “cat neuron”);
- Exaggerate the patterns present in an image (deep dream).

Inception-v4, Inception-ResNet and the impact of residual connections on learning

C. Szegedy et al.

Adding residual connections to Inception networks speeds up training.

Question answering via integer programming over semi-structured knowledge

D. Khashabi et al.

Factoid question answering systems just look for an already written answer in a large corpus, but cannot combine separate pieces of information to create a new, never-seen sentence. Given tables of knowledge (65, for a total of 5000 rows, origin unknown), integer programming can find a way to join them to best answer a given question.

Do deep convolutional nets really need to be deep (or even convolutional)?

G. Urban et al.

The results of a deep convolutional network can be reproduced by a shallower network, but it still needs to be deep (one hidden layer is not enough) and convolutional.

Tweet2vec: character-based distributed representations for social media
B. Dhingra et al.

Character-level bidirectional LSTMs or GRUs can learn vector embeddings that generalize well to rare, abbreviated or misspelt words, frequent on Twitter.

Detecting relative anomaly
R. Neuberg and Y. Shi

To detect anomalies:

- From the distance matrix, compute a similarity matrix via a Gaussian kernel and use its first eigenvector as a measure of centrality (similar to PageRank); with the normalized similarity matrix, this is actually equivalent to a kernel density estimator.
- Consider an observation highly normal if its degree is in the top $\alpha\%$; label an observation anomalous if the length of the shortest path to the highly normal observations is high (in the top $\beta\%$)

Unifying count-based exploration and intrinsic motivation
M.G. Bellemare et al.

Practical applications of reinforcement learning still rely on ϵ -greedy policies for exploration. *Intrinsic motivation* (IM) achieves exploration using *novelty* signals, e.g., prediction error or value error. Sequential density models (probability distributions on the set of sequences of states) can be used to define pseudo-counts: count-based reinforcement learning algorithms then apply (experience replay, actor-critic, etc.).

Model-free episodic control
C. Blundell et al.

Gradient-based reinforcement learning is slow: to speed it up, remember (not learn) successful strategies and re-enact them when the agent encounters a similar state. (In humans, the hippocampus does that.)

Resnet in Resnet: generalizing residual architectures
S. Targ et al.

Combination of two-dimensional cochleogram and spectrogram features for deep learning-based ASR
A. Tjandra et al. (2015)

The **cochleogram**, a convolution with the *gammatone filter*

$$g(t) = t^{n-1} e^{-2\pi b t} \cos(2\pi \omega t)$$

n : filter order
 $b = 110 \omega + 25.2$: bandwidth

is an alternative to MFCC (Mel frequency cepstral coefficients) features.

Visually identifying rank
D.F. Fouhey et al.

Can CNNs (or SVMs with VLFeat features) recognize the rank of a matrix? Results are not as disastrous as you may think.

High-dimensional probability estimation with deep density models
O. Rippel and R.P. Adams

Dimension reduction of a dataset Y in \mathcal{Y} to a simpler space \mathcal{X} can be obtained by two functions $f : \mathcal{X} \rightarrow \mathcal{Y}$ and $g : \mathcal{Y} \rightarrow \mathcal{X}$ (neural nets with sigmoid functions) minimizing the divergence between the marginals of $g(Y)$ and the desired marginals (Beta distribution with $\alpha \gg 1$) with a penalty for poorly conditioned f (we want it invertible) and another one to ensure $g \approx f^{-1}$.

FractalNet: ultra-deep neural networks without residuals
G. Larson et al.

Fractal networks are defined recursively,

where f is, for instance, a convolutional layer, and trained with *drop path* (each join drops each input with some probability, but keeps at least one) and global (keep only one path, with layers in the same column).

Random rotation ensembles
R. Blaser and P. Fryzlewicz (2016)

To reduce the artifacts (and the number of trees needed) in ensembles of decision trees, randomly rotate the feature space before training the base learners.

***Accelerating Eulerian fluid simulation
with convolutional networks***
J. Tompson et al.

Machine learning and convolutional nets can help solve PDEs.

***Compressing deep convolutional networks
using vector quantization***
Y. Gong et al. (2014)

Compress dense weight matrices with:

- Matrix factorization;
- Scalar quantization, by replacing the matrix entries with their signs, or by clustering them with k -means;
- Product quantization: split the matrix into blocks of columns; for each block, cluster the rows with k -means;
- Residual quantization: cluster the rows, then the residuals, and iterate a few times.

***The sketchy database:
learning to retrieve badly drawn bunnies***
P. Sangkloy et al.

A **siamese network** is a pair of convnets detecting if two inputs are similar or not; they use a contrastive loss.

$$\text{Loss} = \lambda d(S, I_+) + (1 - \lambda)(m - d(S, I_-))_+$$

$\lambda = 0$ or 1
 S : source image
 I_+ : matching image
 I_- : non-matching image
 m : margin

Triplet networks are similar, but their loss is of the form “ S is closer to I_+ than to I_- ”.

$$\text{Loss} = (d(S, I_+) - d(S, I_-))_+$$

For a dataset of sketch-photo pairs, the two (or two of the three) convnets are different.

***Interaction networks for learning
about objects, relations and physics***

To design a data-driven physics engine, learn:

- Object-centric functions, which map the state of an object at time t to its state at time $t + 1$ (or, rather, a state increment);
- Relation-centric functions, which map the states of two objects and the characteristics of the relation (e.g., the spring constant) to their state increments;
- An aggregation function, which combines the state increments.

***On the modeling of musical solos
as complex networks***
S. Ferretti (2016)

From a piece of music, create a network, with pitch-duration pairs as nodes (you can also add rests and chords), and directed arcs to denote succession; the usual graph statistics (degree distribution, centralities, etc.) can help classify the piece.

***A first look at music composing using LSTM
recurrent neural networks***
D. Eck and J. Schmidhuber

LSTMs can generate the global structure RNNs cannot capture.

***DeepBach: a steerable model
for Bach chorales generation***
G. Hadjeres and F. Pachet

Represent the data as 6 sequences, corresponding to the 4 voices (either the midi pitch or a “hold” symbol), the beat (12341234...) and the presence of a fermata; the last two are fixed.

Model the data as $v_i = f(v_{<i}, v_{>i})$, where f is a neural net, processing $v_{<i}$ and $v_{>i}$ with LSTMs (in opposite directions).

Generate new chorales with Gibbs sampling.

The **pseudo-log-likelihood** is a Gibbs-inspired approximation of the log-likelihood.

$$\begin{aligned} \text{Log-likelihood} &: \log P(V_1, \dots, V_n | \theta) \\ \text{Pseudo-log-likelihood} &: \sum_i \log P(V_i | V_{\neq i}, \theta) \end{aligned}$$

***An information-theoretic approach
to machine-oriented music summarization***
F. Raposo et al.

Text summarization extracts relevant and diverse (bits of) sequences; for music, this can create harsh discontinuities. Compute MFCC features on a moving window, model them as a (mixture of) multivariate Gaussians, use this distribution as a (machine-oriented) summary, and somehow turn it into a human oriented summary. Implementation in C++ using openSMILE (feature extraction) and Marsyas (synthesis).

***Text extraction from the web
via text-to-tag ratio***
T. Weninger and W.H. Hsu

To detect relevant text in the midst of today's HTML pages tag soup:

- Remove empty lines, comments, `<script>` and `<style>` blocks;
- In each line, count the number of (non-tag) characters, the number of tags, the ratio $\text{text}/\max(1, \text{tag})$;
- Apply k -means on smoothed ratios and pick the cluster with the largest average ratio,
- Or pick lines whose smoothed ratio is above a one standard deviation threshold,
- Or apply some technical analysis indicator.

This could be combined with

- Other line metrics, e.g., entropy;
- Template detection (often, pages on the same web site belong to the same or a few templates);
- Machine learning algorithms to detect boilerplate (not unlike span detection).

CETR: content extraction via tag ratios
T. Weninger et al. (2010)

Instead of clustering the 1-dimensional text-to-tag ratio x , cluster $(x, |\dot{x}|)$ (after smoothing).

***A machine learning approach
to webpage content extraction***
J. Yao and X. Zuo

After discarding `<nav>` and `<aside>` elements (contents should be in `<article>`), consider blocks rather than lines and train a machine learning classifier (SVM, naive Bayes) using the following features: number of words, average sentence length, text density, link density (and the ratios wrt the previous block), block number (rescaled to $[0, 1]$), id and class attributes.

***CrossCat: a fully Bayesian nonparametric
method for analyzing heterogeneous,
high-dimensional data***
V. Mansinghka et al.

CrossCat is a hierarchical nonparametric Bayesian model for tabular data, used by BayesDB, whose generative process looks like:

- Partition the columns, using a Chinese restaurant process (CRP);
- Likewise partition the rows;
- Sample the parameters for each column (variable) in each intersection;
- Sample the rows in each intersection.

***BayesDB: a probabilistic programming system
for querying the probable implications of data***
V. Mansinghka et al.

When you insert data in a table, BayesDB estimates a model that allows it to:

- Sample new rows from the resulting joint or conditional distribution;
- Compute the likelihood of each row, to detect outliers;
- Retrieve similar rows;
- Compute the mutual information (MI) between pairs of variables (or, rather, the probability that the posterior MI is nonzero), which is better than correlation at detecting dependencies;
- Infer missing values.

The univariate models (“data types”) are:

- Numeric: normal-gamma;
- Count: Poisson-gamma;
- Binary: asymmetric Beta-Bernoulli;
- Categorical: multinomial with symmetric Dirichlet prior.

***Identifying almost identical files using
context-triggered piecewise hashing***
J. Kornblum (2006)

To check if two files are almost identical:

- Compute a hash on a rolling window of moderate size and note the positions at which it takes a specific value (trigger); discard the hashes;
- Compute a hash for the parts between two triggers.

[One could also compute a longer rolling hash and only keep the values if the first bytes have a specified value.] This is implemented in `ssdeep`; similar algorithms include `tlsh` and `sdhash`. Some use CTPH as features in machine learning algorithms to detect or cluster spam, malware, bot control centers, etc.

An introduction to topology
M.J. Dominus (2010)

A *valuation* for classical logic is a map

$$v : \{\text{formulas}\} \longrightarrow \{\top, \perp\}.$$

Instead of $\{\top, \perp\}$, one can use $(\mathcal{P}(X), \cap, \cup)$ or any other boolean algebra. *Tautologies* are formulas whose value is \top (or $X \in \mathcal{P}(X)$).

For *intuitionistic logic*, where $\neg p \vee p$ is not a theorem, one replaces Boolean algebras with sufficiently large *Heyting algebras*, e.g., $\mathcal{P}(\mathbf{R})$:

$$\begin{aligned} A \vee B &= A \cup B \\ A \wedge B &= A \cap B \\ A \rightarrow B &= (A^c \cup B)^\circ \\ \neg A &= A^{c^\circ}. \end{aligned}$$

The *compactness principle* (i.e., Tychonov's theorem) says that if any finite subset of a set of axioms has a model, then so does the whole set – for instance, with the real numbers axioms and $\varepsilon < 1$, $\varepsilon < 1/2$, $\varepsilon < 1/3$, ..., $\varepsilon > 0$, this allows for infinitesimals.

**Tensor rank and the ill-posedness
of the best low-rank approximation problem**
V. de Silva and L.H. Lim (2006)

Many properties of the rank of a matrix do not generalize to tensors of order $k \geq 3$:

- The *outer product rank*

$$\text{rank}_{\otimes} A = \text{Min} \left\{ n : \exists x_{ij} \ A = \sum_{i=1}^n x_{1i} \otimes \cdots \otimes x_{ki} \right\}$$

and the multilinear rank rank_{\boxplus} (k -tuple of the dimensions of the spaces spanned by the columns of the k matricizations of the tensor) do not coincide.

- A tensor in $\mathbf{R}^{d_1 \times \cdots \times d_k}$ can have rank greater than $\text{Min}(d_1, \dots, d_k)$.
- Tensor rank is not upper semi-continuous; many tensors (a non-negligible set) do not have a best rank r approximation: for instance, the rank-3 tensor

$$A = x_1 \otimes x_2 \otimes y_3 + x_1 \otimes y_2 \otimes x_3 + y_1 \otimes x_2 \otimes x_3$$

can be approximated arbitrarily close by the rank-2 tensors

$$A_n = n \left(x_1 + \frac{1}{n} y_1 \right) \otimes \left(x_2 + \frac{1}{n} y_2 \right) \otimes \left(x_2 + \frac{1}{n} y_2 \right) \\ - n x_1 \otimes x_2 \otimes x_3.$$

**Scalable latent tree model
and its application to health analytics**
F. Huang et al.

The *multivariate information distance*

$$d(X, Y) = -\log \frac{\prod \sigma_i [\text{Cov}(X, Y)]}{\sqrt{\det \text{Cov}(X, X) \det \text{Cov}(Y, Y)}}$$

where the σ_i are the top- k singular values generalizes the correlation to multivariate random variables (on a tree, this distance is additive).

To learn a *latent tree graphical model* (an undirected graphical model, with no loops, and both observed and unobserved variables), compute the matrix of multivariate information distances; build the corresponding minimum spanning tree; find triplets of nodes for which the distance is additive: this indicates the presence of a hidden node; add it and iterate. To estimate the model parameters, compute a low rank tensor decomposition of the third moment of triplets of variables $E[X_1 \otimes X_2 \otimes X_3]$.

**High-dimensional neural spike train analysis
with generalized count
linear dynamical systems**
Y. Gai et al.

The Poisson distribution $p(k) \propto \lambda^{-k} e^{-k} / k!$ is a special case of the **generalized count** (GC) distribution, $p(k) = e^{\theta k + g(k)} / k!$ which can account for over- or under-dispersion.

It can be used in latent variable models $y_{ij}|x_j \sim \text{Poisson}(\exp c'_{ij} x_j + d)$ where the state x_j is modeled by a Gaussian dynamic system $x_{j,t+1}|x_{j,t} \sim N(Ax_{j,t} + b, Q)$.

Large scale unusual time series detection
R.J. Hyndman et al. (2015)

To detect outliers in a dataset of time series: compute features for each time series (mean, variance, autocorrelation, trend, linearity, curvature, seasonality, peakedness, troughiness, spectral entropy, lumpiness, spikiness, level shift, variance change, flat spots, crossing points, Kullback-Leibler, etc. – scagnostics), reduce the dimension (PCA), and use 2-dimensional outlier detection algorithms (alpha-hull or density-based).

**Topology data analysis of critical transitions
in financial networks**
M. Gidea (2017)

Compute the correlation matrix of asset returns on a moving window, convert it to a distance $d_{ij} = \sqrt{1 - c_{ij}}$, compute the persistence diagram of the corresponding Rips filtration (with `TDA::ripsDiag`) and look at the Wasserstein or bottleneck distance between two dates: they may help forecast crises.

[How different is it from the L^2 distance between the correlation matrices?]

**Network-based anomaly detection
for insider trading**
A. Kulkarni et al.

Build a network with insiders (of the same company) as nodes and an edge whenever the length of the *longest common subsequence* (LCS) of ordered trade dates exceeds some threshold (5 for sales, 10 for purchases). Look at the *egonets*, *i.e.*, the subgraphs induced by the nodes at distance at most one from a given node. Identify outliers by the residuals of $\log \#E \sim \log \#V$ for the *egonets*, and the local outlier factor (LOF) comparing the density of a node with that of its neighbours; they are hubs or bridges between highly connected components.

The same approach applies to hypergraphs (a hyper-edge between a set of insiders if the length of the LCS of trade dates exceeds some threshold); the profit of the transactions in those hyperedges tends to be positive.

Graph-based anomaly detection
C.C. Noble and D.J. Cook (2003)

To detect repetitive patterns (substructures) in a graph, compare the description length of the graph before and after contracting this substructure

$$\text{DL}(G) - (\text{DL}(G|S) + \text{DL}(S)).$$

Compress the most frequent substructure and iterate (“Subdue” algorithm).

To detect anomalies in a graph. compute

$$A = 1 - \frac{1}{n} \sum_{i=1}^n (n - i + 1) \frac{\text{DL}_{i-1}(S) - \text{DL}_i(S)}{\text{DL}_0(S)}$$

for each substructure S , where $DL_i(S)$ is the description length of S after i steps of the algorithm.

To detect anomalies in a graph, one could also find substructures S such that

$$\text{size of } S \times \text{number of instances of } S$$

be small.

RolX: Structural role extraction and mining in large graphs
K. Henderson et al. (2012)

To identify “roles” in a network (e.g., star center, clique member, peripheral node, etc.), compute node features (degree, number of within-egonet edges, average and maximum neighbour degree, number of triangles, etc.) and soft-cluster them with nonnegative matrix factorization (NMF).

It's who you know: graph mining using recursive structural features
K. Henderson et al. (2010)

Recursive graph features are built as follows:

- Number of within-egonet edges;
- Number of edges leaving or entering the egonet;
- Mean or sum of a feature over the egonet.

Prune the features by discarding those similar to previous ones; prune them further by focusing on those with good predictive power on node attributes.

Applications include graph de-anonymization, graph isomorphism, graph-based anomaly detection.

Graph-based anomaly detection and description: a survey
K. Akoglu et al.

Statistical industry classification
Z. Kakushadze and W. Yu (2017)

To cluster stocks, use excess returns, normalized by the squared volatility (rather than the volatility, to reduce the influence of volatile stocks – in practice, consider something like $r/\sigma \text{Max}(\bar{\sigma}, \sigma)$ to avoid creating a similar problem with low-volatility stocks).

To choose the number of clusters, use the *effective rank* of the correlation matrix:

$\lambda_1, \dots, \lambda_n$ eigenvalues

$$p_i = \frac{\lambda_i}{\sum \lambda_j}$$

$$H = -\sum p_i \log p_i \text{ (spectral) entropy}$$

$$\text{erank } C = \exp H.$$

The effective rank: a measure of effective dimensionality
O. Roy and M. Vetterli (2007)

Instead of minimizing the rank of a matrix, minimize its **effective rank**: compute its singular values $\sigma_1 \geq \dots \geq \sigma_m \geq 0$, rescale them $p_i = \sigma_i / \sum \sigma_j$, compute the *spectral entropy* $H = -\sum p_i \log p_i$ and take its exponential.

Statistical risk models
Z. Kakushadze and W. Yu (2017)

To estimate the number of factors in a statistical risk model, use the effective rank: compute the eigenvalues, rescale them to have a probability distribution, compute its entropy, and the corresponding effective number of values.

Since the “market” factor dominates, the result is often close to 1: if this is not desirable, remove the largest eigenvalue and add 1 back at the end.

Optimization can be approximated with a weighted regression on the first principal components, with the inverse of the specific variances as weights.

Decoding Chinese stock market returns: three-state hidden semi-Markov model
Z. Liu and S. Wang (2016)

The *Taylor effect* is yet another stylized fact: $\text{Cor}(|r_t|^\theta, |r_{t-\tau}|^\theta)$ is maximum for $\theta = 1$.

In a hidden Markov model (HMM), the sojourn time follows a geometric distribution. **Hidden semi-Markov models** (HSMM, estimated with the EM algorithm) relax that restriction by separately modeling the sojourn time and the state transitions.

Spatial dependence in asset pricing models
B. Zhu and S. Milcheva

To price real estate firms, add the physical distance between their properties to the CAPM or the factor model used.

$$r_i = \alpha_i + \rho \sum_{j \neq i} w_{ij} r_j + \sum_k \beta_{ik} f_k + \varepsilon_i, \quad w_{ij} \propto d_{ij}^{-1} \text{ or } d_{ij}^{-2}$$

Time series copulas for heteroskedastic data
R. Loaiza-Maya et al. (2016)

In presence of heteroskedasticity, the dependence structure of a time series (X_{t-1}, X_t) cannot be described by the common parametric copulas: the observations gather in the four corners, or along an “X”, instead of one or two corners and along a diagonal.

One can use *mixtures of rotated copulas* (or D-vines (drawable vines) of them, in higher dimensions).

DEA portfolio modeling
S.M. Gasser (2016)

Data envelopment analysis (DEA) is often used as a screening step, to select stocks according to multiple criteria, before portfolio optimization. Instead, one can directly use the DEA efficiency score to compute the portfolio weights (just rescale them).

Deep learning for finance: deep portfolios
J.B. Heaton et al. (2016)

Use autoencoders for non-linear PCA regression to replicate an index, or to explain returns (as with the CAPM or factor models).

The volatility of bitcoin
A. Urquhart (2017)

The *heterogeneous auto-regressive* (HAR) model is an alternative to GARCH models with high frequency data:

$$\sigma_{[t,t+1]} \sim \sigma_{[t-1,t]} + \sigma_{[t-7,t]} + \sigma_{[t-30,t]}.$$

Efficient algorithms for computing risk parity portfolio weights
D. Chaves et al. (2012)

The risk parity portfolio can be computed using Newton's method to solve

$$\begin{aligned} Vw &= \lambda w^{-1} \\ w'1 &= 1 \end{aligned}$$

(the unknowns are λ and w),

$$\begin{aligned} J &= \begin{pmatrix} V + \lambda \text{diag}(w^{-2}) & -w^{-1} \\ 1' & 0 \end{pmatrix} \\ \begin{pmatrix} w \\ \lambda \end{pmatrix} &\leftarrow \begin{pmatrix} w \\ \lambda \end{pmatrix} - J^{-1} \begin{pmatrix} Vw - \lambda w^{-1} \\ 1'w - 1 \end{pmatrix} \end{aligned}$$

or by iterating

$$\begin{aligned} w_i &\leftarrow \frac{\beta_i^{-1}}{\sum \beta_j^{-1}} \\ \beta_i &\leftarrow \frac{(Vw)_i}{w'Vw}. \end{aligned}$$

These algorithms are not guaranteed to converge.

A fast algorithm for computing high-dimensional risk parity portfolios
T. Griveau-Billion et al.

The usual algorithm to find long-only risk parity portfolios, sequential quadratic programming (SQP) to equalize the total contributions to risk, *i.e.*, minimize

$$\sum_{i < j} (\text{TCTR}_i - \text{TCTR}_j)^2,$$

does not scale.

Use coordinate descent to minimize $\sqrt{w'Vw} - \sum b_i \log w$ (where the b_i are the risk budgets): w_i is the positive solution of

$$\sigma_i w_i^2 + \left(\sum_{j \neq i} w_j \rho_{ij} \sigma_j \right) w_i - b_i \sqrt{w'Vw} = 0.$$

Constrained Kelly portfolios under α -stable laws
N. Wesselhöfft (2016)

Add a CVaR constraint to the growth-optimal strategy, and assume α -stable returns.

Managing diversification
A. Meucci (2010)

The eigendecomposition $E'\Sigma E = \Lambda$ of the variance matrix Σ of asset returns X defines *principal portfolios*, with returns $E'X$. Their contributions to portfolio variance $w'\Sigma w$ are $(E^{-1}w) \odot (E^{-1}w) \odot \text{diag } \Lambda$; dividing by $w'\Sigma w$ gives the *diversification distribution* whose entropy defines the **effective number of uncorrelated bets**.

If market exposure is not under our control, remove the first principal portfolio. If there are more constraints, write them as $Aw = b$ and compute the corresponding **conditional eigenvectors**

$$e_i = \underset{\substack{e \text{ such that} \\ e'e=1 \\ Ae=0 \\ \forall j < i \ e'\Sigma e_j=0}}{\text{Argmax}} e'\Sigma e.$$

They can be computed (using Lagrange multipliers) as

$$\begin{aligned} B &= \begin{pmatrix} A \\ e'_1 \Sigma \\ \vdots \\ e'_{j-1} \Sigma \end{pmatrix} \\ P &= I - B'(BB')^{-1}B \\ e_i &= \underset{\|e\|=1}{\text{Argmax}} e'P\Sigma P'e. \end{aligned}$$

We still have $E'\Sigma E = \Lambda$, with Λ diagonal, but $E' \neq E^{-1}$.

One can then look at the mean-entropy frontier.

Building diversified portfolios that outperform out-of-sample
M. López de Prado

Hierarchical risk parity (HRP) aims to circumvent *Markowitz's curse*: the more correlated the investments, the greater the need for diversification, and yet the more likely we will receive unstable solutions. Other approaches include: constraints, Bayesian priors, robust optimization, numerically stable variance estimators (shrinkage, factor models, graphical lasso).

Compute the sample correlation matrix ρ , the corresponding distances $d_{ij} = \sqrt{1 - \rho_{ij}}$ and the distances between those distances $\delta_{ij} = \|d_{\cdot,i} - d_{\cdot,j}\|_2$; perform

single linkage hierarchical clustering and use it to re-order the covariance matrix: it is now near-diagonal.

By analogy with the (unconstrained) minimal variance portfolio, $w = V^{-1}1/1'V^{-1}1$, whose weights are the inverses of the variances when the variance matrix is diagonal:

- Start with the full set of assets $L = \{1, \dots, n\}$ and initial weights $(1, \dots, 1)'$;
- Split L in two, $L = L_1 \cup L_2$ [they use two halves, but with a more balanced hierarchical clustering (e.g., complete linkage), it would make more sense to use it];
- Compute the variances of the corresponding inverse-variance-weighted portfolios

$$V = \begin{pmatrix} V_1 & \\ & V_2 \end{pmatrix}$$

$$w_i \propto (\text{diag } V_1)^{-1}$$

$$v_i = w_i' V w_i;$$

- Rescale the weights [this does not preserve the sum of the weights]

$$w_{I_1} \leftarrow \alpha w_{I_1}$$

$$w_{I_2} \leftarrow (1 - \alpha) w_{I_2}$$

$$\alpha = \frac{v_2}{v_1 + v_2};$$

- Continue recursively.

***Interconnectedness risk
and active portfolio management***
E. Baitinger and J. Papenbrock (2016)

Peripheral stocks, for some measure of centrality (betweenness, closeness, eccentricity, degree, eigenvector) of the minimum spanning tree (or some other “strongly filtered graph”) built from the correlation matrix of daily returns, estimated on a 6-month moving window, have higher risk-adjusted returns. Build a portfolio by minimizing the average centrality (with a few constraints: $w'1 = 1, \|w - w_0\|_1 \leq \varepsilon$ – it is a linear problem); compare with minimum variance, minimum average correlation, maximum diversity, maximum entropy, hierarchical risk parity; measure the performance with Jensen’s alpha, the upside capture ratio

$$UC = \frac{E[\text{portfolio returns} | \text{market up}]}{E[\text{market returns} | \text{market up}]},$$

the downside capture ratio, or the certainty equivalent return for $U(W) = W^{1-\gamma}/(1-\gamma)$ for $\gamma \in \{3, 5, 10\}$.

***Interconnectedness risk
and active portfolio management:
the information-theoretic perspective***
E. Baitinger and J. Papenbrock (2017)

Build minimum centrality portfolios from the *mutual information* rather than the correlation [one could also use the *distance correlation*]. In R check `entropy::mi.plugin` or `infotheo::mutinformation`.

***The real side
of the high-volume return premium***
D. Israeli et al. (2017)

Abnormal volume around earnings announcements increases investor recognition and firm visibility, decreases the cost of capital, and increases future investments. The effect remains after controlling for sales, cash flow, current investments, leverage, Tobin’s Q, earnings surprises, abnormal returns around earnings, etc., but is more pronounced for financially-constrained firms (low assets, low payout ratio) and has been decreasing as information becomes more readily available.

Tobin’s Q is

$$Q = \frac{\text{Market value of assets}}{\text{Book value of assets}}$$

$$= \frac{BV(\text{assets}) + MV(\text{equity}) - BV(\text{equity})}{BV(\text{assets})}$$

***The limits of arbitrage and stock mispricing:
evidence from decomposing
the market to book ratio***
N.M. Al-Shammasi (2017)

Stocks with easily-identified peers have a lower mispricing. The nearest stock is that with the closest *propensity score*, i.e., predicted value of a logistic regression $1_{S\&P\ 500} \sim \text{Fama-French}$. [Other measures of proximity may be more meaningful: density (LOF), correlation, mutual information, distance correlation, cointegration test, etc.]

***Programmed selection
of cyclical turning points***
G. Bry and C. Boschan (1971)

To detect business cycles on a “clean” time series:

- Find local minima and maxima, with a 5-month or 2-quarter window;
- Prune them to ensure there are no consecutive minima or maxima; keep the most extreme;
- Prune them to ensure “up” and “down” periods are at least 5 months long, and the cycles (up-then-down or down-then-up) 15 months;
- Remove extrema too close to or inconsistent with the extremities.

For a real-world time series:

- Apply the procedure to the 12-month moving average;
- Pick the local extrema of the Spencer curve (a moving average with more weight at the center) best matching those points (most extreme in a 5-month radius);
- Pick the local extrema of the raw data best matching those points.

Dating the Euro area business cycle

M. Artis et al.

Markov switching models can help identify business cycles.

The local maxima and minima of a price time series give a set of candidate latent state sequences: we can compute the likelihood of each of them and pick the best. Duration constraints can be imposed by enlarging the state space to contain the (S_1, \dots, S_{15}) satisfying the constraints; the only transitions are $(S_1, \dots, S_{15}) \rightarrow (S_2, \dots, S_{15}, *)$. For monthly data, it may be necessary to filter the time series to remove low frequency patterns, e.g., with a band-pass filter or an HP filter.

Noise fit, estimation error and a Sharpe information criterion

D. Paulsen and J. Söhl (2016)

The realized information ratio tends to be much lower than the forecasted one: correct it.

$$\text{IR}_{\text{out}} = \text{IR}_{\text{in}} - \frac{\# \text{parameters or assets}}{\text{IR}_{\text{in}} \times \# \text{periods}}$$

Option-based benchmark indices – a review of performance and (in)appropriate measures

M. Natter (2017)

Jensen's alpha (the CAPM intercept) is inappropriate to measure the performance of option strategies (for which there are now many indices and even a few ETFs):

- Let the CAPM beta vary with time (e.g., make it a linear or 2-valued function of market returns);
- Add a straddle factor to the CAPM;
- Correct Jensen's alpha for skewness (Leland):

x : market log-returns

y : strategy log-returns

$$b = \frac{E[x]}{\text{Var}[x]}$$

$$\beta = \frac{\text{Cov}(e^x, -e^{-by})}{\text{Cov}(e^x, -e^{-bx})}$$

$$\alpha = E[y] - \beta E[x]$$

- Adjust the Sharpe ratio for higher moments (Stutzer index):

$$I = \text{Max}_{\theta} - \log E[e^{\theta y}]$$

$$\text{IR} = \sqrt{2I} \times \text{sign } E[y].$$

Information geometry and statistical manifolds

M. Suzuki (2014)

Consider a family of probability distributions indexed by an open set $\Omega \subset \mathbf{R}^n$, $S = \{p(\cdot, \xi) : \xi \in \Omega\}$. The Fisher information matrix

$$g_{ij}(\xi) = E[\partial_i \ell_{\xi} \partial_j \ell_{\xi}] = -E[\partial_i \partial_j \ell_{\xi}]$$

where $\ell_{\xi} = \log p(\cdot, \xi)$ and $\partial_i = \partial/\partial \xi_i$, defines a Riemann structure on S . For instance, the Gaussian (1-dimensional) family is the Poincaré half plane

$$\Omega = \mathbf{R} \times \mathbf{R}_+^{\times}$$

$$S = \{N(\mu, \sigma^2) : (\mu, \sigma) \in \Omega\}$$

$$g_{ij}(\mu, \sigma) = \begin{pmatrix} \sigma^{-2} & 0 \\ 0 & 2\sigma^{-2} \end{pmatrix}$$

The α -connection,

$$\begin{aligned} \Gamma_{ijk}^{\alpha} &= \langle \nabla_{\partial_i}^{\alpha} \partial_j, \partial_k \rangle \\ &= E \left[\left(\partial_i \partial_j \ell_{\xi} + \frac{1-\alpha}{2} \partial_i \ell_{\xi} \partial_j \ell_{\xi} \right) \partial_k \ell_{\xi} \right], \end{aligned}$$

for $\alpha \in \{-1, 0, +1\}$, satisfies

$$\Gamma_{ijk}^{\beta} = \Gamma_{ijk}^{\alpha} + \frac{\alpha - \beta}{2} T_{ijk}$$

$$T_{ijk} = E[\partial_i \ell_{\xi} \partial_j \ell_{\xi} \partial_k \ell_{\xi}]$$

$$\nabla^{\alpha} = (1 - \alpha) \nabla^0 + \alpha \nabla^1 = \frac{1 + \alpha}{2} \nabla^1 + \frac{1 - \alpha}{2} \nabla^{-1}$$

where

- ∇^0 is the Levi-Civita connection (compatible with the metric, torsion-free);
- ∇^1 is called the *exponential connection*; it is flat if S is an exponential family;
- ∇^{-1} is called the *mixture connection*; it is flat if S is a mixture family.

Computations with ∇^1 and ∇^{-1} are often easier than those with ∇^0 : they involve divergences rather than geodesic distances.

Information geometry for neural networks

D. Wagenaar (1998)

Families of distributions are often parametrized by an open of \mathbf{R}^n : this endows them with a geometric structure (differential manifold), but the Euclidean distance is inappropriate. Fisher information gives a better (parametrisation-independent) Riemannian structure:

$$g_{\mu\nu} = E[\partial_{\mu} \ell \partial_{\nu} \ell] = -E[\partial_{\mu} \partial_{\nu} \ell].$$

A *parallel transport* is a differentiable way of comparing tangent spaces at different points, when they are linked by a curve,

$$\Phi_{P \rightarrow P'} : T_{P'} M \longrightarrow T_P M,$$

with $\Phi_{P \rightarrow P} = \text{Id}$. Its first Taylor expansion, for $P = \gamma(0)$, $P' = \gamma(\varepsilon)$, $\dot{\gamma}(0) = \partial_{\mu}$, can be written

$$\Phi_{P \rightarrow P'}(\partial_{\nu}) = \partial_{\nu} + \varepsilon \Gamma_{\mu\nu}^{\rho} \partial_{\rho} + o(\varepsilon)$$

and defines a *connection* Γ .

Tangent vectors have several interpretations:

- 1-jets, i.e., equivalence classes of curves;
- Derivatives, ∂_{μ} ;

– Random variables, $\partial_\mu \ell$, *i.e.*, functions of X .

This last interpretation is specific to statistical manifolds and allows us to define two new connections. A connection is a mapping between $T_\theta M$ and $T_{\theta+\delta\theta}M$, whose bases are

$$\begin{aligned}\partial_\mu \ell(\theta) \\ \partial_\mu \ell(\theta + \delta\theta) = \partial_\mu \ell(\theta) + \partial_\mu \partial_\nu \ell(\theta) \delta\theta^\nu + O(\delta\theta^\mu \delta\theta^\nu).\end{aligned}$$

We can modify the second term to make its expectation disappear (this looks desirable since $E[\partial_\mu \ell(\theta)] = 0$) in two ways

$$\begin{aligned}\partial_\mu \partial_\nu \ell(\theta) + E[\partial_\mu \ell \partial_\nu \ell] \\ \text{or } \partial_\mu \partial_\nu \ell(\theta) - \partial_\mu \ell \partial_\nu \ell.\end{aligned}$$

Projecting the random variable onto $T_\theta M$,

$$\text{proj} : A \mapsto E[A \partial_\nu \ell] g^{\mu\nu} \partial_\mu \ell$$

gives

$$\begin{aligned}\Gamma_{\mu\nu}^\lambda &= E[\partial_\mu \partial_\nu \ell \partial_\rho \ell] g^{\rho\lambda} \\ \text{and } \Gamma_{\mu\nu}^\lambda &= E[\partial_\mu \partial_\nu \ell \partial_\rho \ell + \partial_\mu \ell \partial_\nu \ell \partial_\rho \ell] g^{\rho\lambda}.\end{aligned}$$

This defines the family of α -connections

$$\Gamma_{\mu\nu}^{(\alpha)\lambda} = E\left[\partial_\mu \partial_\nu \ell \partial_\rho \ell + \frac{\alpha-1}{2} \partial_\mu \ell \partial_\nu \ell \partial_\rho \ell\right] g^{\rho\lambda}.$$

The metric connection

$$\Gamma_{\mu\nu}^\lambda = \frac{1}{2} [\partial_\mu g_{\nu\rho} + \partial_\nu g_{\mu\rho} - \partial_\rho g_{\mu\nu}] g^{\rho\lambda}$$

is $\Gamma^{(0)}$.

Parallel transport does not usually preserve scalar products. Two connections Γ and Γ^* are *dual* if the vector fields X and Y^* , defined as the parallel transport of $X|_{\gamma(0)}$ and $Y|_{\gamma(0)}$ wrt Γ and Γ^* along a curve γ satisfy

$$\forall t \quad \langle X(t), Y^*(t) \rangle = \langle X(0), Y(0) \rangle.$$

The α and $-\alpha$ connections are dual.

For dually flat connections, Γ , Γ^* , there exist local coordinate systems θ , $\tilde{\theta}$, such that $\Gamma \equiv 0$ and $\Gamma^* \equiv 0$, and potential functions $\Theta(\theta)$, $\tilde{\Theta}(\tilde{\theta})$ such that $\tilde{\theta}_\mu = \partial_\mu \Theta(\theta)$ (and conversely). The *divergence* between two points P and Q is

$$D(P, Q) = \Theta(\theta_P) + \tilde{\Theta}(\tilde{\theta}_Q) - \theta_P^\mu \tilde{\theta}_{Q,\mu}.$$

It behaves like a distance, but is easier to compute: there is no need to integrate along a geodesic.

$$\begin{aligned}D(P, Q) &\geq 0 \\ D(P, Q) = 0 &\equiv P = Q \\ \left. \frac{\partial D(P, Q)}{\partial \theta} \right|_{P=Q} &= 0 \\ \frac{\partial^2 D(P, Q)}{\partial \theta^\mu \partial \theta^\nu} &= g_{\mu\nu}(P)\end{aligned}$$

A computational approach to Fisher information geometry with applications to image analysis W. Mio et al.

Given two probability density functions (pdf) on $[0, 1]$, how can we deform one into the other? Those pdfs form an infinite dimensional statistical manifold (we can represent a pdf p with its log-likelihood $\phi = \log p$):

$$\begin{aligned}\mathcal{P} &= \{ \phi : \int e^\phi = 1 \} \\ T_\phi \mathcal{P} &= \{ f : \int f e^\phi = 0 \} \\ \langle f, g \rangle &= \int f g e^\phi\end{aligned}$$

(for the scalar product, use the Hessian of the Kulback-Leibler divergence). Discretizing the pdf on an equispaced grid gives

$$\begin{aligned}\mathcal{P}_n &= F^{-1}(1) \\ F : \begin{cases} \mathbf{R}^n & \longrightarrow \mathbf{R} \\ \phi & \longmapsto \sum e^{\phi_i} \end{cases} \\ \langle f, g \rangle_\phi &= \sum f_i g_i e^{\phi_i} \\ T_\phi \mathcal{P}_n &= \{ f : \langle f, \mathbf{1} \rangle_\phi = 0 \} \\ dF_\phi(f) &= \sum f_i e^{\phi_i} = \langle f, \mathbf{1} \rangle_\phi\end{aligned}$$

Geodesics in a given direction can be computed by iterating the following steps (?).

$$\begin{aligned}\phi_0 &: \text{starting point} \\ f_0 &: \text{direction} \\ \phi_1 &\leftarrow \phi_0 + \varepsilon f \\ \phi_1 &\leftarrow \phi_1 + \alpha \mathbf{1}, \text{ with } \alpha \text{ s.t. } F\phi_1 = 1 \\ f_1 &\leftarrow f_0 - \langle f_0, \mathbf{1} \rangle_{\phi_1} \mathbf{1} \\ f_1 &\leftarrow \|f_0\| \frac{f_1}{\|f_1\|}\end{aligned}$$

For the geodesic between two points, use the shooting method to find the correct direction to reach the desired target in unit time.

Those geodesics can help compute Fréchet means, perform PCA or k -means.

Computational information geometry for machine learning F. Nielsen (MLSS 2015)

1. A statistic t is *sufficient* for a parameter θ if

$$P(X | t(X), \theta) = P(X | t(X)).$$

The probability can then be decomposed as (Fisher–Neyman theorem)

$$P(x; \theta) = g(t(x), \theta) h(x).$$

This motivates the **exponential family**:

$$p(x; \theta) = \exp[\langle t(x), \theta \rangle - F(\theta) + k(x)]$$

$t(x)$: sufficient statistic
 $k(x)$: auxiliary term
 $F(\theta)$: normalization constant.

Many common distributions are exponential (Uniform, Cauchy and stable distributions are not exponential).

The normalizing constant

$$F(\theta) = \log \int \exp[\langle t(x), \theta \rangle + k(x)] dx$$

is convex. Its convex conjugate is

$$F^*(\eta) = \sup_{\theta \in \Theta} \langle \eta, \theta \rangle - F(\theta),$$

for $\eta \in H$, $H = \{\nabla F(\theta) : \theta \in \Theta\}$, and the supremum is obtained for $\theta = \nabla F^*(\eta) = (\nabla F)^{-1}(\eta)$. The *canonical divergence* is (Fenchel–Young inequality)

$$A_F(\theta : \eta) = F(\theta) + F^*(\eta) - \langle \eta, \theta \rangle \geq 0.$$

Exponential families have two parametrizations.

$$\begin{array}{ccc} \text{natural} & & \text{expectation} \\ \theta \in \Theta & \longleftrightarrow & \eta \in H \\ \theta = \nabla F^*(\eta) & & \eta = \nabla F(\theta) = E[t(X)]. \end{array}$$

The maximum likelihood estimator is easy to compute in expectation coordinates: $\eta = E[t(X)]$.

2. The Fisher information is the variance of the *score*, i.e., the information a random variable X carries about a parameter θ . It defines a metric on statistical manifolds

$$g_{ij}(\theta) = E[\partial_i \ell \partial_j \ell] = -E[\partial_i \partial_j \ell] = 4 \int \partial_i \sqrt{p} \partial_j \sqrt{p} dx.$$

The *exponential map* maps (a star-shaped neighbourhood of the origin in) $T_x M$ to M : $v \mapsto \exp_x(v) = \gamma_v(1)$; its inverse is \log_x . Location-scale families (Gaussian, Cauchy, Student, etc.) are hyperbolic (they have negative curvature); the multinomial family is spherical.

On a statistical manifold, one can interpret tangent vectors as random variables, e.g., $\partial_i p(x)$, $\partial_i \ell(x)$, $2\partial_i \sqrt{p(x)}$, or, more generally, $\partial_i f_\alpha(x)$, where

$$f_\alpha(u) = \begin{cases} \frac{2}{1-\alpha} u^{\frac{1-\alpha}{2}} & \alpha \neq 1 \\ \log u & \alpha = 1 \end{cases}$$

For a univariate Gaussian, the Fisher information is

$$I(\mu, \sigma) = \sigma^{-2} \begin{pmatrix} 1 & 0 \\ 0 & 2 \end{pmatrix};$$

after rescaling, this is the Poincaré half plane. Positive matrices are also hyperbolic spaces, e.g., the Poincaré disk (conformal) or the Klein disk (not conformal).

Information geometric optimization uses the natural gradient $I^{-1} \nabla f$ instead of the gradient ∇f .

Jeffrey's prior, $q(\theta) \propto \sqrt{|g(\theta)|}$, is invariant under reparametrization.

3. The Riemannian metric is not the only way of defining geodesics and “distances”. Given two probability distributions p and q , one can consider curves between them:

$$\begin{aligned} \gamma_m : \quad & r(x, t) = \alpha p(x) + (1 - \alpha) q(x) \\ \gamma_e : \quad & \log r(x, t) = \alpha \log p(x) + (1 - \alpha) \log q(x) + c. \end{aligned}$$

They are geodesics for the dual *mixture* (m) and *exponential* (e) **connections**. For the exponential family, they are flat, and $\Gamma \equiv 0$, resp. $\Gamma^* \equiv 0$, in the $\theta = \nabla F^*(\eta)$ and $\eta = \nabla F(\theta)$ coordinate. The metric tensor can be recovered from the *potential functions* F and F^* :

$$\begin{aligned} g_{ij}(\theta) &= \frac{\partial^2 F(\theta)}{\partial \theta_i \partial \theta_j} & \Gamma_{ijk}^\alpha &= \frac{1 - \alpha}{2} \frac{\partial^3 F(\theta)}{\partial \theta_i \partial \theta_j \partial \theta_k} \\ g^{ij}(\eta) &= \frac{\partial^2 F^*(\eta)}{\partial \eta_i \partial \eta_j} & \kappa &= \frac{1 - \alpha^2}{4} \end{aligned}$$

If $p(x; \theta) = \exp[\langle \theta, x \rangle - F(\theta)]$, F is the *cummulant* dunction and F^* the *negentropy*. Since $\nabla^{(e)} = \nabla^{(1)}$ and $\nabla^{(m)} = \nabla^{(-1)}$ are flat, the geodesics are easier to compute than those for the Levi-Civita connection $\nabla^{(0)}$.

4. If P and Q belong to the same exponential family, the canonical and Bregman **divergences** are related.

$$\begin{aligned} A_F(\theta : \eta) &= F\theta + F^*\eta - \langle \eta, \theta \rangle \\ B_F(\theta_1 : \theta_2) &= F\theta_1 - F\theta_2 - \langle \theta_1 - \theta_2, \nabla F\theta_2 \rangle \\ KL(P \parallel Q) &= B_F(\theta_P : \theta_Q) = B_{F^*}(\eta_P : \eta_Q) \\ &= A_F(\theta_Q : \eta_P) = A_{F^*}(\eta_P : \theta_Q) \end{aligned}$$

(The Bregman divergence is the residual of the first order Taylor expansion.)

5. The **maximum entropy** distribution p with prescribed moments $E[t(X)]$ minimizes the Kullback-Leibler divergence with the uniform distribution $q = (\frac{1}{n}, \dots, \frac{1}{n})$.

$$\begin{aligned} \text{Find} \quad & p \\ \text{To maximize} \quad & D(p : q) = \sum p_i \log \frac{p_i}{q_i} \\ \text{Such that} \quad & \forall j \sum_i p_i t_{ij} = m_j \\ & \sum_i p_i = 1 \\ & \forall i \ p_i \geq 0 \end{aligned}$$

Using Lagrange multipliers, we see that this distribution is exponential $p(x) \propto q(x) \exp\langle \theta, t(x) \rangle$.

The KL-Pythagoras theorem,

$$KL(p : q) = KL(p : p^*) + KL(p^* : q)$$

holds if p and p^* satisfy the moment constraints, the submanifold defined by those constraints is m-flat, and p^* is the e-projection of q on it.

6. The maximum entropy estimator is the e-projection of a prior onto the moment manifold.

The maximum likelihood estimator is the m-projection of the empirical distribution p_{emp} onto the model submanifold M ,

$$p_\theta = \underset{p \in M}{\text{Argmin}} D(p_{\text{emp}} : p).$$

Those **information projections** are defined as

$$\text{e-projection}_M(q) = \underset{p \in M}{\text{Argmin}} D(p : q)$$

$$\text{m-projection}_M(q) = \underset{p \in M}{\text{Argmin}} D(q : p)$$

The e- (resp. m-) projection is unique if M is m- (resp. e-) flat.

7. The Riemannian distance (*Rao distance*) is difficult to compute explicitly (it is not known in closed form for multivariate normals), but lets you use the exponential (and logarithm) map between the tangent space and the manifold.

One often switches between conformal models (e.g., the Poincaré disk, good for visualization) and non-conformal ones (e.g., the Klein disk, whose geodesics are straight lines – good for computations).

8. Many geometric notions can be generalized to divergences.

The cosine law ($c^2 = a^2 + b^2 - 2ab \cos \hat{C}$) becomes

$$\begin{aligned} D(P : R) &= D(P : Q) + D(Q : R) - \|\dot{\gamma}_{PQ}\| \|\dot{\gamma}_{QR}^*\| \cos \theta \\ &= D(P : Q) + D(Q : R) - \langle \theta_P - \theta_Q, \eta_R - \eta_Q \rangle \end{aligned}$$

where θ is the angle between the ∇ -geodesic γ_{PQ} and the ∇^* -geodesic γ_{QR} .

The *Bregman sphere* is defined as follows.

$$F : \mathbf{R}^d \longrightarrow \mathbf{R}$$

$$\mathcal{F} = \{ (x, F(x)) : x \in \mathbf{R}^d \} \quad \text{hypersurface}$$

$$H_p(x) = \langle x - p, \nabla F_p \rangle + F_p \quad x, p \in \mathbf{R}^p$$

$$\mathcal{H}_p = \{ (x, H_p(x)) : x \in \mathbf{R}^d \} \quad \text{tangent space } T_{(p, F_p)} \mathcal{F}$$

$$F \cap (\mathcal{H}_p + (\mathbf{0}, r)) \quad \text{Bregman sphere}$$

Vantage point trees partition the space with Bregman spheres to speed up nearest neighbour queries. One can (algorithmically) compute the smallest Bregman enclosing ball, test if a point is inside a Bregman ball defined by $n + 1$ support points (to compute Delaunay triangulations), etc.

9. There are many divergences

$$\text{Csiszár} \quad I_f(p, q) = \sum q_i f\left(\frac{p_i}{q_i}\right)$$

$$\text{KL} \quad KL(p : q) = \sum p_i \log \frac{p_i}{q_i}$$

$$\text{Bregman} \quad B_F(x, y) = Fx - Fy - \langle x - y, \nabla Fy \rangle$$

$$\text{Canonical} \quad A_F(\theta : \eta) = F\theta + F^*\eta - \langle \eta, \theta \rangle$$

$$\begin{aligned} \text{Skew-Jensen} \quad J_\alpha(x, y) &= \alpha Fx + (1 - \alpha)Fy \\ &\quad - F(\alpha x + (1 - \alpha)y) \end{aligned}$$

and many divergence-based k -means generalizations.

Multiclass classification

Y. Keshet (2014)

The all-against-one and all-pairs multiclass classification schemes reduce the problem to binary classification

$$\underset{i}{\text{Argmax}} P(X = i)$$

$$\text{or } \underset{i}{\text{Argmax}} \sum_{j \neq i} P(X = i \mid X \in \{i, j\});$$

they can be generalized to an arbitrary set of binary comparisons $P(X \in I \mid X \in J)$, $I \subsetneq J$ with error correcting codes (ECOC: error correction output codes).

Multiclass classifiers (softmax, SVM, etc.) are usually of the form $\underset{i}{\text{Argmax}} \text{Score}(X, i)$. (the formula is the same, but there is only one model).

Multi-label classification with error-correcting codes

C.S. Ferng and H.T. Lin

Error correcting codes (ECOC) can also be used for multi-label classification (predicting a *set* of labels instead of just one).

Here are the common error correcting codes.

- Repetition: repeat each bit 3 times.
- Hamming(7,4): 4 data bits and 3 parity bits.

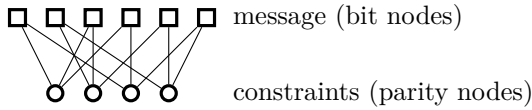

$$p_1 = d_1 \oplus d_2 \oplus d_4$$

$$p_2 = d_1 \oplus d_3 \oplus d_4$$

$$p_3 = d_2 \oplus d_3 \oplus d_4$$

- Low-density parity check (LDPC) codes do not really specify how to encode a message (this is left as an exercise for the user) but rather which messages are valid. A binary vector x is valid if $Px = 0$, where P is the binary matrix (parity matrix) defining the code. It usually has the same number of 1s in each

row, and the same number of 1s in each column. It can be represented as a bipartite graph.

One can decode a message (*i.e.*, find the closest valid message) using message passing.

- BCH are the most commonly-used codes.

$q = 2$ prime number
 $n = q^m - 1$
 $d < n$
 $\alpha \in \mathbf{F}_{q^m}$ generator of \mathbf{F}_{q^m}
 $m_i \in \mathbf{F}_q[X]$ minimal polynomial of α^i
 $g = \text{lcm}(m_1, \dots, m_d)$
 Code words = $\{ P \in \mathbf{F}_q[X] : \deg P < n \text{ and } g|P \}$

**Stochastic portfolio theory:
a machine learning perspective
Y.L.K. Samo and A. Vervuurt**

Stochastic portfolio theory shows that, under reasonable assumptions, a (continuously-rebalanced) portfolio with weights $w_i \propto \text{MCap}_i^p$ (diversity-weighted portfolio), for $p \in (0, 1)$, a.s. outperforms the market. The amplitude of the performance and the time needed to reach it depend on p : small, quick out-performance if p is close to 1, larger, but more delayed if p is close to 0 (the $1/N$ portfolio).

To find the best p , empirically, *i.e.*, that maximizing the excess returns (after 10bp transaction costs), one can use a grid search ($p \in [-8, 8]$) or a Bayesian approach (Metropolis-Hastings), with a uniform prior on p , and $\text{Gamma}(\text{ExcessReturns}(p); a, b)$ as likelihood, where a and b reflect the investor's risk appetite (e.g., a bullish investor could want mean= 7 and sd= .5).

A non-parametric approach,

$$w_i \propto f(\text{MCap}_i)$$

$$\log f \sim \text{GP}(0, k),$$

where k is a rational quadratic kernel,

$$k(x, y) = a \left[1 + \frac{(x - y)^2}{b} \right]^c,$$

prefers midcaps, and can be generalized to account for other predictors, e.g., the ROA,

$$w_i \propto f(\text{MCap}_i, \text{ROA}_i)$$

$$\log f \sim \text{GP}(0, k_{\text{MCap}} \times k_{\text{ROA}}).$$

**Diversity-weighted portfolios
with negative parameter
A. Vervuurt and I. Karatzas (2015)**

Diversity-weighted portfolios $w_i \propto \text{MCap}_i^p$, with $p < 0$, are also worth considering.

**Bayesian Lipschitz constant
estimation and quadrature
J.P. Calliess**

Probabilistic numerics provides quadrature rules tailored to a given prior: for instance, the trapezoidal rule comes from a random walk prior and is suboptimal if we know the function is smoother.

**What works best when? A framework
for systematic heuristic evaluation
I. Dunning et al. (2015)**

Use machine learning to select which heuristic (or machine learning algorithm) to use on a new problem (MaxCut or quadratic unconstrained binary optimization).

$$\text{MaxCut:} \quad \text{Maximize} \sum_{i,j} w_{ij} (1 - y_i y_j)$$

$$\text{QUBO:} \quad \text{Maximize} x' Q x$$

Train on real (non-simulated) data, with the following graph metrics as features: number of nodes, number of edges, assortativity, approximate maximum independent set, Laplacian eigenvalues, approximate chromatic number; mean, standard deviation, minimum, maximum, skew, kurtosis of degree, weight, average neighbour degree (as a function of the node degree), clustering coefficient, core number.

**Obtaining calibrated probability estimates from
decision trees and naive Bayesian classifiers
B. Zadrozny and C. Elkam**

Machine learning classifiers may provide accurate class forecasts and rankings, but rarely accurate probability estimates.

- Since predictors, in a naive Bayes classifier, are often correlated, the probabilities are close to 0 or 1: a histogram method can rescale them.
- Decision trees try to make leaves homogeneous: observed probabilities are shifted towards 0 or 1; probabilities in small leaves have high variance. *Laplace smoothing* replaces probabilities k/n with $(k+1)/(n+2)$, *i.e.*, shrinks them towards $1/2$ – but this need not be the base rate. Instead, shrink them towards the base rate b , $k/n \mapsto (k+bm)/(n+m)$ (*m-estimation*), with $bm = 10$, or towards the parent node. Splitting criteria generating smaller trees (e.g., $h(p, 1-p) = \sqrt{p(1-p)}$) may help.

**Scalable inference
for structured Gaussian process models
Y. Saatçi (2011)**

A structured Gaussian process (GP) is a GP whose covariance matrices have a special structure, often allowing more efficient computations:

- Bounded rank, as in linear regression;

- Toeplitz, for 1-dimensional kernels evaluated on a regular grid;
- Gauss-Markov processes, for some 1-dimensional kernels (e.g., Matérn);
- Block structure, if there is a change point;
- Additivity, as in GAMs;
- Kronecker product, if the kernel is a tensor product evaluated on a (not necessarily regular) grid).

Generalized GPs (i.e., non-Gaussian “GP”s, e.g., Poisson GPs for count data) can be estimated using the Laplace approximation or expectation maximization.

1. A linear stochastic differential equation (SDE) with constant coefficients

$$f^{(m)}(x) + a_{m-1}f^{(m-1)}(x) + \dots + a_0f(x) = W(x)$$

defines a GP with the Markov property

$$\frac{d}{dx} \begin{pmatrix} f \\ f' \\ \vdots \\ f^{(m-1)} \end{pmatrix} = \begin{pmatrix} 0 & 1 & 0 & \dots & 0 \\ \vdots & \ddots & \ddots & \ddots & \vdots \\ 0 & \dots & 0 & 1 & \vdots \\ -a_0 & \dots & \dots & \dots & -a_m \end{pmatrix} \begin{pmatrix} f \\ f' \\ \vdots \\ f^{(m-1)} \end{pmatrix} + \begin{pmatrix} 0 \\ \vdots \\ 0 \\ 1 \end{pmatrix} W;$$

it is a state space model: it can be estimated with a Kalman smoother (after sorting the data along x). The SDE can be seen as a *linear time-invariant* (LTI) system, $f = Tw$, $w = \text{noise}$. It is characterized by its impulse function $h = T\delta$:

$$P\phi = \phi * h \\ k(\tau) = q\delta(\tau) * h(\tau) * h(-\tau).$$

Starting with

$$k(\tau) = q\delta(\tau) * h(\tau) * h(-\tau) \\ Tw = w * h$$

$$\sum a_k f^{(k)}(x) = w(x)$$

and taking the Fourier transform

$$S(\omega) = q |H(\omega)|^2 \\ F(\omega) = W(\omega)H(\omega) \\ \sum a_k (i\omega)^k F(\omega) = W(\omega)$$

gives

$$S(\omega) = q |H(\omega)|^2 = a \left| \frac{F(\omega)}{W(\omega)} \right|^2 \\ = \frac{1}{|\sum a_k (i\omega)^k|^2} \\ = \frac{1}{|\text{polynomial in } i\omega|^2} \\ = \frac{1}{\text{polynomial in } \omega^2}.$$

For the Matérn family,

$$S_\nu(\omega) \propto \frac{1}{(\lambda^2 + \omega^2)^{\nu+1/2}}.$$

For instance, $\nu = 7/2$ gives

$$A = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ -\lambda^4 & -4\lambda^3 & -6\lambda^2 & -4\lambda \end{pmatrix}$$

(this also explains why the paths of a Matérn GP are a.s. differentiable $\nu - 1/2$ times).

For the square exponential kernel, $S(\omega) \propto \exp(-\alpha\omega^2)$ is not the inverse of a polynomial, but can be approximated using polynomials (it may be easier to use a Matérn kernel, though).

Splines can also be expressed as GPs.

2. The Bayesian online change point detection (BOCPD) algorithm combines a base model and a hazard function; the parameters of the Bayesian model change at each changepoint.

r_t	length of the current run
$y_{t-r}, \dots, y_{t-1}, y_t$	current run
$P[y_t y_{t-r}, \dots, y_{t-1}]$	base model

The posterior $P[r_t | y_1, \dots, y_{t-1}]$ can be used to compute predictions robust to regime changes (with a message passing algorithm). For Gaussian processes, this is untractable, but it can be approximated with a grid or HMC; in both cases, prune highly unlikely run length values.

3. Additive GPs are GAMs with GP components.

4. The covariance matrices of a GP with a product kernel on a (not necessarily regular) grid are Kronecker products and therefore amenable to efficient computations.xs

Bandit algorithms for searching large spaces **L.R.M. Dorard (2012)**

A bandit game is a 1-state Markov decision process (MDP).

The *many-arm bandit* problem has too many arms (actions) to explore them all, but they are often arranged in a tree: one can use a Gaussian process to model the reward of a leaf, from the features of the path from the root (explicit features are not needed – a kernel suffices, e.g., that given by the number of nodes in common).

Both bandit problems and Bayesian optimization are exploration/exploitation problems.

Sum-product networks: a new deep architecture **H. Poon and P. Domingos**

The *network polynomial* of an (unnormalized) probability distribution P on $\{0, 1\}^n$ is $\sum_{I \subseteq [1, n]} P[x_I = 1, x_{\bar{I}} = 0] x_I x_{\bar{I}} \in \mathbf{R}[x_1, \dots, x_n, \bar{x}_1, \dots, \bar{x}_n]$. It can be represented as a *sum-product network*, i.e., a network

whose inputs are $x_1, \dots, x_n, \bar{x}_1, \dots, \bar{x}_n$ and with two types of nodes,

(Not all sum-product networks represent network polynomials, but there are simple sufficient conditions to ensure it.)

Adversarial perturbations of deep neural networks D. Warde-Farley et al.

Deep neural networks are affected by adversarial examples: one can take a correctly classified input and modify it slightly to produce a different output. Worryingly, adversarial examples seem model-agnostic. The problem is not with the excessive non-linearity of neural nets but their insufficient non-linearity: instead of a linear situation

we would prefer

Generative adversarial networks (GAN) simultaneously learn a generator, which transforms noise into an adversarial example, and a discriminator, whose role is to tell if the input came from the data or the generator – a minimax game.

A consistent multivariate test of association based on ranks of distances R. Heller et al. (2012)

To test the independence of two quantitative random variables X and Y , a permutation test for

$$\sum_{i \neq j} \chi^2 [X \in B(x_i, d_{ij}^X) \perp\!\!\!\perp Y \in B(y_i, d_{ij}^Y)]$$

is an alternative to the distance correlation (`energy::dcov.test`).

Stochastic gradient Riemannian Langevin dynamics on the probability simplex S. Patterson and Y.W. Teh

Langevin dynamics,

$$d\theta_t = \nabla \log \pi(\theta) dt + 2\sigma dW_y,$$

i.e., gradient updates plus noise

$$\begin{aligned} \theta_{n+1} &\leftarrow \theta_n + \varepsilon [\nabla_{\theta} \log p(\theta) + \sum \nabla_{\theta} \log p(x_i|\theta)] + \zeta \\ \zeta &\sim N(0, \varepsilon) \end{aligned}$$

(you can add a Metropolis-Hastings (MH) correction for the discretization, *i.e.*, only accept the proposal with the MH probability) can be preconditioned by using the Fisher information Riemannian structure (or some approximation, if it is intractable) and used on mini-batches.

Among the many parametrizations of the probability simplex,

$$\begin{aligned} \pi_n &= 1 - \sum_1^{n-1} \theta_i \\ \pi_k &= \frac{e^{\theta_k}}{1 + \sum_1^{n-1} e^{\theta_i}} \\ \pi_k &= \frac{\theta_k}{\sum \theta_i} \\ \pi_k &= \frac{e^{\theta_k}}{\sum e^{\theta_i}} \end{aligned}$$

the expanded mean $\pi_k = |\theta_k| / \sum |\theta_i|$, $G(\theta) = \text{diag } \theta^{-1}$ (Fisher information from a Gamma-Poisson model – the parametrization is redundant) works better.

MCMC for continuous-time discrete-state systems V. Rao and Y.W. Teh

A *semi-Markov (jump) process* (sMJP) on N states is defined by an $N \times N$ matrix of hazard functions describing the state transitions. When the hazard functions are constant, it is a Markov jump process. To sample from a sMJP, proceed as for non-homogeneous Poisson processes.

Temporal disaggregation of time series C. Sax and P. Steiner (2013)

The `tempdisagg` package disaggregates time series, *i.e.*, converts annual time series to monthly (or quarterly) ones, using auxiliary monthly series (countries providing quarterly GDP estimates interpolate annual numbers in this way). It is a 2-step process: first, interpolate the series using GLS and assuming it is $AR(p)$; then, tweak it, so that the sum, average, first or last value of the monthly series be consistent with the annual one.

Compressive spectral clustering N. Tremblay et al.

Spectral clustering on large graphs using subsampling (of matrix columns), random sampling (of graph signals, *i.e.*, functions defined on the (finite) set of nodes) or iterative node aggregation.

***A general framework
for updating belief distributions***
P.G. Bissiri et al. (2013)

In Bayesian statistics, the belief update

$$\begin{aligned}\text{Posterior}(\theta) &\propto \text{Prior}(\theta) \cdot \text{Likelihood}(\text{Data}|\theta) \\ &\propto \text{Prior}(\theta) \cdot \exp -\text{loss}(\text{Data}; \theta)\end{aligned}$$

still makes sense for an arbitrary loss function (e.g., from robust statistics, instead of minus the log-likelihood), which can have much fewer parameters than a full model and is more robust to “model” misspecification. This can be theoretically justified by

$$\text{Posterior}(\theta) = \underset{\nu}{\text{Argmin}} \text{KL}(\nu \parallel \text{prior}) + \int_{\Theta} \text{loss}(\text{Data}; \theta) \nu(d\theta).$$

***A survey on independence-based
Markov networks learning***
F. Schlüter (2013)

Algorithms to learn the structure of a Markov network are

- Either score-based: start with 1-variable potentials; add merged potentials, if they improve the model enough; iterate;
- Or independence-based: compute the Markov blanket (MB) of each node with independence tests and join them (OR rule):
 - The grow-shrink (GS) algorithm adds the variables needed to the MB, and then removes those no longer needed;
 - The incremental association MB (IAMB) algorithm is similar, but adds the best variables first;
 - The GS inference Markov network (GSIMN) algorithm uses the triangle theorem to reduce the number of tests;
 - etc. (prefer IAMB variants or IPC-MB).

***Using Markov blankets
for causal structure learning***
J.P. Pellet and A. Elisseff (2008)

A random variable X_i is *strongly relevant*, *weakly relevant* or *irrelevant* to a target Y if

- (i) $P(Y|X_{\setminus i}) \neq P(Y|X_{\setminus i}, X_i)$
- (ii) $\exists S \subset X_{\setminus i} \quad P(Y|S) \neq P(Y|S, X_i)$
- (iii) $\forall S \subset X_{\setminus i} \quad P(Y|S) = P(Y|S, X_i)$

In a faithful Bayesian network, the **Markov blanket** of a node (*i.e.*, the children, parents and spouses (children’s parents), *i.e.*, the neighbours in the moral graph) is the set of strongly relevant variables; feature selection algorithms can estimate them. It is possible to recover the Bayesian network up to *observational equivalence* (*i.e.*, (unoriented) adjacencies and (oriented) V-structures) by looking for spouse links in triangles (*i.e.*, finding d-separation sets), removing them, and orienting the remaining two edges.

***Numeric experiments
on the commercial quantum computer***
R.H. Warren (2013)

Adiabatic quantum computers (D-wave – the only commercial quantum computers available) solve unconstrained binary quadratic optimization problems

$$\underset{s}{\text{Argmin}} s'Js + h's.$$

Many combinatorial optimization problems can be cast in this form.

This looks unrelated to textbook quantum computers, which do linear algebra in $(\mathbb{C}^2)^{\otimes n}$.

***A unified framework for modeling and solving
combinatorial optimization problems:
a tutorial***
G.A. Kochenberger and F. Glover (2004)

Many combinatorial optimization problems can be reformulated as *unconstrained* quadratic binary programs. Most constraints can be recast as penalties, e.g.,

$$\begin{aligned}x + y \leq 1 &\rightsquigarrow Pxy \\ x + y \geq 1 &\rightsquigarrow P(1 - x - y + xy) \\ x + y = 1 &\rightsquigarrow P(1 - x - y + 2xy) \\ x \leq y &\rightsquigarrow P(x - xy) \\ \sum x_i \leq 1 &\rightsquigarrow P \sum_{i < j} x_i x_j\end{aligned}$$

with P sufficiently large.

***Solving the optimal trading trajectory problem
using a quantum annealer***
G. Rosenberg et al.

Small multi-period portfolio optimization problems can be solved with a quantum computer (50 assets, 10 periods already require more than the 1152 bits D-Wave offers).

***Quantum algorithms for supervised
and unsupervised machine learning***
S. Lloyd et al. (2013)

When data is stored in a qRAM (quantum RAM), computing distances and inner products (e.g., for k-means) of vectors in N -dimensional space takes time $O(\log N)$.

Quantum machine learning enhances privacy: the user only accesses an exponentially small fraction of the data.

***Predicting the present with Bayesian
structural time series***
S.L. Scott and H. van de Veerdijk (2013)

Nowcasting models a time series from its past values and from contemporaneous easy-to-measure time series, $y_t \sim y_{t-1} + x_t$. Combine a structural model for the time series with spike-and-slab priors for the regression coefficients.

Cuckoo filter: practically better than Bloom
B. Fan et al. (2014)

A **cuckoo hash table** has two hash functions, h_1 and h_2 , and stores an element x , either in $h_1(x)$ or $h_2(x)$ – if both are occupied, it displaces one of its occupants, which moves to its other location, possibly displacing other elements – if this fails after 500 iterations, the hash table is full.

They can be adapted to work as Bloom filters with deletion (for the same space usage as a Bloom filter).

***Model-based variable decorrelation
in linear regression***
C. Théry

To estimate a regression in the presence of correlated variables, one can use

- Shrinkage (ridge, lasso), variable selection (spike-and-slab);
- Clusters of variables with the same coefficients

or model the correlation structure, e.g., with a sparse set of regressions between the predictors – the **CorReg** package uses MCMC to find a set of linear relations in which response variables are never predictors.

***Resizable, scalable, concurrent hash tables
via relativistic programming***
J. Triplett et al.

Hash tables can be resized while in use.

***progenyClust:
an R package for progeny clustering***
C.W. Hu and A.A. Qutub (2016)

To choose the number of clusters (in k -means, etc.), look at their stability, rather than just their compactness or how distinct they are. For instance:

- Cluster the data into C_1, \dots, C_k ;
- Sample N elements from each C_i
- Cluster the resulting data;
- Look at the cooccurrence matrix: let Q_{ab} indicate whether a and b are in the same (new) cluster; we expect this matrix to be approximately block-diagonal;
- Repeat R times, average the Q matrices, and compute

$$\text{Stability} = \frac{P[a \sim' b \mid a \sim b]}{P[a \sim' b \mid a \not\sim b]}$$

where $a \sim b$ (resp. $a \sim' b$) indicates that a and b were (are) in the same old (new) cluster.

Check the R packages: **progenyClust**, **cclust**, **clusterSim**, **Nbclust**, **fpc**, **mclust**.

***mclust 4: clustering,
classification and density estimation
using Gaussian finite mixture models***
L. Scrucca et al. (2016)

The **mclust** package provides EM clustering (**Mclust**) with various variance structures; the best one and the number of clusters can be selected with the BIC (**mclustBIC**) or the *integrated complete likelihood criterion* (ICL) to limit cluster overlap (**mclustICL**); the data can be plotted after dimension reduction (**MclustDR**). The likelihood ratio test (with a bootstrap-estimated p -value) can compare models with k and $k + 1$ clusters. Model-based hierarchical clustering merges the two clusters with the smallest likelihood decrease; it can be used to initialize the EM algorithm./ Mixture models can also estimate densities (**densityMclust**) or classify observations (**mclustDA** – each class is a mixture of one (EDDA) or more Gaussians).

***Conditional fractional Gaussian fields
with the package FieldSim***
A. Brouste et al. (2016)

The **FieldSim** package simulates fractional Gaussian fields on the line, plane or sphere, and their variants (fractional and multifractional Brownian fields, Brownian sheets, anisotropic fields):

$$R(x, y) = \frac{1}{2}(\|x\|^{2H} + \|y\|^{2H} - \|x - y\|^{2H})$$

$$R(x, y) \propto \|x\|^{H(x)+H(y)} + \|y\|^{H(x)+H(y)} - \|x - y\|^{H(x)+H(y)}$$

$$R(x, y) = \frac{1}{2^d} \prod_{i=1}^d (|x|_i^{2H_i} + |y|_i^{2H_i} - \|x_i - y_i\|^{2H_i})$$

$$R(x, y) = v(x) + v(y) - v(x - y).$$

***keyplayer: an R package for locating
key players in social networks***
W. An and Y.H. Liu (2016)

There are many measures of centrality: degree, closeness (harmonic mean of pairwise distances), betweenness (proportion of shortest paths that go through a node i), eigenvector, M -reach degree, M -reach closeness (similar to degree and closeness, with the node of interest replaced by the set of nodes at most M steps away – there are two such neighbourhoods, $\{j : d(i, j) \leq M\}$ and $\{j : d(j, i) \leq M\}$: use both), fragmentation (harmonic mean after removing node i), diffusion ($\sum_{k \leq T} P^k$)**1**.

Centrality measures can be aggregated for a group of nodes: min, max, sum or $1 = \prod_G (1 - c_i)$ if the centralities can be interpreted as probabilities.

***CryptRndTest: an R package for testing
the cryptographic randomness***
H. Demirhan and N. Bitirim (2016)

More tests of randomness for a sequence of bits, letters or numbers:

- Adaptive χ^2 : divide the alphabet into subsets and perform a χ^2 test on them;

- Birthday spacing: number of duplicated values of spacings between ordered birthdays in a year of pre-defined length
- Bookstack (?);
- $\gcd(x_{2n}, x_{xn+1})$ should be iid;
- The number of steps to compute these gcd's should also be iid;
- Interpret the sequence of bits as a random walk and look at the distribution of excursions, heights (in excursions) and expansions (max-min);
- Number of different bit patterns (just the number, not their frequency).

clustering.sc.dp: optimal clustering with sequential constraint by using dynamic programming
T. Szkaliczki (2016)

The k -means optimization problem can be solved exactly, in polynomial time, with dynamic programming, in dimension 1 or in dimension n when only consecutive items can form a cluster: let $D[i, m]$ be the best score when clustering x_1, \dots, x_i into m clusters.

Spatio-temporal interpolation using gstat
B. Gräler et al. (2016)

Spatial and temporal dependence structures can be combined in many ways.

$$\begin{aligned} C(h, u) &= C_s(h)C_t(u) \\ C(h, u) &= kC_s(h)C_t(u) + C_s(h) + C_t(u) \\ C(h, u) &= C(\sqrt{h^2 + (\kappa u)^2}) \\ C(h, u) &= C(\sqrt{h^2 + (\kappa u)^2}) + C_s(h) + C_t(u) \end{aligned}$$

simplexreg: an R package for regression analysis of proportional data using the simplex distribution
P. Zhang et al.

The simplex distribution on $[0, 1]$ is

$$\begin{aligned} p(y) &\propto y^{\alpha-1}(1-y)^{\beta-1} \exp \frac{-d_{\alpha\beta}(y; \mu)}{2\sigma^2} \\ d_{\alpha\beta}(y; \mu) &= \mu^{2\alpha-1}(1-\mu)^{2\beta-1} \frac{y(1-y)}{(y-\mu)^2}. \end{aligned}$$

Special cases include the beta distribution ($\sigma \rightarrow \infty$) and the standard simplex distribution ($\alpha = \beta = \frac{1}{2}$).

PerMallows: an R package for Mallows and generalized Mallows models
E. Iruruzki et al. (2016)

The **Mallows model** is a distribution on \mathfrak{S}_n , with applications in recommender systems, information retrieval, preference elicitation:

$$p(\sigma) \propto \exp -\theta d(\sigma, \sigma_0)$$

where σ_0 is the mode, θ a dispersion parameter, and d a distance, e.g.,

- Kendall's τ (or bubble sort) distance: the number of inversions;
- Cayley's distance: the minimum number of transpositions;
- Hamming's distance: the number of positions that disagree;
- Ulam's distance: the number of items not in the longest common subsequence (LCS).

The *generalized Mallows model* (GMM) has a different dispersion parameter θ for each position i , to give more importance to some of them.

The **Bradley-Terry** model for pairwise comparisons is

$$P[i > j] = \frac{p_i}{p_i + p_j}$$

where p_i is the skill of i (it could depend on covariates).

FuzzyStatProb: an R package for the estimation of fuzzy stationary probabilities from a sequence of observations of an unknown Markov chain
P.J. Villacorta and J.L. Verdegay (2016)

A subset A of X is determined by its indicator function $1_A : X \rightarrow \{0, 1\}$.

A fuzzy subset of X is a function $\mu : X \rightarrow [0, 1]$.

A fuzzy number is a function $\mu : \mathbf{R} \rightarrow [0, 1]$ such that the α -cuts $[\mu \geq \alpha]$ are compact, convex, non-empty (for $\alpha \in [0, 1]$), decreasing,

$$\alpha \leq \beta \implies [\mu \leq \beta] \subset [\mu \geq \alpha]$$

and continuous

$$[\mu \geq \alpha] = \bigcap_{\beta < \alpha} [\mu \geq \beta],$$

The estimated transition probabilities of a Markov chain can be modeled as fuzzy numbers, by stacking their confidence intervals, with a crisp constraint that they add up to 1.

gramEvol: grammatical evolution in R
F. Noorian et al. (2016)

A derivation of a context-free grammar (CFG) can be encoded as a sequence of numbers, each indicating which (left-most) rule to apply (if the number is larger than the number of applicable rules, use the modulo operator). Canonical genetic algorithms (on strings) can manipulate those derivations (add a length limit, and ignore the end of the string, once no non-terminals remain: all (sufficiently long) strings encode valid derivations).

Application of *grammatical evolution* (GE) include symbolic regression, feature generation, regular expression discovery, decision tree construction, ensembling (with hyperparameters), etc.

Most other implementations (libGE, AGE, GEVA, PonyGE, PyNevrGer, GEM, GERET) look unmaintained.

Computation of graphlet orbits for nodes and edges in sparse graphs
T. Hočevár and J. Demšar (2016)

To build a vector embedding of nodes in a graph (“graphical n -grams”), count the graphlets (connected induced subgraphs of size at most k containing the node) and the orbits (position of the node in the graphlet, up to automorphism). The `orca` package computes those graphlet and orbit counts efficiently (start with the smallest graphlets and notice that graphlet inclusions induce linear relations between graphlets and orbit counts). The embedding can be used with the `FNN` package to find nodes with a neighbourhood structure similar to that of a query node.

Copula regression spline sample selection models: the R package `SemiParSampleSel`
W. Wojtyś (2016)

To model data missing not at random, try

$x \sim N(\mu, \sigma)$	value
$y \sim N(\nu, 1)$	missingness score
$x \mathbf{1}_{y>0}$	observed

and use a copula for (x, y) .

Laplace’s rule of succession in information geometry
Y. Ollivier

The *sequential normalized maximum likelihood* estimator is the maximum likelihood estimator if the new value y had already been observed

$$\begin{aligned}\theta^{\text{ML}} &= \underset{\theta}{\text{Argmax}} \sum_i \log p_{\theta}(x_i) \\ \theta^{\text{ML}+y} &= \underset{\theta}{\text{Argmax}} \log p_{\theta}(y) + \sum_i \log p_{\theta}(x_i) \\ p^{\text{SNML}}(y) &\propto p_{\theta^{\text{ML}+y}}(y)\end{aligned}$$

(since $\theta^{\text{ML}+y}$ depends on y , $p_{\theta^{\text{ML}+y}}(y)$ is not a probability and has to be normalized).

For exponential families, $\frac{1}{2}(p^{\text{ML}} + p^{\text{SNML}})$ is close to the Bayesian predictor obtained from the Jeffreys prior; it generalizes the “add-one-half” rule (Laplace’s “add-one” rule corresponds to a uniform prior on a Bernoulli distribution).

On the chi square and higher-order chi distances for approximating f -divergences
F. Nielsen (2013)

The Taylor expansion of a (convex) analytic function f gives an expansion of the f -divergence as a series of χ^2 divergences. There are closed form formulas (no integrals) for the (Pearson, Neyman, Vajda) χ^2 divergences for exponential families.

Barycentric subspace analysis on manifolds
X. Pennec (2016)

There are many generalizations of principal component analysis (PCA) to manifolds:

- Tangent PCA: start with the Fréchet mean and do all the computations in its tangent space (this only works if the distribution is sufficiently centered around the mean);
- Principal geodesic analysis minimizes the least squares distances to totally geodesic subspaces (it is often approximated by tPCA);
- Geodesic PCA: find the geodesic best fitting the data (it does not necessarily go through the mean); add a second geodesic orthogonal to the first, etc.

A *barycentric subspace* is the locus of weighted means of $k - 1$ points. The *Fréchet* (*Karcher*) mean is a global (local) minimizer of $\sum w_i d(x, x_i)^2$; the *exponential* mean is a solution of $\sum w_i \overrightarrow{xx_i} = 0$ where $\overrightarrow{xx_i} = \log_x(x_i)$ is the Riemannian logarithm. A Fréchet mean is a Karcher mean, which is an exponential mean.

Barycentric subspace analysis returns the *flag* (nested subspaces of increasing dimensions) of barycentric subspaces minimizing the unexplained variance.

Morphology, geometry and statistics in nonstandard imaging
E. Chevallier (2015)

The pixels of an image are no longer limited to points in a Euclidian space:

- Colours form a (non-flat) Riemannian space;
- With *diffusion tensor imaging* (DTI), voxels are 3×3 positive definite matrices (representing the distribution of the velocities of water molecules in this voxel).

Mathematical morphology is based on two operations:

Erosion	$\varepsilon(I)_p = \inf_{q \in N(p)} I_q$
Dilatation	$\delta(I)_p = \sup_{q \in N(p)} I_q$
Opening	$\gamma = \delta \varepsilon$
Closing	$\phi = \varepsilon \delta$

For arbitrary pixel values, e.g., elements of $[0, 1]^3$, one can try to impose a total order (not on all possible values, but on the values actually taken):

- With space-filling curves;
- By solving the TSP on the set of pixel values;
- By solving a combinatorial optimization problem looking for a total order avoiding pairs of points close in in colour space by distant in the order, but allowing problematic triplets of values provided they occur in different regions of the space.

For pixel values in an unordered finite set of labels, one can define a dilatation and an erosion for each label i , extending or reducing the area occupied by this label (for the erosion, fill in the blanks with, e.g., the nearest value). For $n > 2$ labels, there are n dilatations and n

erosions. This can be generalized to discrete probability distributions on the set of labels (“fuzzy labels”).

To estimate a density (image histogram) on a Riemannian space (e.g., a colour space, with the Riemannian structure given by MacAdam ellipses, or Luo & Rigg’s chromaticity discrimination ellipses (BFD-P), or Berns’s colour difference tolerance (RIT-DuPont), or spaces of Gaussian laws, with the Fisher or Wasserstein (earth’s mover’s) distance) only short geodesics are needed: a local Euclidean approximation suffices.

Logarithmic time one-against-some
H. Daumé III et al.

For extreme multiclass classification (*i.e.*, a very large number of classes), build a decision tree, optimizing the decrease in entropy of the label distribution (but only for nodes whose recall is better than that of their children, to ensure the counts are reliable), and use it to select $O(\log K)$ candidates; then, use one-against-some (instead of the reference, one-against-all).

Bag of tricks for efficient text classification
A. Joulin et al.

Use a linear classifier with Huffman-coding-based hierarchical softmax, bag-of-words and n -grams, and the hashing trick.

Optimizing non-decomposable performance measures: a tale of two classes
H. Narasimhan et al. (2015)

Performance measures for unbalanced classification problems are non-decomposable, and not amenable to large scale optimization algorithms such as stochastic gradient descent (SGD). Try to approximate the objective with a linear function of TPR and TNR (e.g., if it is a ratio of linear functions: F-mean, Jaccard coefficient) or use a primal-dual approach (for concave functions of TPR and TNR: G-mean, H-mean).

Learning stationary time series using Gaussian processes with nonparametric kernels
F. Tobar et al.

Kernel choice encapsulates smoothness, stationarity and periodicity assumptions on the function. The model

$$\begin{aligned}k &\sim \text{GP}(0, k) \\ x &\sim \text{GP}(0, \sigma^2 \delta) \text{ white noise} \\ f &= h * x\end{aligned}$$

is equivalent to

$$\begin{aligned}h &\sim \text{GP}(0, k) \\ f &\sim \text{GP}(0, k(\cdot) * k(-\cdot))\end{aligned}$$

i.e., it defines a prior on nonparametric models. Use a decaying squared exponential kernel,

$$k(t, s) \propto e^{-\alpha t^2} e^{-\alpha s^2} e^{-\gamma(t-s)^2}.$$

Local and global sparse Gaussian process approximations
E. Snelson and Z. Ghahramani

Sparse Gaussian process approximations replace the training set with a smaller set of “inducing points” (either from the training set, or arbitrary points) and can be global or local (for wiggly functions); the local and global approaches can be combined.

Gaussian process kernels for pattern discovery
A.G. Wilson and R.P. Adams (2013)

Stationary kernels k are determined by their spectral density S : $k(t) = \int S(s) e^{2\pi i s' t} ds$. The omnipresent square exponential kernel has a Gaussian spectral density centered at the origin. Modeling the spectral density as a mixture of (non-centered) Gaussians gives a larger variety of kernels.

Pseudo-marginal Bayesian inference for Gaussian processes
M. Filippone and M. Girolami (2014)

To sample from $p(f, \theta|y)$, where θ are hyperparameters, f latent variables, and y observed data, one can alternatively sample from $p(f|\theta, y)$ and $p(\theta|f, y)$ – but the distribution of the hyperparameters is too concentrated and leads to slow convergence and mixing. Instead, the **pseudo-likelihood** approach samples from $p(\theta|y)$, using $p(\theta|y) \propto p(y|\theta)p(\theta)$ and the unbiased estimator

$$\begin{aligned}p(y|\theta) &\approx \frac{1}{N} \sum \frac{p(y|f_i)p(f_i|\theta)}{q(f_i|y, \theta)} \\ f_i &\sim q(\cdot|y, \theta) \text{ importance sampling.}\end{aligned}$$

Distributed Gaussian processes
A.P. Deisenroth and J.W. Ng (2015)

Train local experts on subsets of the data (e.g., using KD-trees), and combine them, e.g., as a mixture of experts, a product of experts, or a Bayesian committee machine (beware, many of those lead to over- or under-confident forecasts).

Thoughts on massively scalable Gaussian processes
A.G. Wilson et al.

Use inducing points and the structure of the covariance matrix: Toeplitz (regular 1-dimensional grid), Kronecker (arbitrary n -dimensional grid) or block-Toeplitz with Toeplitz blocks.

Mollifying networks

C. Gulcehre et al.

To minimize a badly-behaved function f , **mollify** it, *i.e.*, minimize $f * k_\varepsilon$, where k_ε is \mathcal{C}^∞ , $f * k_\varepsilon$ is convex, and $f * k_\varepsilon \rightarrow f$ when $\varepsilon \rightarrow 0$. If $f * k_\varepsilon$ is difficult to compute, use a Monte Carlo approximation – this is equivalent to adding noise to the input.

In addition, for neural nets:

- For each unit, either use the (noisy) activation function, or let the signal pass through, randomly (cf. ResNet);
- Bound the activation function using its linear approximation (if the noise is high).

The concave-convex procedure (CCCP)

A.L. Yuille and A. Rangarajan (2003)

To minimize the sum of a convex and concave function, $E = E_+ + E_-$, the CCCP build a sequence x_0, x_1, \dots such that $\nabla E_+(x_{n+1}) = -\nabla E_-(x_n)$; it monotonically decreases E . If finding x such that $\nabla E_+(x) = -\nabla E_-(x_0)$ is not obvious, iterate $x_{n+1} \leftarrow \text{Argmin}_x E_+(x) + \langle x, \nabla E_-(x_0) \rangle$ (these are convex problems).

Most functions are of this form: if the Hessian of E is bounded, adding a sufficiently large strictly convex function λF gives a convex function and a decomposition $E = (E + \lambda F) + (-\lambda F)$.

Applying the CCCP to minimize $E_+(x) + E_-(x)$ is equivalent to minimizing $E_+(x) + \langle x, y \rangle + E_-^*(y)$ wrt x and y alternatively, where E_-^* is the Fenchel-Legendre transform (aka convex conjugate) of E_- .

Hyperparameter optimization of deep neural networks

using non-probabilistic RBF surrogate model

I. Ilievski et al.

Non-probabilist alternative to Bayesian optimization using radial basis function (RBF) surrogates.

Hyperbolic geometry of complex networks

D. Krioukov et al. (2010)

The curvature of a graph can be defined by looking at how the number of nodes at distance (at most) d of a given node changes with d , and comparing it with the length (area) of a circle (disk) of radius r in the hyperbolic plane of constant curvature k . For instance, for a b -ary tree, $n_d \sim b^d$ and $\text{area}_d \sim e^{k^2 d}$.

(The actual model is more complicated and considers nested or overlapping disks in the hyperbolic plane.)

Fast generation of complex networks with underlying hyperbolic geometry

M. von Looz et al.

A random hyperbolic graph is obtained by taking vertices at random in the Poincaré disk and joining pairs

whose distance is below R . Naively computing all pairwise distances is quadratic: use a suitable data structure, e.g., a *polar quad-tree*.

Cryptographic secure pseudo-random bits generation: the Blum-Blum-Shub generator

P. Junod (1999)

The BBS cryptographic RNG is defined by

$$p, q \equiv 3(4) \quad \text{large primes}$$

$$n = pq$$

$$s \in \mathbf{Z}/(n), \quad s \neq 0$$

$$x_0 = s^2$$

$$x_n = x_{n-1}^2$$

$$z_n = \text{parity}(x_n)$$

(for such n 's, squaring is a permutation of quadratic residues (*i.e.*, squares) modulo n).

Object spreadsheets: a new computational model for end-user development of data-centric web applications

M. McCutchen et al. (2016)

The spreadsheet computation model (data flow, graph computations) is not adapted to spreadsheets: it considers tabular or hierarchical data as unstructured and has no relational operators to manipulate data.

Changing that computation model to focus on columns rather than cells, and separating the tabular (developer) view from the user interface (UI) could help build data-centric applications (which are often, currently, shared Google spreadsheets).

Bayesian learning via stochastic gradient Langevin dynamics

M. Welling and Y.W. Teh (2011)

Langevin dynamics can be seen as gradient descent with added noise; it “converges” to the whole posterior distribution instead of just its mode. Since stochastic gradient descent is already a noisy gradient descent, it can be modified, by adding the right amount of noise, to sample from the posterior.

A piecewise deterministic scaling limit of lifted Metropolis-Hastings in the Curie-Weiss model

J. Bierkens and G. Roberts (2016)

Given a Markov chain $P(x, y)$ on a state space S , e.g., a Metropolis-Hastings chain, and a function $\eta : S \rightarrow \mathbf{R}$,

$$\begin{pmatrix} T^+ & \text{diag } T^{+-} \\ \text{diag } T^{-+} & T^- \end{pmatrix}$$

$$\begin{aligned}
T^+(x, y) &= P(x, y) \mathbf{1}_{\eta y \geq \eta x} \\
T^-(x, y) &= P(x, y) \mathbf{1}_{\eta y \leq \eta x} \\
T^{+-}(x) &= \left(\sum_{y \neq x} T^+(x, y) - T^-(x, y) \right)_+ \\
T^{-+}(x) &= \left(\sum_{y \neq x} T^-(x, y) - T^+(x, y) \right)_-
\end{aligned}$$

defines a (non-reversible, “lifted”) Markov chain on $S \times \{\pm 1\}$ with the same stationary distribution.

***Irreversible Monte Carlo algorithms
for efficient sampling***
K.S. Turitsyn et al. (2010)

***Piecewise deterministic Markov processes,
applications in biology***
R. Yvinec

Piecewise deterministic Markov processes (PDMP, an example of a non-diffusion) are ODEs, switching at random (Poisson) times, e.g., a cell growing (ODE) and dividing (Poisson), or a gene, turned on or off (Poisson) regulating some reaction (ODE).

***Scalable MCMC for large data problems using
data subsampling and the difference estimator***
M. Quiroz et al.

An approximate acceptance probability, computed from a subsample (in a big data problem), is sufficient to ensure a Metropolis-Hastings chain has the desired stationary distribution.

Liftings of tree-structured Markov chains
T.P. Hayes and A. Sinclair

Lifting a markov chain (replacing each state with a set of states) can improve mixing time. For instance, to the diffusive behaviour of

one can add momentum.

***The zig-zag process and super-efficient
sampling for Bayesian analysis of big data***
J. Bierkens et al. (2016)

The *zigzag process* is a continuous-time piecewise deterministic Markov process (PDMP) on $\mathbf{R}^d \times \{\pm 1\}^d$: $\xi : \mathbf{R}_+ \rightarrow \mathbf{R}^d$ is piecewise linear, with $\xi' = \theta$, $\theta : \mathbf{R}_+ \rightarrow \{\pm 1\}^d$; a single component of θ flips at random times, at rates $\lambda_i(\xi_t, \theta_t)$; it can be sampled with Poisson thinning. Adding momentum makes the chain

non-reversible (Hamiltonian Monte Carlo (HMC) also adds momentum, but remains reversible) but aids mixing. The *bouncy particle sample* is similar, but the momentum is arbitrary: $\theta_t \in \mathbf{R}$. If the rates are strictly positive, the chain is ergodic.

Given a target probability density π , the canonical zigzag process is defined by

$$\begin{aligned}
\psi &= -\log \pi + \text{constant} \\
\lambda_i(\xi, \theta) &= [\theta_i \partial_i \psi(\xi)]_+.
\end{aligned}$$

When $\psi = \sum_j \psi_j$ (e.g., in big data applications), *sub-sampling* (using a different ψ_i at each iteration) does not change the invariant distribution (but mixing deteriorates); *control variates*, e.g., writing

$$\psi(\xi) = \psi(\xi^*) + \sum_j \psi_j(\xi) - \psi_j(\xi^*),$$

(as in variance-reduced stochastic gradient) improves mixing.

***Bayesian linear mixed models using Stan:
a tutorial for psychologists, linguists
and cognitive scientists***
T. Sorensen et al. (2016)

***DehazeNet: an end-to-end system
for single image haze removal***
B. Cai et al.

Use a convolutional neural net with convolutions of different sizes and bilateral ReLUs  to estimate the transmission map (the haze intensity – easy if you have a depth map) and de-haze. Commonly-used features include:

- Dark channel, $D(x) = \min_{y \in N_x} \min_{c \in \{r, g, b\}} I_c(y)$, where x is the pixel position and N_x its neighbourhood (in haze-free patches, at least one colour channel is close to zero – except the sky);
- Maximum contrast $C(x) = \max_{y \in N_x} \sum_{z \in N_y} \|I(z) - I(y)\|^2$;
- Colour attenuation $A(x) = I^{\text{value}}(x) - I^{\text{saturation}}(x)$;
- Hue disparity $H(x) = |I_{\text{si}}^{\text{hue}}(x) - I^{\text{hue}}(x)|$ where $I_{\text{si}}^c(x) = \max\{I^c(x), 1 - I^c(x)\}$, $c \in \{r, g, b\}$.

***A hierarchical latent variable
encoder-decoder model for generating dialogues***
I.V. Serban et al.

Add latent (stochastic, unobserved) variables to a RNN to capture larger structures (in a usual RNN, the input and the output are stochastic, but they only control the local structure of the sentences).

Cross-stitch networks for multi-task learning

I. Misra et al.

When using neural nets for different tasks on the same input, one needs to choose when to split the two networks.

Instead, cross-stitch units use two representations at each level, but blends them.

$$\begin{pmatrix} \tilde{x}_A \\ \tilde{x}_B \end{pmatrix} = \begin{pmatrix} \alpha_{AA} & \alpha_{AB} \\ \alpha_{BA} & \alpha_{BB} \end{pmatrix} \begin{pmatrix} x_A \\ x_B \end{pmatrix}$$

LSTM-based deep learning models for non-factoid answer selection

M. Tan et al. (2016)

Model questions with a CNN on top of a bidirectional RNN with LSTM units and an attention model; use a similar network for potential answers; compare them with cosine similarity.

Bridging nonlinearities and stochastic regularizers with Gaussian error linear units

D. Hendrycks and K. Gimpel

Dropout randomly sets the outs to zero: it is a stochastic zero map.

Zero-out randomly lets the input pass through: it is a stochastic identity map.

ReLU is a deterministic zero or identity map, depending on the sign of the input.

The *stochastic zero-identity* map applies the identity with probability $\Phi(x) = P[Y \leq x]$, $Y \sim N(0, 1)$, and the zero map otherwise; in expectation, it is the (non-convex, non-monotonic) *Gaussian error linear unit* $\text{GELU}(x) = x\Phi(x)$.

Very deep convolutional networks for natural language processing

A. Conneau

On character streams, very deep CNNs outperform (shallow) LSTM RNNs.

Decoupled neural interfaces using synthetic gradients

M. Jaderberg et al.

Instead of waiting for the gradients in back-propagation, try to predict them using local information.

Surprisal-driven feedback in recurrent networks

K. Rocki

Monitoring the discrepancy between forecasts and actual observations can improve RNNs.

Densely connected convolutional networks

G. Huang et al.

Connect each layer to each other layer (there are $\frac{1}{2}n(n-1)$ connections instead of n).

LIFT: learned invariant feature transform

K.M. Yo et al. (2016)

Three CNNs, in a sequential pipeline, image \rightarrow detector \rightarrow crop \rightarrow orientation estimator \rightarrow rotate \rightarrow descriptor, trained on SIFT features.

XNOR-Net: ImageNet classification using binary convolutional neural nets

M. Rastegari et al. (2016)

Binary networks (binary weights, or both binary weights and inputs) are much faster (thanks to bitwise operations) and sufficiently accurate.

Synthesizing the preferred inputs for neurons in neural networks via deep generator networks

A. Nguyen et al. (2016)

Activation maximization (finding the image that excites a neuron the most) yields uninterpretable results unless one uses a *natural image prior*, e.g., from a GAN.

Virtual worlds as proxy for multi-object tracking analysis

A. Gaidon et al.

Virtual worlds provide photo-realistic labeled data.

DeMo Dashboards: visualizing and understanding genomic sequences using deep neural networks

J. Lanchantin et al.

Interpreting deep neural nets is more important in biomedical application, e.g., predicting transcription factor binding sites (TFBS) using a CNN on top of a bidirectional RNN with LSTM units:

- Saliency: importance of the nucleotide, *i.e.*, derivative of the output wrt the input;
- Score, as a time series;
- Sequence that maximizes the TFBS probability.

***Faster training of very deep networks
via p -norm gates***
T. Pham et al. (2016)

P-norm gates,

$$y = \alpha_1 x_1 + \alpha_2 x_2, \quad \alpha_1^p + \alpha_2^p = 1, \quad p \geq 1,$$

are between residual gates ($p = \infty$, $\alpha_1 = \alpha_2 = 1$) and highway gates ($p = 1$).

Layer normalization
J.L. Ba et al.

Batch normalization normalizes the output of a single neuron within a mini-batch; *layer normalization* normalizes the outputs of all neurons in a layer, for a single training case; it is applicable to RNNs.

***RAISR: rapid and accurate
image super resolution***
Y. Romano et al.

Image upscaling (“super-resolution”) algorithms used to be simple interpolators (nearest neighbour, bilinear, bicubic), but more recent algorithms use an *image prior* and learn a non-linear map

low-resolution patch \mapsto high-resolution patch

e.g., using sparse coding or CNNs. To speed up the computations, one can instead learn a (linear) map

bilinear upscaled LR patch \mapsto (sharpened) HR patch

refining a cheaply-upscaled image. To make the algorithm more adaptive, cluster the image patches (coarsely, by hashing the local gradient statistics, angle, strength, coherence, from an eigen analysis) and learn a filter for each cluster.

***A+: adjusted anchored neighborhood
regression for fast super-resolution***
R. Timofte et al.

Sparse coding for image super-resolution.

***Image super-resolution
using deep convolutional networks***
C. Dong et al.

CNNs for image super-resolution.

***Enriching word vectors
with subword information***
P. Bojanowski et al.

To compute word embeddings of rare words or in morphologically rich languages, represent words as bags of n -grams.

***Charagram: embedding words and sentences
via character n -grams***
J. Wieting et al.

Character n -gram count vector embedding for sentences, trained with the paraphrase pairs database (for word or sentence similarity), or the Penn treebank (for POS tagging).

Correlated topic models
B.M. Blei and J.D. Lafferty

Correlation between topics can be introduced in latent Dirichlet analysis (LDA) by replacing the Dirichlet distribution

$$Y_i \stackrel{\text{iid}}{\sim} \Gamma(\alpha_i, \theta) \\ X = Y/(Y'\mathbf{1}) \sim \text{Dir}(\alpha_1, \dots, \alpha_n)$$

with a **logistic normal distribution**

$$Y \sim N(\mu, \Sigma) \\ X = Y/(Y'\mathbf{1}).$$

***Content-based recommendations
with Poisson factorization***
P. Gopalan et al.

The collaborative topic **Poisson factorization** is suited to sparse, long-tailed data, and amenable to variational inference.

k : topics

v : words

d : documents

u : users

$$\beta_{vk} \sim \Gamma$$

$$\theta_{dk} \sim \Gamma$$

$$w_{dv} \sim \text{Poisson}(\theta'_d \beta_v)$$

$$\eta_{uk} \sim \Gamma$$

$$\varepsilon_{dk} \sim \Gamma$$

$$r_{ud} \sim \text{Poisson}(\eta'_u(\theta_d + \varepsilon_d))$$

Learning to search better than your teacher
K.W. Chang et al. (2015)

Structured prediction problems (e.g., building the parse tree of a sentence) can be turned into reinforcement learning problems by expressing the prediction as a sequence of actions (e.g., growing the tree). **Learning to search** tries to replicate a reference policy (*i.e.*, a map state features \rightarrow action) instead of solving the full reinforcement learning problem. Locally optimal learning to search (LOLS) tries to modify the reference policy (no longer assumed optimal) to improve the performance.

**Deep unsupervised learning
using nonequilibrium thermodynamics**
J. Sohl-Dickstein et al. (2015)

To model a probability distribution (e.g., pixels in the MNIST dataset), find a diffusion that transforms it into a tractable one (e.g., Gaussian).

**Stochastic differential equation
mixed effects models for tumor growth
and response to treatment**
J.L. Forman and U. Picchini

Biological phenomena are often modeled by ODEs, but SDEs may be a better choice; as state space models, they can be estimated with particle filters (sequential Monte Carlo, SMC). Mixed effects SDE (SDEM) can be estimated with approximate Bayesian computations (ABC) or *synthetic likelihood* (similar to ABC, but we assume the summary statistics are Gaussian, *i.e.*, we only look at the mean and variance: it is a simulated method of moments).

**A note on the validity of cross-validation
for evaluating time series prediction**
C. Bergmeir et al. (2015)

Even in presence of auto-correlation, most estimators remain consistent (the variance of the limiting distributions and the resulting tests are affected, though); likewise, cross-validation can be applied to time series without any modification.

**Faster principal component regression via
optimal polynomial approximation to $\text{sgn}(x)$**
Z. Allen-Whi and Y. Li (2016)

To project a vector $v \in \mathbf{R}^n$ to the subspace spanned by the eigenvectors of A with eigenvalues at least λ_0 , without computing the eigenvectors, compute $g(A) = \text{sign}(\lambda - \lambda_0 - \varepsilon)$; use a polynomial approximation of g .

**DART: dropouts meet
multiple additive regression trees**
K.V. Rashmi and R. Gilad-Bachrach (2015)

Boosted regression trees, with dropout of complete trees.

Tensors and their eigenvectors
B. Sturmfels (2016)

A symmetric $n \times n \times \dots \times n$ tensor $T = (t_{i_1 \dots i_d})$ can be seen as a homogeneous polynomial of degree d in n variables $T = \sum t_{i_1 \dots i_d} x_{i_1} \dots x_{i_d}$ (symmetric matrices correspond to bilinear forms) and, therefore, as a hypersurface in \mathbf{P}^{d-1} .

A vector $v \in \mathbf{R}^n$ is an eigenvector of T if $(\nabla T)v = \lambda v$ for some λ . Algebraic geometry can help count the number of eigenvalues or singular values of (symmetric) tensors.

Code-based cryptography
I. Márquez-Corbella (FUN 2016)

Quantum computers can solve the integer factorization and the discrete log problems in reasonable time. Code-based cryptography relies on NP-completeness and could form the base of **post-quantum cryptosystems**. A linear code is a subspace of \mathbf{F}_q^n of dimension k , defined either as the kernel of a *parity check matrix* H or as the image of a linear map $G : \mathbf{F}_q^k \rightarrow \mathbf{F}_q^n$ of rank k . The *syndrome* of a received word x is Hx ; it is also the syndrome of the error. In the *McEliece cryptosystem*, the public key is a generator matrix G with added noise, and the private key is an efficient decoding algorithm for G . In the *Niederreiter cryptosystem*, the public key is a parity check matrix and the private key is an efficient syndrome decoder.

While promising, most code-based cryptosystems have been broken – Goppa codes are the main exception.

Determinantal point processes
A. Kulesza and B. Taskar (2012)

Determinantal point processes (DPP) are distributions over subsets $Y \subset \mathcal{Y}$ of the form

$$\begin{aligned} P(A \subset Y) &= \det(K_A) & 0 \preceq K \preceq I \\ P(Y = Y) &\propto \det(L_Y) & L \succcurlyeq 0 \\ P(Y = Y) &= \frac{\det(L_Y)}{\det(L + I)}. \end{aligned}$$

The two formulations are related by $K = I - (L + I)^{-1}$ and the first one is slightly more general (it allows $P(Y = \emptyset) \neq 0$).

DPPs favour diverse sets:

$$\begin{aligned} P(i, j \in Y) &= K_{ii}K_{jj} - K_{ij}^2 \\ &= P(i \in Y)P(j \in Y) - K_{ij}^2 \\ &< P(i \in Y)P(j \in Y) \end{aligned}$$

Applications of DPPs include ranking search results or summarizing documents by extracting a few sentences. They remain tractable until $|\mathcal{Y}| = 10,000$.

To sample from a DPP:

- Compute the eigen decomposition $L = \sum \lambda_n v_n v_n'$;
- Select a subset V of eigenvectors, including v_i with probability $\lambda_i/(\lambda_1 + 1)$;
- Select $i \in \mathcal{Y}$ with probability

$$\frac{1}{|V|} \sum_{v \in V} (v' e_i)^2;$$

- Replace V with an orthonormal basis of $e_i^\perp \cap \text{Span } V$;
- Repeat until V is empty.

Finding the model of a DPP is NP-hard. The function $\log P$ is submodular (easy to minimize, hard to maximize – the greedy algorithm for approximate maximization only works for *monotone* submodular functions).

Alternatives to DPP include:

- Matérn repulsive process: start with a Poisson point process and remove points more than ε apart (either both points, or just the last one)
- Pairwise Markov process

$$P(\mathbf{Y} = Y) \propto \prod_{i \in Y} \psi_1(i) \prod_{i,j \in Y} \psi_{12}(i,j);$$

- Area interaction process

$$P(\mathbf{Y} = Y) \propto \gamma^{-\sum_{y \in Y} \text{Area } B(y, \varepsilon)};$$

- Determinants can be replaced with permanents, immanents, α -determinants or hyperdeterminants;
- Quasi-random (low discrepancy) processes.

The L matrix can be written $L = B'B$, $B = U \text{diag}(q)$, where q measures the (unary) quality of the items, and the columns ϕ_i of U are (normalized) features for item i .

DPPs are similar to Markov random fields (MRF), but they allow negative interactions – inference for pairwise MRFs is tractable, approximately, provided the potentials are associative, *i.e.*, endpoints tend to have the same value.

For sampling, normalization, marginalization, the dual representation $C = BB'$, instead of the larger $L = B'B$, is often sufficient (you still need B , though).

The likelihood can be expressed as a single determinant

$$\begin{aligned} P(Y) &= \frac{\det L_Y}{\det(L + I)} \\ &= \det(I_Y K + I_{\bar{Y}}(I - K)) \\ &= |\det(K - I_{\bar{Y}})|. \end{aligned}$$

To fit a DPP, use feature vectors ϕ for the items $L_{ij} = q_i q_j \phi_i' \phi_j$, and parametrize the quality $q_i = \exp \frac{1}{2} \theta' \phi_i$ (one can use different features for the quality). Mixtures of DPPs are also easy to fit.

A k -DPP is a DPP constrained with $|\mathbf{Y}| = k$ (it is no longer a DPP): we still have $P(\mathbf{Y} = Y) \propto \det L_Y$, but the normalization constant is different

$$P(\mathbf{Y} = Y) = \frac{\det L_Y}{\sum_{|X|=k} \det L_X} = \frac{\det L_Y}{e_k(\lambda_1, \dots, \lambda_n)}$$

where $\lambda_1, \dots, \lambda_n$ are the eigenvalues of L and e_k is the elementary symmetric polynomial

$$e_k(\lambda_1, \dots, \lambda_n) = \sum_{\substack{J \subset [1, n] \\ |J|=k}} \prod_{i \in J} \lambda_i,$$

which can be computed recursively as $e_k^n = e_k^{n-1} + \lambda_n e_{k-1}^{n-1}$. The sampling algorithm for DPPs can be adapted to k -DPPs (use exactly k eigenvectors).

Structured DPPs (SDPP), *i.e.*, DPPs whose quality and diversity feature factor multiplicatively and addi-

tively,

$$\begin{aligned} q(y) &= \prod_{\alpha \in F} q_\alpha(y_\alpha) \\ \phi(y) &= \sum_{\alpha \in F} \phi_\alpha(y_\alpha) \end{aligned}$$

can be handled with message passing algorithms. They can model paths, grammar derivations, etc.

Diversity networks

Z. Mariet and S. Sra (2016)

To reduce the number of neurons in a neural net, sample a diverse set of neurons using a determinantal point process (DPP), $P(Y) \propto \det L_Y$, with a Gaussian RBF kernel $L_{ij} = \varepsilon + \exp -\beta \|v_i - v_j\|^2$ and fuse the remaining neurons.

Discriminants, resultants and multidimensional determinants

I.M. Gelfand et al. (1994)

Let A be a set of monomials. The *discriminant* of $f \in \text{Span } A$ is an irreducible polynomial in the coefficients of f that vanishes whenever f has a multiple root (x_1, \dots, x_k) with $\forall i \ x_i \neq 0$.

The *resultant* of polynomials f_0, \dots, f_k in k variables is an irreducible polynomial in their coefficients, vanishing whenever they have a common root; it is the discriminant of $f_0(\mathbf{x}) + \sum_{i \geq 1} y_i f_i(\mathbf{x})$.

The *determinant* of a matrix $(a_{ij})_{ij}$ is the discriminant of the bilinear form $\sum a_{ij} x_i x_j$. The *hyperdeterminant* of a tensor $(a_{i_1 \dots i_r})_{i_1 \dots i_r}$ is the discriminant of the homogeneous polynomial $\sum a_{i_1 \dots i_r} x_{i_1} \dots x_{i_r}$.

Learning with submodular functions: a convex optimization perspective

F. Bach (2013)

1. Submodular functions are a combinatorial analogue of *concave* functions, in an attempt to build a theory of “combinatorial convex optimization”. Surprisingly, they also have many *convex* aspects. They generalize matroidal ranks. It turns out that both maximizing (NP-hard) and minimizing (polynomial) submodular functions are interesting problems.

There are three main uses of submodular functions in optimization:

- As the objective of a combinatorial optimization problem;
- To penalize the support of a vector: lasso, group lasso, etc. (structured sparsity);
- To penalize the level set of a vector (clustering).

2. A set function $f : 2^V \rightarrow \mathbf{R}$ is **submodular** if

$$\forall A, B \quad F(A) + F(B) \geq F(A \cup B) + F(A \cap B);$$

it suffices to check (diminishing returns)

$$F(A \cup \{k\}) - F(A) \geq F(A \cup \{k, \ell\}) - F(A \cup \{\ell\}).$$

The following operations preserve submodularity: restriction, extension ($F(A) = G(B \cap A)$), contraction ($F(A) = G(A \cup B) - G(B)$, on $V \setminus B$), partial minimization.

Examples include $|A|$, $\mathbf{1}_{A \neq \emptyset}$, $\#\{i : A \cap G_i \neq \emptyset\}$ where $V = \coprod G_i$ is a partition, or the number of edges from A to $V \setminus A$ in an undirected graph.

A vector $s \in \mathbf{R}^p$ defines a **modular** function

$$s(A) = \sum_{i \in A} s_i, \quad A \subset [1, n].$$

The submodular and **base polyhedron** are

$$\begin{aligned} P(F) &= \{s \in \mathbf{R}^p : \forall A \subset [1, p] \quad s(A) \leq F(A)\} \\ B(F) &= \{s \in P(F) : s(V) = F(V)\} \end{aligned}$$

A **polymatroidal rank function** is a non-decreasing submodular function. A submodular function F can be expressed as a sum of a modular and a polymatroidal function (set $s_k = F(V) - F(V \setminus \{k\})$): $G = F - s$ is polymatroidal).

3. A submodular function F is defined on the vertices of the hypercube $[0, 1]^p$. Its **Lovász extension** (or *Choquet integral*) is the linear interpolation on the $n!$ simplexes corresponding to the orderings of $(x_1, \dots, x_p) \in [0, 1]^p$.

A set function F is submodular iff its Lovász extension is convex; they have the same minima.

The Lovász extension has a probabilistic interpretation:

$$f(w) = E_{u \sim U(0,1)} [F\{i : w_i \geq u_i\}]$$

The *multilinear extension* is neither convex nor concave:

$$\begin{aligned} \tilde{f}(w) &= E_{B \sim w} [F(B)] \\ &= \sum_{A \subset V} F(A) \prod_{i \in A} w_i \prod_{i \notin A} (1 - w_i). \end{aligned}$$

4. A **greedy algorithm** can maximize linear functions on the base polyhedron; in particular, this gives its extreme points.

5. The **convex closure** of $F : 2^V \rightarrow \mathbf{R}$ is the largest convex function $f : \mathbf{R}^p \rightarrow \mathbf{R} \cup \{\infty\}$ such that $\forall A \subset V \quad f(\mathbf{1}_A) \leq F(A)$. It can be obtained by Fenchel biconjugation; it is an extension of F , i.e., $f(\mathbf{1}_A) = F(A)$; it has the same minima. For submodular functions, it is the Lovász extension.

A penalty Ω can add **structural sparsity** to machine learning models,

$$\underset{w}{\text{Argmin}} \text{Loss}(y, x, w) + \lambda \Omega(w).$$

For instance, $\Omega = \#\text{supp } w = \|w\|_0$ or $\Omega(w) = F(\text{supp } w)$, for some set function F , e.g., a partition count.

The convex envelope of $w \mapsto F(\text{supp } w)$, on the ℓ^∞ ball, for a non-decreasing submodular function F , is $\Omega_\infty : w \mapsto f(\|w\|)$, where f is the Lovász extension of F . For instance, the counting function gives the lasso, and the partition count $\sum \|\cdot\|_\infty$, which is not exactly the group lasso – the ball has spurious edges.

Those spurious edges can be removed by replacing $F(\text{supp } w)$ with

$$\frac{1}{p} \|w\|_p^p + \frac{1}{q} F(\text{supp } w), \quad \frac{1}{p} + \frac{1}{q} = 1, \quad p \in (1, \infty).$$

For $\Omega(w) = \#\text{supp } w$, this gives $\Omega_p = \|\cdot\|_p$; for partition counting, this gives the group lasso $\Omega_p = \sum \|\cdot\|_p$.

But those spurious edges can be used: they create clustering of the components of w . For instance,

$$\begin{aligned} F(A) &= \mathbf{1}_{A \neq \emptyset, V}, \\ f(w) &= \text{Max} |w_i - w_j| \end{aligned}$$

creates clusters for the largest and smallest values. Similarly,

$$\begin{aligned} F(A) &= \text{Max}\{|A|, |V \setminus A|\}, \\ f(w) &= \sum_k \text{Min}(n - k, k) |w_{(k+1)} - w_{(k)}| \end{aligned}$$

creates a cluster in the middle and therefore highlights outliers.

6a. Concave functions of cardinality, $F(A) = \phi(|A|)$ are submodular.

6b. *Cut functions*,

$$F(A) = \sum_{\substack{i \in A \\ j \notin A}} d_{ij}$$

(for undirected graphs, they can also be written $F(A) = \frac{1}{2} \mathbf{1}'_A Q \mathbf{1}_A$, where Q is the graph Laplacian) are submodular, with Lovász extension $f(w) = \sum d_{ij} (w_i - w_j)_+$. Examples include the total variation (in one dimension, for a chain $\bullet \cdots \bullet$, or in two dimensions, for a grid \boxtimes) or the isotonic penalty (for the graph of an order relation).

If $G : 2^{V \cup W} \rightarrow \mathbf{R}$ is submodular, then so is its *partial minimization*

$$F : \begin{cases} 2^V & \rightarrow \mathbf{R} \\ A & \mapsto \underset{B \subset W}{\text{Min}} G(A \cup B) \end{cases}$$

A function is *regular* if it is the partial minimization of a cut function.

6c. Given a non-negative function $D : 2^V \rightarrow \mathbf{R}_+$, the *set cover function*

$$F : \begin{cases} 2^V & \rightarrow \mathbf{R} \\ A & \mapsto F(A) = \sum_{B \cap A \neq \emptyset} D(B) \end{cases}$$

is modular and its Lovász extension is

$$f(w) = \sum_B D(B) \max_{k \in B} w_k.$$

The corresponding Ω_p norm is an overlapping group lasso penalty, with no double counting (contrary to $\sum D(B) \|w_B\|_p$). Möbius inversion

$$\begin{aligned} F(A) &= \sum_{B \subset A} G(B) \\ G(A) &= \sum_{B \subset A} (-1)^{|A \setminus B|} F(B) \end{aligned}$$

can recover D ,

$$\begin{aligned} F(V) - F(V \setminus A) &= \sum_{B \subset A} D(B) \\ D(A) &= \sum_{B \subset A} (-1)^{|A| - |B|} (F(V) - F(V \setminus B)). \end{aligned}$$

Set covers can also be defined as $F(A) = \mu(\bigcup_{k \in A} S_k)$, where $S_k \subset W$, for a measure space (W, μ) . Examples include:

- Contiguous subsets of a chain;
- Contiguous 2-element subsets of a chain, to avoid isolated points;
- Convex subsets of a 2-dimension grids, to prefer convex supports;
- Tree structures, to ensure that if a variable is there, then so are its ancestors (gene networks, wavelet bases, models with interactions).

6d. Given a weighted directed graph W , consider flow functions, with sources $S \subset W$ and sinks $V \subset W$. The *maximum net flow* out of $A \subset V$,

$$F(A) = \max_{\phi \text{ flow}} \phi(W, A) - \phi(A, W),$$

is submodular (from the maxflow-mincut theorem, it is the partial minimization of a cut function).

6e. Given discrete random variables (X_1, \dots, X_p) , the *joint entropy* $F(A)$ of $(X_k)_{k \in A}$ defines a modular function. If (X_1, \dots, X_n) is Gaussian, the joint entropy is $H(X_A) = \frac{1}{2} \log \det(2\pi e Q_{AA})$ and $F(A) = \log \det Q_{AA}$ defines a submodular function.

To cluster points x_1, \dots, x_n , compute their (Gaussian, etc.) kernel $k_{ij} = k(x_i, x_j)$ and try to approximate it as two independent ones, *i.e.*,

$$K \approx \begin{pmatrix} K_A & 0 \\ 0 & K_{V \setminus A} \end{pmatrix}$$

for some $A \subset V = [1, n]$. With a prior $p(A) \propto \prod_{k \in A} \eta_k \prod_{k \notin A} (1 - \eta_k)$ (*i.e.*, each point has probability η_k of being in A , and the point memberships are independent), the negative likelihood becomes

$$\begin{aligned} \ell(A) &= D_{\text{KL}} \left(K \left\| \begin{pmatrix} K_A & 0 \\ 0 & K_{V \setminus A} \end{pmatrix} \right. \right) \\ &= - \sum_{k \in A} \log \eta_k - \sum_{k \notin A} \log(1 - \eta_k). \end{aligned}$$

The first term, the mutual information, is submodular, the second, modular. (*Determinantal point processes*, used to ensure diversity in recommender system results, rely on the same idea.)

6f. Given a positive semidefinite matrix Q and a function $h : \mathbf{R}_+ \rightarrow \mathbf{R}$, $F(A) = \text{tr } h(Q_A A)$ defines a submodular function for some choices of h (concavity is not enough), e.g., $h(\lambda) = \lambda^p$, $p \in [0, 1]$.

7. To minimize a convex Lipschitz function on a convex set:

- Projected gradient;
- *Ellipsoid*: if you cut an ellipsoid in half, it can be circumscribed by a smaller one (slow in practice);
- *Kelley's method* is a **bundle method**: it keeps the information from all the previous iterations. The points previously examines give a piecewise lower bound of the objective function: Kelley's method minimizes this lower bound;
- The ellipsoid method creates a lot of empty space: we can consider polytopes instead, and their centers of gravity; the center of gravity is not efficiently computable, but can be replaced with the *analytic center*. The analytic center of $\{w : \forall i \ a'_i w \leq b_i\}$, $\text{Argmin}_w \sum -\log(b_i - a'_i w)$, can be computed with Newton's algorithm.

To minimize $\Psi + h$, where Ψ is smooth and strongly convex, and h convex (non-smooth) and positively homogeneous, notice that h can be written $h(w) = \sup_{s \in K} s'w$, for some convex set K .

- *Simplicial methods* are bundle methods that replace h with a piecewise approximation, inner (convex hull) or outer,

and iterates

$$w_{t+1} \leftarrow \underset{w}{\text{Argmin}} \Psi(w) + \max_{1 \leq i \leq t} s'_i w, \quad s_i = h'(w_i).$$

- *Proximal methods* (aka proximal gradient, forward-backward splitting, iterative shrinkage thresholding) replace Ψ with a first-order approximation and add a further penalty to avoid moving too fast

$$\underset{w}{\text{Min}} \Psi(w_0) + (w - w_0)' \Psi'(w_0) + h(w) + \lambda \|w - w_0\|_2^2$$

(there is one optimization at each step (the proximal operator) but, for many penalties, it can be computed in closed form)

Quadratic programs can be solved with an **active set** method, based on the following remarks: if the indices of the non-zero components (“active set”) are known, the problem is easy to solve; it is easy to check if a solution is optimal and, if not, to find a variable to add

to or remove from the active set. This applies, for instance, to least squares with a polyhedral penalty (the epigraph of h is a polyhedron – minimizing h amounts to solving a linear program).

8. If f is the Lovász extension of a submodular function F , the *separable optimization* problem

$$\text{Minimize}_{w \in \mathbf{R}^p} f(w) + \sum \psi_i(w_i)$$

(proximal problem) has dual

$$\text{Maximize}_{s \in B(F)} - \sum \psi_i^*(-s_i).$$

It can be solved by solving the family of submodular optimization problems

$$A^\alpha = \text{Argmin}_{A \subset V} F(A) + \sum_{i \in A} \psi'_i(\alpha)$$

(the second term is the modular function $\psi'(\alpha) \in \mathbf{R}^p$) and setting

$$u_i = \sup\{\alpha \in \mathbf{R} : i \in A^\alpha\}.$$

Since $\alpha < \beta \implies A^\beta \subset A^\alpha$, solving the initial convex optimization problem gives the solution to all those submodular optimization problems (the solution is not unique: $\{i : u_i > \alpha\}$ and $\{i : u_i \geq \alpha\}$ are the minimal and maximal minimizers).

9. The *divide-and-conquer* algorithm solves the dual problem

$$t \leftarrow \text{Argmin}_{t: t(V)=F(V)} \sum_i \psi_i^*(-t_i)$$

$$A \leftarrow \text{Argmin} F - t$$

If $F(A) = t(A)$, return t

$$s_A \leftarrow \text{Argmin}_{s \in B(F_A)} \sum_{i \in A} \psi_i^*(-s_i)$$

$$s_{V \setminus A} \leftarrow \text{Argmin}_{s \in B(F^A)} \sum_{i \notin A} \psi_i^*(-s_i)$$

return $(s_A, s_{V \setminus A})$

where $F_A = F|_A$ and $F^A(B) = F(A \cup B) - F(A)$ (contraction).

For quadratic separable problems, *i.e.*, $\psi_i(w_i) = \frac{1}{2}w_i^2$, the dual is $\text{Min}_{s \in B(F)} \frac{1}{2} \|s\|_2^2$. The **Frank-Wolfe minimum norm point** algorithm solves the optimization problem

$$\begin{aligned} &\text{Find} && \eta \\ &\text{To minimize} && \|\sum \eta_i x_i\|_2^2 \\ &\text{Such that} && \eta \geq 0, \eta' \mathbf{1} = 1 \end{aligned}$$

(*i.e.*, the point in the convex hull of the x_i 's closest to the origin) where the x_i 's are the extreme points of $B(F)$ (they do not have to be explicitly computed), using an active set algorithm.

To minimize a convex function on a convex polytope, the **conditional gradient** approximates it with a linear function, finds the minimizer, and moves towards it.

10. Combinatorial algorithms to minimize a submodular function F use

$$\text{Min}_{A \subset V} F(A) = \text{Max}_{s \in B(F)} s_-(V) = F(V) - \text{Min}_{s \in B(F)} \|s\|_1,$$

where $(s_-)_k = \text{Min}\{s, 0\}$: for instance, the simplex can minimize s_- on $B(F)$.

Instead, one can use convex optimization algorithms to solve $\text{Min}_{w \in [0,1]^p} f(w)$:

- Ellipsoid method;
- Subgradient

$$s_t \leftarrow \text{Argmax}_{s \in B(F)} w'_t s$$

$$w_{t+1} \leftarrow \text{Project}_{[0,1]^p}(w_t - \gamma_t s_t);$$

- Conditional gradient;
- Analytic center cutting plane (ACCP – in practice, this performs best).

One could also solve $\text{Min}_{s \in B(F)} \frac{1}{2} \|s\|_2^2$ or, equivalently, $\text{Min}_{w \in [0,1]^p} f(w) + \frac{1}{2} \|w\|_2^2$ (minimum norm point).

11. Maximizing submodular functions is NP-hard, but, for non-decreasing ones, the **greedy algorithm** (start with $A = \emptyset$ and iteratively add $k \in V \setminus A$ that maximizes $F(A \cup \{k\})$) has a performance guarantee: $F(A) \geq (1 - e^{-1})F(A^*)$. In general, local search (look at $A \cup \{k\}$ and $A \setminus \{k\}$) can help.

Submodular maximization can be expressed as a (non-convex) continuous optimization

$$\text{Max}_{A \subset V} F(A) = \frac{1}{2} F(V) + \frac{1}{2} \text{Max}_{s \in B(F)} \|s\|_1.$$

Differences of submodular functions $F - G$ can be minimized (locally) by iterating

- Find $s \in \mathbf{R}^p$ (*i.e.*, a modular function) such that $s(A) = G(A)$ and $\forall B \ s(B) \leq G(B)$;
- Update $A \leftarrow \text{Argmin}(F - s)$.

The minimum has a geometric interpretation, in terms of Hausdorff distance

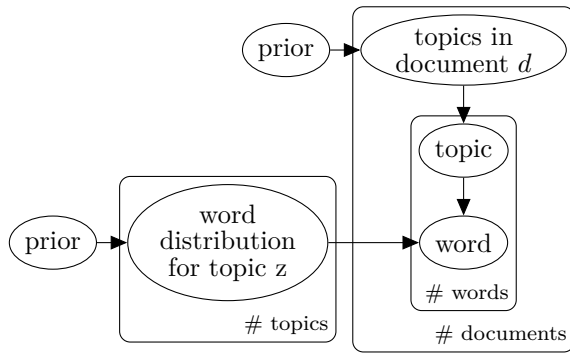

$$\begin{aligned} \text{Min}_{A \subset V} F(A) - G(A) = \\ \frac{1}{2} (F(V) - G(V)) - \frac{1}{2} \text{Min}_{s \in B(G)} \text{Max}_{t \in B(F)} \|t - s\|_1. \end{aligned}$$

Probabilistic topic models M. Steyvers and T. Griffiths

Topic models can be expressed as matrix factorizations:

$$\begin{matrix} \text{cooccurrences} & = & \text{mixture components} & \times & \text{mixture weights} \\ \text{word} \times \text{document} & & \text{word} \times \text{topic} & & \text{topic} \times \text{document} \end{matrix}$$

but, contrary to LSA (SVD), there are constraints on the matrices (probabilities are non-negative and sum to 1) and there is a prior. They can be estimated via Gibbs sampling.

Rethinking LDA: why priors matter H.M. Wallach et al.

Prefer asymmetric Dirichlet priors for the document-topic distribution.

Dynamic topic models D.M. Blei and J.D. Lafferty (2006)

Time-dependent topic models, in which the logarithms of the parameters of the Dirichlet distributions follow random walks, can be estimated via variational inference. (The topics are constant, but their vocabulary changes: for instance, in the “atomic physics” topic, “matter” declined and “quantum” rose in the 20th century.)

From word embeddings to document distances M. J. Kusnet et al. (2015)

To compute the distance between two sentences or texts, (e.g., to retrieve the document closest to a given one), replace them with clouds of points using a vector embedding and use the *earth moving distance* (EMD) between the two clouds. Approximations of the EMD include:

- The distance between the centroids (to quickly identify potential candidates);
- A relaxed (greedy) EMD, in which the whole mass of each word is moved towards the closest word.

Trans-gram, fast cross-lingual word embeddings J. Coulmance et al. (2016)

The skipgram model can also deal with multilingual aligned sentences by defining the context of a word as the set of words in the aligned sentences.

Partially collapsed Gibbs samplers: theory and methods D.A. van Dyk and T. Park (2008)

In some of the steps of a Gibbs sampler, integrating out (marginalizing) some of the variables instead of conditioning on them can improve convergence. Care should be taken to preserve the stationary distribution:

- Move some of the variables from being conditioned to being sampled;

- Re-order the steps so that those new variables are not used;
- Marginalize them.

Example:

$$\begin{array}{cccc} W|XYZ & W|XYZ & WY|XZ & Y|XZ \\ X|WXY & X|WXY & WZ|XY & Z|XY \\ Y|WXZ & WY|XZ & W|XYZ & W|XYZ \\ Z|WXY & WZ|XY & X|WXY & X|WXY \end{array} \rightsquigarrow$$

Metropolis-Hastings within partially collapsed Gibbs samplers D.A. van Dyk and X. Jiao (2014)

Naive use of a Metropolis Hastings step in a PCG sampler (when no closed form distribution is available) often changes the stationary distribution.

A field guide to forward-backward splitting with a Fasta implementation T. Goldstein et al. (2014)

To minimize $f + g$, where f is convex and smooth and g convex, the **proximal gradient** (forward-backward splitting, FBS) method is

$$\begin{aligned} \hat{x}_{k+1} &\leftarrow x_k - \tau \nabla f(x_k) \\ x_{k+1} &\leftarrow \text{prox}_g(\hat{x}_{k+1}, \tau) \end{aligned}$$

where

$$\text{prox}_g(x, \tau) = \underset{z}{\text{Argmin}} \tau g(z) + \frac{1}{2} \|x - z\|^2.$$

If g is differentiable, the second step is a “backward gradient step”, $x_{k+1} \leftarrow \hat{x}_{k+1} - \tau \nabla g(x_{k+1})$: the gradient is evaluated at the new point.

Applications include

- Constrained optimization $\text{Argmin}_{x \in C} f(x)$; the proximal operator of the indicator function of C is the projection, and the algorithm is the projected gradient;
- Lasso: $\text{Argmin}_{\|x\|_1 \leq \lambda} \frac{1}{2} \|Ax - b\|^2$;
- Penalized regression

$$\text{Argmin}_x \frac{1}{2} \|Ax - b\|^2 + \mu \|x\|_1;$$

the proximal operator is soft-thresholding,

$$\text{prox}_{\|\cdot\|_1}(x, \tau) = \text{sign}(x)(|x| - \tau)_+;$$

- Democratic representation

$$\text{Argmin}_x \frac{1}{2} \|Ax - b\|^2 + \mu \|x\|_\infty;$$

- Low rank approximation

$$\text{Argmin}_x \|X - Y\|_F + \mu \|X\|_*;$$

the proximal operator of the nuclear norm is the soft-thresholding of the singular values;

- Phase retrieval.

Implementation details are important:

- To choose the step size, approximate f as a quadratic function $f(x) \approx \frac{1}{2}a \|x\|^2 + \langle x, b \rangle + x$, and set $\tau = 1/a$;
- Fista acceleration: after the proximal step, continue to move in the same direction;
- Backtracking line search: if the objective does not decrease (or if it increases more than some threshold, for non-monotone line search), half the step size;
- Stop when the relative residual

$$\frac{\|\nabla f + \nabla g\|}{\varepsilon + \max\{\|\nabla f\|, \|\nabla g\|\}} \text{ or } \frac{\|\nabla f + \nabla g\|}{\varepsilon + \|\nabla f(x_1) + \nabla g(x_1)\|}$$

is below some threshold.

The Frank-Wolfe algorithm

To minimize a convex function f on a bounded *polygonal* region:

- Start in x_k ;
- Linearize the objective f at x_k ;
- Solve the resulting linear program: c_k^* ;
- The direction $\overrightarrow{x_k x_k^*}$ is a descent direction: use a linear search to select the next point

$$x_{k+1} = \underset{x \in [x_k, x_k^*]}{\operatorname{Argmin}} f(x);$$

- Iterate.

No free lunch theorems for optimization **D.H. Wolpert and W.G. Macready (1997)**

Without any assumption on the function to be minimized, no algorithm can be guaranteed to be good.

Copositive programming **J. Matoušek and B. Gärtner**

Copositive matrices form a convex cone

$$X = \{M \text{ symmetric} : \forall x \geq 0 \quad x' M x \geq 0\}.$$

Its dual is the set of completely positive matrices

$$P = \{M : \exists x_i \geq 0 \quad M = \sum x_i x_i'\}.$$

Copositive programming is NP-hard.

Extending formulations in mixed-integer convex programming **M. Lubin et al.**

To solve mixed integer *convex* programs, prefer polyhedral (but still integral) relaxations to branch-and-bound non-linear programming (NLP): MILP solvers are fast.

Unit tests for stochastic optimization **T. Schaul et al.**

Build unit tests for stochastic optimization algorithms (variants of stochastic gradient descent):

- Start with prototypes , , , ,  (Gaussian),  (Laplace);

- Concatenate them;
- Add noise to the gradient (additive Gaussian or Laplace (for outliers), multiplicative, dropout);
- Compose them into higher-dimensional signals, e.g., with $(x, y) \mapsto (x^p + y^p)^{1/p}$, rotate;
- Add some curl (in reinforcement learning (RL), those algorithms are fed non-gradients);
- Let the function slowly change with time (also common in RL).

Implementation in `lua-torch`.

A tutorial on spectral clustering **U. von Luxburg (2007)**

Given a cloud of points, one can build similarity graphs (prefer connected ones):

- ε -neighbourhood graph (set ε to the length of the longest edge in the minimum spanning tree);
- k -nearest neighbour graph, $k = \log n$;
- Mutual k -nearest neighbour graph, $k > \log n$;
- Fully-connected graph, with Gaussian similarity,

$$s(x_i, x_j) = \exp - \frac{\|x_i - x_j\|^2}{2\sigma^2}$$

(set σ to ε , or to the mean distance to the k th nearest neighbour, $k = \log n$).

Given a graph, with weight and degree matrices W and D , one can consider its Laplacians (there are three of them):

- $L = D - W$;
- $L_{\text{sym}} = D^{-1/2} L D^{-1/2}$;
- $L_{\text{rw}} = D^{-1} L$.

Spectral clustering is k -means (or any other clustering algorithm) on the span of the first k eigenvectors of L , L_{sym} (requires normalization) or L_{rw} ; prefer L_{rw} .

The ratio and normalized cut problems, finding a graph partition that minimizes

$$\text{RatioCut}(A_1, \dots, A_n) = \frac{1}{2} \sum \frac{W(A_i, \bar{A}_i)}{|A_i|}$$

$$\text{or } \text{NCut}(A_1, \dots, A_n) = \frac{1}{2} \sum \frac{W(A_i, \bar{A}_i)}{\text{vol } A_i}$$

where $\text{vol } A = \sum_{i \in A} d_i$, are NP-hard, but their convex relaxations are equivalent to spectral clustering (for a partition $V = A \sqcup \bar{A}$, consider the vector $f_i = \sqrt{|\bar{A}| / |A|}$ or $\sqrt{\text{vol } \bar{A} / \text{vol } A}$ if $i \in A$, and the inverse otherwise; notice that

$$f' L f = |V| \cdot \text{RatioCut}(A, \bar{A}) \quad \text{and } f \perp \mathbf{1}$$

$$\text{or } f' L f = \text{vol}(V) \cdot \text{RatioCut}(A, \bar{A}) \quad \text{and } D f \perp \mathbf{1}.$$

Both L and L_{rw} promote dissimilarity between clusters (good cuts), but L_{rw} also promotes similarity within clusters.

The transition matrix of a random walk on a graph is $P = D^{-1} W = I - L_{\text{rw}}$; random walks are related to cuts: $\text{NCut}(A, \bar{A}) = P(\bar{A}|A) + P(A|\bar{A})$.

The *commute distance* c_{ij} is the expected time for the random walk to go from i to j and back,

$$c_{ij} = \text{vol}(V)(e_i - e_j)'L^\dagger(e_i - e_j);$$

therefore $\sqrt{c_{ij}}$ can be used as a Euclidian distance.

The commute time embedding and the unnormalized spectral embedding (via L) are related but different; for connected graphs, they are very similar.

The graph Laplacian is close to that of a graph in which the communities are disconnected; therefore, the eigenvalues and eigenvectors are also close (Davis-Kahan theorem – how close depends on the *spectral gap*). This is more useful for L , L_{rw} than for L_{sym} , S (similarity matrix) or W (weights), because the eigenvalues are ordered, bounded away from zero, and (contrary to L_{sym} , the eigenvectors are unscaled.

The Laplacian spectrum of graphs **B. Mohar (1991)**

The Laplacian of a graph is $Q = \text{diag}(D) - A$, where A is the adjacency matrix and $D = A\mathbf{1}$ is its degree vector;

$$\langle Qx, x \rangle = \sum_{(u,v) \in E} a_{uv}(x_u - x_v)^2.$$

Equivalently, $Q = CC'$, where C is the oriented incident $|V| \times |E|$ -matrix with entries

$$c_{ve} = \begin{cases} +1 & \text{if } e = * \rightarrow v \\ -1 & \text{if } e = v \rightarrow * \\ 0 & \text{otherwise.} \end{cases}$$

On a lattice, C is a discretization of the gradient, Q of the Laplacian.

Bounds on the eigenvalues $0 = \lambda_1 \leq \lambda_2 \leq \dots \leq \lambda_n$ are known. The second eigenvalue,

$$\lambda_2 = \min_{\substack{x \perp \mathbf{1} \\ x \neq 0}} \frac{\langle Qx, x \rangle}{\langle x, x \rangle}$$

is a measure of connectivity. It is related to (appears in inequalities involving) expander graphs, diameter, number of edges in a maximal cut, isometric number, mean distance, independence number, genus, vertex connectivity, edge connectivity, etc.

The eigenvectors y for λ_2 can be used for 1-dimensional dimension reduction (heuristically, they reduce the length of the jumps $|i - j|$ for edges $i - j$); $\{v : y_v > c\}$ and $\{v : y_v < c\}$ are connected (if $\forall v y_v \neq c$).

The number of spanning trees in G is the coefficient of x in the characteristic polynomial of its Laplacian.

Spectral clustering of graphs **with the Bethe Hessian** **A. Saade et al. (2014)**

The *non-backtracking matrix* of a graph is the (symmetric) binary matrix, indexed by edges, identifying

patterns of the form $i \rightarrow j \rightarrow k$ with $i \neq k$: $B_{i \rightarrow j, \ell \rightarrow k} = \delta_{j\ell}(1 - \delta_{ik})$.

The *Bethe Hessian*, a smaller, symmetric matrix, is a deformation of the Laplacian, $H(r) = (r^2 - 1)\mathbf{1} - rA + D$.

The eigenvalues of B are the roots of $\det H(r)$. The eigenspaces of B , and $H(r)$, for $r = \rho(B)$ (the spectral radius of B can be approximated as $\langle d^2 \rangle / \langle d \rangle - 1$; the approximation can then be refined by looking for the closest root of $\det H(r)$) can help separate communities.

An overview of low-rank matrix recovery **from incomplete observations** **M.A. Davenport and J. Romberg (2016)**

Low-rank matrix recovery can be approximated as follows.

Minimize $_X \|X - X_0\|_F^2$ subject to $\text{rank } X = r$ (SVD)

Minimize $_X \|X - X_0\|_F^2 + \lambda \|X\|_*$

Minimize $_X \|AX - y\|_2^2 + \lambda \|X\|_*$

Minimize $_{L,R} \|ALR' - y\|_2^2 + \frac{1}{2}\lambda \|L\|_* + \frac{1}{2}\lambda \|R\|_*$

Minimize $_X \|X\|_*$ subject to $AX = y$

One can use *iterative hard thresholding* (IHT, projected gradient: move in the direction of $\nabla \|AX - y\|_2^2$, use the SVD to reduce the rank to r , iterate) or alternating projections

$$R \leftarrow \underset{R}{\text{Argmin}} \|ALR' - y\|_2^2$$

$$L \leftarrow \underset{L}{\text{Argmin}} \|ALR' - y\|_2^2$$

Instead of the nuclear norm $\|\cdot\|_*$, one can consider the max-norm, or the log-determinant (it is not convex, but it is a smooth rank proxy for positive semi-definite matrices).

Solving systems of quadratic equations is equivalent to finding a rank-1 matrix $X = vv'$ satisfying linear constraints $\langle X, A_i \rangle = b_i$ (*lifting*)

$$\text{Minimize}_X \|X\|_* \text{ subject to } \forall i \langle X, A_i \rangle = b_i.$$

Applications include *phase retrieval*: recovering v from the magnitudes $|\langle v, a_i \rangle| = y_i$,

$$\text{Minimize}_X \|X\|_* \text{ subject to } \forall i \langle X, a_i a_i' \rangle = y_i^2.$$

Compressive PCA **for low-rank matrices on graphs** **N. Shahid et al.**

Given a matrix $Y \in \mathbf{R}^{p \times n}$, build the k -nearest graph on its columns (resp. rows), with Gaussian weights, compute its Laplacian and its eigenvalue decomposition. The matrix Y is (k_r, k_c) -low rank on graphs if its columns (resp. rows) are in the span of the first k_c (resp. k_r) eigenvectors. (For big data, sample the rows and columns of Y .) Low rank matrices on graphs capture non-linear low-rank structures.

***Pursuits in structured
non-convex matrix factorizations***
R. Khanna et al.

At each step, greedily add the best rank-1 matrix for the linearized objective.

Riemannian pursuit for big matrix recovery
M. Tan et al. (2014)

The matrix lasso, for low rank matrix reconstruction

$$X = \underset{X}{\operatorname{Argmin}} \frac{1}{2} \|b - \mathcal{A}X\|_2^2 + \lambda \|X\|_*$$

does not scale well, because of the high-dimensional SVD needed to compute the nuclear norm $\|X\|_*$. Instead, one can use *fixed rank* methods: rank r matrices form a Riemannian manifold

$$\begin{aligned} \mathcal{M}_n &= \{X \in \mathbf{R}^{n \times n} : \operatorname{rank} X = r\} \\ &= \{U \operatorname{diag}(\sigma) V' : U \in \operatorname{St}_r^n, V \in \operatorname{St}_r^n, \|\sigma\|_0 = r\} \\ \operatorname{St}_r^m &= \{U \in \mathbf{R}^{m \times r} : U'U = I\} \quad (\text{Stiefel manifold}). \end{aligned}$$

The rank r is unknown: progressively increase it.

Convex banding of the covariance matrix
J. Bien et al. (2014)

Banded covariance matrices can be recovered (if the order on the variables is known) with a *hierarchical group lasso* penalty (sum of weighted unsquared L^2 norms – the weights are needed to avoid overpenalizing overlapping regions).

***3D shape reconstruction from 2D landmarks:
a convex formulation***
X. Zhou et al. (2014)

To reconstruct a 3D shape from a set of 2D landmarks W , assume that the shape is an unknown linear combination of simpler shapes $W = \Pi(R \sum c_i B_i + T)$, where Π is the camera matrix, R the rotation, T a translation, and B_i the simpler shapes. This can be simplified to $W = \bar{R} \sum c_i B_i$, $\bar{R} \bar{R}' = I$.

Since the convex hull of the Stiefel manifold $\{X : X'X = I\}$ is the unit (spectral norm) ball, one can consider the convex relaxation

$$\underset{R_i}{\operatorname{Argmin}} \left\| W - \sum R_i B_i \right\|_F^2 + \lambda \sum \|R_i\|_2.$$

***Multi-scale structure and topological anomaly
detection via a new network statistic:
the onion decomposition***
L. Hébert-Dufresne et al.

To build the k -core decomposition of a network:

- Remove isolated nodes;
- Remove nodes connected to 1 (later, k) fewer nodes; iterate (because this lowers the degree of the remaining nodes);

- Increase k and iterate.

The *onion decomposition* keeps track of the nodes in each inner iteration. The *onion spectrum* is the number of nodes in each layer of the onion decomposition; various micro/meso/macro characteristics are visible on it (assortativity, loops/trees, core/periphery, centrality).

It is easy to generate random graphs with prescribed onion spectrum, and they have the same characteristics (e.g., shortest path length distribution) as real-world networks.

***Statistical models for cores decomposition
of an undirected random graph***
V. Karwa et al.

The k -core of a graph is the maximal subgraph in which every vertex has degree at least k . The *shell index* of a node indicates the highest core in which it is. Erdős-Rényi random graphs specify the degree distribution, but the degree is only a coarse measure of centrality: instead, one can use the shell index distribution.

***A fast quartet tree heuristic
for hierarchical clustering***
R. Cilibrasi and M.B. Vitányi (2014)

In a tree, each subset of 4 nodes has one of 3 possible layouts (“quartet topologies”),

Randomized hill-climbing (C implementation in the CompLearn library) can find the tree maximizing the number of consistent quartet topologies.

***Statistically-consistent k-mer methods
for phylogenetic tree reconstruction***
E.S. Allman et al.

Hierarchical clustering of sequences from n -gram Euclidean distance can be inconsistent: prefer model-based distances.

***Scalable force-directed graph layout algorithms
using fast multipole methods***
E. Yunis et al.

Barnes-Hut is $O(n \log n)$ and considers particle-cluster interactions; the fast multipole method (FMM) considers cluster-cluster interactions to reduce the computations and is $O(n)$. The ExaFMM implementation can also be used for graph layout.

***Efficient and high-quality
force-directed graph drawing***
Y. Hu

Force-directed graph-drawing algorithms include:

- Fruchterman-Reingold: edges are springs; there is a repulsive force for each pair of nodes;

- Kamada-Kawai: springs between all pairs of vertices, with length proportional to the distance in the graph;
- Walshaw: to avoid local minima, start with a coarse graph and progressively refine it; only consider forces from neighbouring vertices;
- Combine this multilevel approach with Barnes-Hut oct-trees and progressive cooling.

***The hidden hyperbolic geometry
of international trade:
world trade atlas 1870-2013***
G. García-Pérez et al. (2016)

Plot the world trade map in the hyperbolic plane (Poincaré disk), not the Euclidian one.

Kriging of financial term structures
A. Cousin et al. (2016)

Adding monotonicity constraints to a Gaussian process makes it non-Gaussian but, after discretization, it remains tractable.

***Trading networks, abnormal motifs
and stock manipulation***
Z.Q. Jiang et al. (2012)

The order book has the (encrypted) identity of the trader: look for abnormal motifs such as \mathcal{Q} (self-buy), \rightleftarrows (stock pool) or \rightleftarrows (preferred counterparty).

***Measuring nonlinear dependence
in time series, a distance correlation approach***
Z. Zhou (2014)

The *distance correlation* can be applied to time series

$$V(X, Y) \propto \iint \frac{f_X(x)f_Y(y)}{|x|^{p+1}|y|^{p+1}} dx dy$$

$$V_k(X) = V(X_n, X_{n+k})$$

$$R_k(X) = \sqrt{\frac{V_k(X)}{V_0(X)}}$$

where f_X is the characteristic function of X .

It can be estimated as

$$\hat{V}_k(X) \propto \sum A_{r\ell} B_{r\ell}$$

$$A_{r\ell} = a_{r\ell} - a_{r\bullet} - a_{\bullet\ell} + a_{\bullet\bullet}$$

$$a_{r\ell} = |x_r - x_\ell|.$$

The distance correlation tests need to be adjusted for dependence.

***Clustering of time series subsequences
is meaningless:
implication for previous and future research***
E. Keogh and J. Lin

Before clustering 1-dimensional time series, one may be tempted to embed them in a d -dimensional space (using a sliding window): the resulting clusters do not depend on the dataset; they are just an artefact of the embedding (the cluster centers are translation-invariant and turn out to be (approximately) sine waves).

***The ladder: a reliable leaderboard
for machine learning competitions***
M. Hardt and A. Blum (2015)

Compare the new loss with the best loss so far, with a 1-sided paired T -test, and only update the performance if it is significantly better (you need to remember the whole loss vector).

***How to scale up kernel methods
to be as good as deep neural nets***
Z. Lu et al. (2014)

Kernel-based algorithms, e.g., support vector machines (SVM), tend to scale quadratically with the number of observations, making them unsuitable for large datasets.

Translation-invariant continuous positive definite kernels, $k(x, y) = k(x - y)$, transform the Dirac measure into the Fourier transform of a non-degenerate probability density function, $k(\delta) = \mathcal{F}p$, i.e.,

$$k(x - y) = \int p(\omega) e^{i\omega'(x-y)} d\omega = E_\omega [e^{i\omega'x} e^{-i\omega'y}].$$

They can be approximated by random features

$$k(x - y) \approx \frac{1}{D} \sum_{i=1}^D \phi_{\omega_i}(x) \phi_{\omega_i}(y)$$

$$\phi_{\omega}(x) = \cos(\omega'x + b_i)$$

$$\omega \sim N(0, \sigma^{-1}I) \quad \text{for a rbf kernel}$$

$$\omega \sim \text{Cauchy}(\sigma) \quad \text{for a Laplace kernel}$$

$$b_i \sim U(0, 2\pi)$$

Computations can be parallelized: train a model on a subset of 25,000 random features; combine the resulting models, e.g., by averaging the log-probabilities of the classes.

Those kernels can be added (multiple kernel learning, MKL: either concatenate the random features of all the models, or fit the models separately and combine the forecasts with non-negative weights), multiplied (just add the corresponding ω_i 's) and even sometimes composed – the resulting kernel is then equivalent to a neural net, with one hidden layer and random weights (echo state network, extreme learning machine, reservoir learning, etc.).

Deep residual learning for image recognition

K. He et al. (2015)

The skip-layer connections in a residual net lead to additive (rather than multiplicative) gradient back-propagation, thereby avoiding vanishing or exploding gradients.

They are also easy to initialize: $f = 0$ or f small.

Deconstructing the ladder network architecture

M. Pezeshki et al. (2016)

Ladder networks, for semi-supervised learning, combine a denoising auto-encoder (for the unsupervised part) with a neural net (for the supervised part), with the decoder and the neural net constrained (or penalized) to share weights.

Semi-supervised learning with ladder networks

A. Rasmus et al. (2016)

A ladder network is a (denoising) auto-encoder that tries to reconstruct, not only the input, but all the intermediate reconstructions.

Binary embeddings with structured hashed projections

A. Choromanska et al.

Pseudo-random projections, with a structured matrix (circulant, Toeplitz, etc.)

$$\begin{pmatrix} x_1 & x_2 & \cdots & x_n \\ x_2 & & & \\ \vdots & \diagdown & & x_2 \\ x_n & \cdots & x_2 & x_1 \end{pmatrix} \quad \begin{pmatrix} x_0 & x_1 & \cdots & \\ x_{-1} & & & \\ \vdots & \diagdown & & x_1 \\ \vdots & & x_{-1} & x_0 \end{pmatrix}$$

followed by the sign function, for dimension reduction (lossy compression), e.g., before feeding data (MNIST) to a neural net.

Are elephants bigger than butterflies?

Reasoning about sizes of objects

H. Bahgerinezhad et al.

To estimate object sizes from images:

- Observe the (depth-adjusted) ratio of bounding box areas, in Flickr images tagged with two objects;
- Arrange those ratios into a graph (not all pairs are observed, and some are noisy);
- Model the sizes as log-normal distributions.

Asynchronous methods for deep reinforcement learning

V. Mnih et al. (2016)

Asynchronously running multiple agents in parallel makes deep reinforcement learning amenable to multicore CPUs instead of GPUs.

The Libra toolkit for probabilistic models

D. Lowd and A. Rooshenas (2015)

Command-line tool to estimate and use graphical models; also check libDAI, OpenGML, BNT, OpenMarkov FastInf.

Tanh-Sinh high-precision quadrature

D.H. Bailey (2006)

To approximate integrals, use

$$\int_{-1}^1 f = \int_{-\infty}^{+\infty} f(g(t))g'(t)dt \approx \sum_{j=-N}^N g'(hj)f(g(hj))$$

with $h = 2^{-12}$ for 1000-digit precision,

$$\text{error} \approx \frac{h^2}{(2\pi)^2} \sum F''(jh)$$

$$F(t) = f(g(t))g'(t)$$

$$g(t) = \tanh\left(\frac{\pi}{2} \sinh t\right).$$

Laplace deconvolution with noisy observations

F. Abramovich et al.

The Laplace deconvolution problem is the task of recovering a function f from a kernel g and

$$q(t) = \int_0^t g(t-s)f(s)ds. \quad (\text{Volterra equation})$$

It could be solved using the Laplace transform but, in practice, the observations of q are discrete and noisy; one can, for instance, expand f in the basis of Laguerre functions ($e^{-t} \times$ Laguerre polynomials).

E pur si muove: Galilean-invariant cosmological hydrodynamical simulations on a moving mesh
V. Springel (2009)

Dynamic (moving, unstructured, Voronoi) meshes, which move with the flow can be used for hydrodynamic cosmological simulations.

To compute a Delaunay triangulation: start with a valid triangulation, add a point, add edges to the vertices of its containing triangle, check the in-circle property for the edges of all the triangles created, flip them if needed.

To regularize a Voronoi tessellation: start with a Poisson sample (or a non-uniform distribution) with periodic boundary conditions, move the points to the center of mass of their cells, iterate 150 times).

Refine/de-refine the mesh whenever/wherever needed.

A linguistic approach to categorical color assignment for data visualization
V. Setlur and M.C. Stone (2015)

Assigning meaningful colours to categories, using n -gram co-occurrence (to assess colourability and infer the main colours) and Google image search and WordNet (to find actual, precise colours, from clipart images).

A survey of predictive modelling under imbalanced distributions
P. Branco et al. (2015)

Evaluating the performance of a classifier or a regression algorithm on unbalanced data requires specific metrics, e.g.:

- F_1 : harmonic mean of recall and precision;
- Geometric mean of sensitivity and specificity;
- Area under the ROC (true positive rate vs false positive rate) curve;
- Area under the precision-recall curve;
- Index of balanced accuracy, $(1 + \alpha \cdot \text{dominance}) \cdot M$, where M is some performance measure, and the dominance is the difference between true positive and negative rates.

There are regression analogues of the ROC curve (for those, you often want the area *over* the curve, AOC):

- RROC: $-\sum(\hat{y}_i - y_i + c)_- \sim \sum(\hat{y}_i - y_i + c)_+$;
- REC curve: $P[|y - \hat{y}| < \varepsilon] \sim \varepsilon$;
- REC surface: probability $\sim t + \text{error}$.

To deal with unbalanced datasets, try:

- Random undersampling of the majority class;
- Random oversampling of the minority class or, better, synthetic data (SMOTE: synthetic minority over-sampling technique);
- Reweighting (not unlike boosting);
- Identify **Tomek links**, *i.e.*, points of different classes that are each other's nearest neighbours, and remove that in the majority (or both);

- **Condensed nearest neighbour** (CNN): find a subset of the data that correctly classifies the training set with 1-nearest neighbours;
- 1-class SVM, auto-encoders;
- Utility-based optimization, e.g., from a cost-benefit matrix (if available).

Check the **unbalanced** (R) or **imbalance-learn** (Python) packages.

Related problems include overlapping, small datasets, high dimension, noise, small disjuncts (the minority class has clusters of different sizes or densities: it is easy to miss the smallest ones).

Are random forests truly the best classifiers?
M. Wainberg et al. (2016)

When playing with hyperparameters, you must use a held-out test set.

Estimating uncertainty for massive data streams
N. Chamandy et al. (2012)

The **Poisson bootstrap** (for streaming data, *i.e.*, when the number of observations is not known), uses weight $\sim \text{Pois}(1)$.

A tutorial introduction to the minimum description length principle
P. Grünwald (2004)

The minimum description length (MDL) principle is an information-theoretic interpretation of penalized likelihood estimators. It finds hypotheses that compress the data the most, often using a decomposition

$$\underset{H \in \mathcal{H}}{\text{Argmin}} L(H) + L(D|H)$$

into model length $L(D)$ (e.g., the order of a Markov chain and its coefficients) and residual length $L(\text{Data}|H)$. The first term (penalty, model complexity) identifies structure in the data, the second (log-likelihood), measures the residual noise.

A probability distribution P on a finite set $\mathcal{Z} = \mathcal{X}^n$ determines an optimal code C with code length $L(z) = \lceil -\log_2 P(z) \rceil$. If $n \gg 1$, the rounding is negligible. The actual code is not needed, only the *code length*, *i.e.*, a function $L : \mathcal{Z} \rightarrow [0, \infty]$ such that $\sum_z 2^{-L(z)} \leq 1$. Probability and code length are related by

$$L = \underset{L}{\text{Argmin}} E_{Z \sim P}[L(Z)]$$

$$L(z) = -\log_2 P(z).$$

(This can be generalized to continuous distributions: $L(z)$ is then the length of the code needed to encode $z \in \mathcal{X}^n$ with “unit precision”.)

The information inequality is

$$E_P[-\log Q(Z)] \geq E_P[-\log P(Z)].$$

The crude, 2-part MDL principle is

$$H = \underset{H}{\operatorname{Argmin}} L(H) + L(D|H),$$

where $L(D|H) = \log_2 P(D|H)$ and $L(H)$ is defined in an ad hoc fashion (for instance, to model a sequence of length n using Markov chains, one could first encode the order of the chain and then the counts – this is finite, and is a sufficient statistic).

Instead of $L(D|H)$, we do not lose much if we use $L(D|\mathcal{H})$: if \mathcal{H} is finite, $\mathcal{H} = \{H_1, \dots, H_k\}$, find the hypotheses H_i with the smallest code length $L(D|H_i)$, consider its code C_i , and encode the data D as $(i, C_i(D))$ (2-part *universal model*). This still works if \mathcal{H} is countably infinite. More generally (this will also work for continuous models), for $\mathcal{H} = \{P(\cdot|\theta), \theta \in \Theta\}$, consider a prior W on Θ and the *Bayesian mixture* $P(\cdot) = \sum_{\theta \in \Theta} P(\cdot|\theta)W(\theta)$. The corresponding code length gives the Bayesian universal model.

The normalized maximum likelihood (NML, aka Shtarkov) distribution

$$P(x^n) \propto P(x^n | H_{\hat{\theta}(x^n)}),$$

which minimizes the worst-case regret,

$$\max_{x^n \in \mathcal{X}^n} L(x^n|P) - L(x^n|P_{\hat{\theta}(x^n)})$$

gives the minimax optimal (NML) model.

The size distribution of inhabited planets **F. Simpson (2016)**

Over 98% of the population lives in a country larger than the median: by analogy, most inhabited planets are smaller than ours, and have fewer and heavier (300 kg) inhabitants.

Memcomputing NP-complete problems in polynomial time using polynomial resources **F.L. Traversa et al. (2014)**

A memcomputer is a non-Turing machine, equivalent to a non-deterministic Turing machine (it can solve NP-complete problems with polynomial resources, even if $P \neq NP$) whose units can both store and process information – they not only store bits but waveforms, e.g., combining $(e^{i\omega_k t})_{1 \leq k \leq n}$ into $\prod_k e^{i\omega_k t}$.

NP-complete problems and physical reality **S. Aaronson**

To solve NP-complete problems in polynomial time, find a physical phenomenon whose description is equivalent to an NP problem, and just observe it.

Dirichlet processes **Y.W. Teh**

The *Dirichlet distribution* is conjugate to the multinomial; it generalizes the Beta distribution (conjugate to

the Bernoulli) from the interval $[0, 1]$ to the simplex Δ_k .

Bayesian density estimation considers the model

$$F \sim \text{Prior}$$

$$x_i \sim F$$

and computes the posterior distribution $F|x_1, \dots, x_n$.

The *Bayesian mixture model* with k components can be written

k	number of components
$\alpha > 0$	strength of the prior
$\pi \sim \text{Dir}\left(\frac{\alpha}{k}, \dots, \frac{\alpha}{k}\right)$	cluster probabilities
$z_i \sim \text{Mult}(\pi)$	cluster membership
$\theta_k \sim H$	cluster parameters
$x_i \sim F_{\theta_{z_i}}$	

For instance, in the Gaussian case, H is the normal-inverse-Wishart distribution, $\theta_k = (\mu_k, V_k)$ and $F_{\theta_k} = N(\mu_k, V_k)$. The *Dirichlet process* (DP) appears when we let $k \rightarrow \infty$ (leaving the number of observations fixed).

There are many ways of defining, constructing or sampling from a Dirichlet process $G \sim \text{DP}(\alpha, H)$. Let Θ be a measurable space, e.g., $[0, 1]$ or $\mathbf{R}^n \times \text{SPD}_n$, H a probability distribution on Θ , e.g., uniform on $[0, 1]$ or Normal-inverse-Wishart on $\mathbf{R}^n \times \text{SPD}_n$, and $\alpha > 0$ the strength of the prior.

A Dirichlet process is a family of random variables $(G(A))_{A \subseteq \Theta}$ whose finite margins are Dirichlet: for all (measurable) partition $\Theta = A_1 \sqcup \dots \sqcup A_n$,

$$(G(A_1), \dots, G(A_n)) \sim \text{Dir}(\alpha H(A_1), \dots, \alpha H(A_n)).$$

A **Dirichlet process** is a random probability distribution G on Θ whose samples are of the form $\sum_{k \geq 1} \pi_k \delta_{\theta_k}$ with (broken stick construction)

$$\begin{aligned} \theta_k &\sim H \\ \pi_k &= \beta_k \prod_{1 \leq \ell \leq k} (1 - \beta_\ell) \\ \beta_k &\sim \text{Beta}(1, \alpha). \end{aligned}$$

This is sometimes written $\pi \sim \text{GEM}(\alpha)$.

The *urn scheme* explains how to sample from a Dirichlet process $G \sim \text{DP}(\alpha, H)$, sample from that sample, $\theta_1, \dots, \theta_n \sim G$, and marginalize G out. Start with a sample $\theta_1 \sim H$. Once you have $\theta_1, \dots, \theta_n$, with probability $\alpha/(\alpha + n)$, sample a new point $\theta_{n+1} \sim H$; with probability $n/(\alpha + n)$, sample from the existing points $\theta_{n+1} \sim \text{Unif}(\{\theta_1, \dots, \theta_n\})$.

The *Chinese restaurant process* (CRP) is similar, but only looks at the partition of $\llbracket 1, n \rrbracket$ induced by the unique values in $(\theta_1, \dots, \theta_n)$.

The **Dirichlet process mixture** model (or infinite mixture model) can be written

Θ	parameter space
H	prior
α	strength of the prior
$G \sim \text{DP}(\alpha, H)$	
$\theta_i \sim G$	
$x_i \sim F_{\theta_i}$	

(note that there are usually duplicated values in the θ_i) or, equivalently

Θ	parameter space
H	prior
α	strength of the prior
$\theta_k \sim H$	cluster k parameters
$\pi \sim \text{GEM}(\alpha)$	cluster probabilities
$z_i \sim \text{Mult}(\pi)$	cluster membership
$x_i \sim F_{\theta_{z_i}}$	i th observation

Hierarchical Bayesian nonparametric models with applications

Y.W. Teh and M.I. Jordan (2009)

A **hierarchical Dirichlet process** (HDP) is a Dirichlet process (DP) whose base distribution is a sample from a DP. For instance, the *HDP mixture model* allows multiple clustering problems to share clusters, e.g., to share topics across documents.

clustering problem cluster	corpus	population
	document	genetic makeup
	topic	subpopulation

The infinite HMM (iHMM) or HDP-HMM is a hidden Markov model (HMM) with an unbounded number of hidden states (one needs to increase the probability of self-transitions to avoid the creation of many redundant states).

The **Pitman-Yor process**, which replaces $\text{Beta}(1, \alpha)$ with $\text{Beta}(1 - d, \alpha + kd)$ and yields the power laws commonly seen in language modeling, also has a hierarchical variant (HPY).

A random measure G is *completely random* if

A_1, \dots, A_n disjoint $\implies G(A_1), \dots, G(A_n)$ independent.

The Dirichlet process is not completely random because it is a probability measure. The *Beta process* is a completely random measure generalizing the Dirichlet process and often used as a prior for *featural representations* (i.e., binary matrices, i.e., clustering problems where an observation can be in several clusters). A sample from a Beta process $B \sim \text{BP}(c, B_0)$ is of the form $B = \sum_{k \geq 1} \omega_k \delta_{\theta_k}$, where $(\omega_k, \theta_k)_{k \geq 1}$ is a sample from a Poisson process on $[0, 1] \times \Theta$ with rate measure $\nu(d\omega, d\theta) = c\omega^{-1}(1 - \omega)^{c-1}d\omega B_0(d\theta)$ where $c > 0$ (concentration).

There is a stick-breaking construction (for $c = 1$)

$$B = \sum \omega_k \delta_{\theta_k}$$

$$v_k \sim \text{Beta}(1, \alpha)$$

$$\omega_k = \prod_{i=1}^k (1 - v_i)$$

$$\theta_k \sim B_0$$

or (2-parameter Beta process)

$$B = \sum_{n \geq 1} \sum_{k=1}^{K_n} \omega_{nk} \delta_{\theta_{nk}}$$

$$K_n \sim \text{Poisson}\left(\frac{c\alpha}{c + n - 1}\right)$$

$$\theta_{nk} \sim B$$

$$\omega_{nk} \sim \text{Beta}(1, c + n - 1)$$

Bayesian nonparametric models

P. Orbanz and Y.W. Teh

A nonparametric Bayesian model is an infinite-dimensional (parametric) Bayesian model, i.e., a finite-dimensional parametric Bayesian model whose dimension increases with sample size. Examples include:

– Gaussian process: $f \sim \text{GP}$ means

$$(f(x_1), \dots, f(x_n)) \sim N;$$

- Dirichlet process $G = \sum_{k \geq 1} \pi_k \delta_{\theta_k}$, $\sum \pi_k = 1$;
- Chinese restaurant process (partitions from a DP);
- Beta process $G = \sum_{k \geq 1} \pi_k \delta_{\theta_k}$;
- Indian buffet process (partitions from a BP);
- Pitman-Yor process;
- Hierarchical DP, BP or PY;
- Dependent DP;
- etc.

Showing that those processes can be tricky:

- Compatible finite-dimensional marginals and Kolmogorov's extension theorem (only for countable families);
- Explicit construction (e.g., stick-breaking);
- Limit of finite-dimensional distributions;
- Exchangeable sequences and de Finetti's theorem.

Consistency of infinite-dimensional Bayesian models is not as common as for finite-dimensional ones.

In R, check the **DPpackage** package.

Natural language processing

M. Collins (Coursera & Columbia, 2013)

1. A language model is a probability distribution on V^+ , the set of sentences written with a vocabulary V . The sample distribution, from a corpus, is not a good model: it assigns a zero probability to sentences never observed. Markov models (**n -gram** models) assume that $P(x_{k+1}|\text{past}) = P(x_{k+1}|x_{1:k}) = P(x_{k+1}|x_{k-n+1:k})$. These probabilities can be estimated as follows:

$$\begin{aligned}
- P(x_x|x_1, x_2) &= \frac{\text{count}(x_1, x_2, x_3)}{\text{count}(x_1, x_2)} \\
- P(x_3|x_1, x_2) &= \lambda_1 \frac{\text{count}(x_1, x_2, x_3)}{\text{count}(x_1, x_2)} + \\
&\quad \lambda_2 \frac{\text{count}(x_2, x_3)}{\text{count}(x_2)} + \\
&\quad \lambda_3 \frac{\text{count}(x_3)}{\# \text{ words}}
\end{aligned}$$

where $\lambda_1, \lambda_2, \lambda_3$ depend on the trigram (x_1, x_2, x_3) , (in particular, $\lambda = 0$ if the denominator is zero), e.g.,

$$\begin{aligned}
\lambda_1 &= \frac{\text{count}(x_1, x_2)}{\text{count}(x_1, x_2) + \gamma} \\
\lambda_1 &= (1 - \lambda_1) \frac{\text{count}(x_2)}{\text{count}(x_2) + \gamma} \\
\lambda_3 &= 1 - \lambda_1 - \lambda_2
\end{aligned}$$

$$- P(x_2|x_1) = \frac{\text{count}^*(x_1, x_2)}{\text{count}(x_1)} \text{ if } \text{count}(x_1, x_2) > 0,$$

where the discounted count is

$$\text{count}^*(x_1, x_2) = \text{count}(x_1, x_2) - \beta$$

and the missing probability mass

$$1 - \sum_{x_2} \frac{\text{count}^*(x_1, x_2)}{\text{count}(x_1)}$$

is assigned to the bigrams with no counts.

2. One can hope to describe sentences with a *context-free grammar* (CFG). For a given (grammatical) sentence, there can be several (left-most) derivations – the sentence can be ambiguous. A **probabilistic CFG** (PCFG) assigns a probability to each rule of the grammar, and therefore defines a probability distribution on the set of derivations (not just the set of sentences). The training data provides the grammar and empirical probabilities from the rules. The *CKY* algorithm uses dynamic programming to find the most likely parse tree (for a grammar in *Chomsky normal form* (CNF), i.e., whose rules are of the form $X \rightarrow Y_1 Y_2$ or $X \rightarrow y$) by computing $\pi(i, j, X) = \text{Max likelihood}(X \rightarrow x_{i:j})$. The *inside algorithm* similarly computes the probability of a sentence using $\pi(i, j, X) = \sum \text{likelihood}(X \rightarrow x_{i:j})$.

3. PCFGs are not sensitive to lexical information: for instance, they cannot notice that **into/IN** (resp. **of/IN**) is more (less) likely to be attached to a VP than to a NP. There is also no way of encoding the “close attachment preference” (a PP is more likely to be attached to a nearby NP than to a distant one). A **lexicalized PCFG** is a PCFG in which each non-terminal is paired with a lexical item (the “head” of the non-terminal), e.g.,

$$S(\text{examined}) \rightarrow_2 NP(\text{lawyer}) VP(\text{examined})$$

(the subscript indicates the origin of the lexical item). Since the number of parameters explodes, they should be regularized, for instance:

$$\begin{aligned}
- P[S(\text{examined}) \rightarrow_2 NP(\text{lawyer}) VP(\text{examined})] &= \\
P[S(\text{examined}) \rightarrow_2 NP VP(\text{examined})] P[\text{lawyer} | \dots]
\end{aligned}$$

- Shrink $P[S(\text{examined}) \rightarrow_2 NP VP(\text{examined})]$ towards $P[S \rightarrow_2 NP VP]$
- Shrink $P[\text{lawyer} | S(\text{examined}) \rightarrow_2 NP VP(\text{examined})]$ towards $P[\text{lawyer} | S \rightarrow_2 NP VP]$.

4. The **noisy channel** model (generative model) to translate from French f to English e is

$$p(e, f) = p(e)p(f|e).$$

It uses a language model for the target, $p(e)$, and a conditional model $p(f|e)$, even though we are eventually interested in $p(e|f)$.

It is too complicated to model $p(f_1 \dots f_n | e_1 \dots e_n, m)$ directly, but $p(f_1 \dots f_n, a_1 \dots a_m | e_1 \dots e_n, m)$, where $a_i \in \llbracket 1, n \rrbracket$ is the position of the English word corresponding to the i th French word, and the a_i can be integrated out. One can use a model for the alignments $P[a_i = j | m, n]$,

	similar languages
	noun/adjective inversions
	SVO vs SOV

another for the word pairings, $[f_i | e_j, a_i = j]$ and multiply them (IBM model 2).

The decoding problem, $\text{Argmax}_e p(e)p(f|e)$, is hard, but the alignment and word pairing models are easier, and useful in other models: use the EM algorithm (do not use hard alignments but weighted mixtures) and start with the uniform alignment probability (IBM model 1).

5. Considering phrases, i.e., consecutive groups of words, improves performance. To translate with a phrase model and a trigram language model, progressively build the translation, keeping track of the “state” (last two words (for the trigram model), last position (for the alignment model), boolean vector indicating which words have already been translated, score). Do not use a completely greedy algorithm, but keep a pool of good partial translations (states) and progressively expand them.

6. (Penalized) **log-linear models** generalize (smoothed) n -gram models: define features, e.g.,

$$\begin{aligned}
f_k(x_1, \dots, x_n) &= \mathbf{1}_{x_n = \text{world}} \\
f_k(x_1, \dots, x_n) &= \mathbf{1}_{x_{n-1}, x_n = \text{hello, world}}
\end{aligned}$$

let

$$p(x_{n+1} | x_1 \dots x_n) \propto \exp[\theta \cdot f(x_1 \dots x_n x_{n+1})]$$

or, writing $y = x_{n+1}$ and $x = (x_1, \dots, x_n)$,

$$\begin{aligned}
p(y|x) &\propto \exp[\theta \cdot f(x, y)] \\
p(y|x) &= \frac{\exp[\theta \cdot f(x, y)]}{\sum_z \exp[\theta \cdot f(x, z)]}
\end{aligned}$$

and find θ that maximizes the penalized log-likelihood

$$L(\theta) = \sum_i \log p(y^{(i)} | x^{(i)}, \theta) = \frac{1}{2} \|\theta\|_2^2$$

using gradient ascent – the gradient is easy to compute,

$$\frac{\partial L}{\partial \theta_k} = \sum_i f_k(x^{(i)}, y^{(i)}) - \sum_i \sum_z p(z|x^{(i)}) f_k(x^{(i)}, z).$$

A **log-linear model** to label a sentence is of the form

$$P[\text{label}|\text{input}, \theta] \propto \exp[\theta \cdot \phi(\text{input}, \text{label})]$$

where $\phi : \text{Inputs} \times \text{Labels} \rightarrow \mathbf{R}^d$ is a feature map. This is reminiscent of multinomial logistic regression

$$\begin{aligned} \text{score} &= \theta \cdot \phi(\text{input}, \text{label}) && \text{log-linear} \\ \text{score} &= \theta_{\text{label}} \cdot \phi(\text{input}) && \text{logistic.} \end{aligned}$$

7. A maximum entropy Markov model (MEMM) is of the form

$$\begin{aligned} P(\text{tag}_1, \dots, \text{tag}_m | \text{word}_1, \dots, \text{word}_m) \\ &= \prod_i P(\text{tag}_i | \text{tag}_1, \dots, \text{tag}_{i-1}, \text{word}_1, \dots, \text{word}_m) \\ &= \prod_i P(\text{tag}_i | \text{tag}_{i-1}, \text{word}_1, \dots, \text{word}_m) \text{ (Markov)} \end{aligned}$$

and each factor is modeled with a log-linear model

$$\begin{aligned} P[\text{tag}_i | \text{tag}_{i-1}, \text{sentence}] &\propto \\ &\exp[\theta \cdot \phi(\text{sentence}, i, \text{tag}_{i-1}, \text{tag}_i)]. \end{aligned}$$

The most likely tag sequence can be estimated with the Viterbi algorithm. MEMMs differ from HMMs in the use of features (they are difficult to add to a HMM).

A **conditional random field (CRF)** is a big log-linear model, in which the feature vector $\Phi(\text{sentence}, \text{sequence of tags})$ is of the form

$$\begin{aligned} \Phi(\text{sentence}; \text{tag}_1, \dots, \text{tag}_m) &= \\ &\sum \phi(\text{sentence}, i, \text{tag}_{i-1}, \text{tag}_i). \end{aligned}$$

It can be used with the Viterbi algorithm and fitted by gradient descent (the big sum in the normalizing constant can be dealt with with the forward-backward algorithm).

One can also consider *trigram MEMM*, modeling $P[\text{tag}_i | \text{tag}_{i-1}, \text{tag}_{i-2}, \text{sentence}]$, and generalizing trigram HMM $P[\text{tag}_i | \text{tag}_{i-1}, \text{tag}_{i-2}]$. Features can include

$$\begin{aligned} x_i &= W \wedge \text{tag}_i = T \\ \text{suffix}(x_i, 3) &= \text{ABC} \wedge \text{tag}_i = T \\ \text{prefix}(x_i, 3) &= \text{ABC} \wedge \text{tag}_i = T \\ \text{tag}_i &= T_1 \wedge \text{tag}_{i-1} = T_2 \wedge \text{tag}_{i-2} = T_3 \\ \text{tag}_i &= T_1 \wedge \text{tag}_{i-1} = T_2 \\ \text{tag}_i &= T \\ x_{i-1} &= W \wedge \text{tag}_i = T \\ x_{i-2} &= W \wedge \text{tag}_i = T \\ x_{i+1} &= W \wedge \text{tag}_i = T \\ x_{i+2} &= W \wedge \text{tag}_i = T \\ x_i &\text{ contains } [: \text{digit}:] \wedge \text{tag}_i = T \\ x_i &\text{ contains } [: \text{upper}:] \wedge \text{tag}_i = T \\ x_i &\text{ contains } [-] \wedge \text{tag}_i = T. \end{aligned}$$

8. The naive Bayes model assumes $X_i \perp\!\!\!\perp X_j \mid Y$:

$$\begin{aligned} P(Y = y, X_1 = x_1, \dots, X_n = x_n) &= \\ P(Y = y) \prod_i P[X_i = x_i | Y = y] \end{aligned}$$

i.e.,

$$p(y, x_1, \dots, x_n) = q(y) \prod_i q_i(x_i | y).$$

The maximum likelihood estimator turns out to be the sample frequencies. If the labels Y are not observed, it is a clustering problem (not unlike k -means, but with discrete variables), which can be tackled with the EM algorithm:

- E-step: estimate the cluster membership probabilities;
- M-step: estimate the parameters.

9. The Viterbi algorithm uses dynamic programming to compute the most likely sequence of hidden states in a HMM, with $T_{i,j}$ = probability of the most likely path of hidden states emitting $o_{i:j}$ and ending in state x_i .

The **forward-backward algorithm** computes

$$\sum_{s:s_j=a} \psi(s) \text{ and } \sum_{\substack{s:s_j=a \\ s_{j+1}=b}} \psi(s)$$

where $\psi(s) = \prod \psi(s_{j-1}, s_j, j)$,

$$\begin{aligned} \psi(s_{j-1}, s_j, j) &= t(s_j | s_{j-1}) e(x_j | s_j) && \text{(HMM)} \\ \psi(s_{j-1}, s_j, j) &\propto \exp[\theta \cdot \phi(x_{1:m}, s_{j-1}, s_j, j)] && \text{(CRF)}. \end{aligned}$$

Those quantities can be used to compute marginal probabilities.

It can be generalized to sequences of parse trees: the *inside-outside algorithm* allows the EM estimation of PCFGs.

Workflow control-flow patterns

A revised view

R. Russell et al. (2006)

Dependencies between tasks are often represented by a directed acyclic graph (e.g., in a **Makefile**), but more complicated dependencies are sometimes needed (sequence, and-split, and-join, or-split, or-join, first-to-complete-or-join, m-out-of-n-or-join, cancellations, interleaving, etc.); they can be modeled with *coloured Petri nets* (CPN).

Temporal evolution of financial-market correlations

D.J. Fenn et al. (2011)

The inverse participation ration of the k th principal component \mathbf{w}_k is $\text{IPR} = \sum_i w_{ik}^4$; the participation ratio, $1/\text{IPR}$, is the effective number of assets contributing to the k th component.

The evolution of boosting algorithms
A. Mayr et al. (2014)

Bagging fits a model on random subsets of the data and averages their forecasts. *Boosting* uses a similar idea, with weighted subsets (giving more weight to currently misclassified observations) and a weighted average of the forecasts. *Statistical boosting* progressively builds an (interpretable) statistical model, instead of averaging forecasts. For instance, if the weak learners are 1-variable GAMs, each boosting iteration adds one variable to the model, in a way similar to the lasso (it provides variable selection and a regularized path). While gradient boosting finds the best (incremental) candidate $h_i(x_i, \beta)$ among $h_1(x_1, \beta), \dots, h_k(x_k, \beta)$ and moves the model slightly in its direction, by adding $\varepsilon h_i(x_i, \beta)$, *likelihood-based boosting* looks at penalized $h_i(x_i, \beta)$, each maximizing $\log \text{lik}(\beta) - \text{penalty}(\beta)$, and adds the best one – thanks to the penalty, there is no need to multiply by ε .

R implementations include `mboost`, `gbm` (gradient boosting); `GAMBoost`, `CoxBoost` (likelihood-based boosting).

***Teaching logic
using a state-of-the-art proof assistant***
C. Kaliszyk et al. (2007)

Coq is used to teach logic, to avoid the almost-but-not-completely-right proofs many students generate, after defining Coq tactics that exactly match the rules of logic as they are taught.

***jHoles: a tool for understanding
biological complex networks
via clique weight rank persistent homology***
J. Binchi et al. (2014)

Look at the persistent homology of the filtered simplicial complex associated to the truncated graphs of a weighted graph. (jHoles converts the weighted graph into a filtered simplicial complex and gives it to JavaPlex to compute the persistent homology.)

Infinite-dimensional word embeddings
E.T. Nalisnick and S. Ravi (2016)

Many statistical or machine learning models have a latent state, with values in a finite-dimensional vector space. One can also use an infinite-dimensional one, e.g., ℓ^2 , by adding a per-dimension penalty.

***Distributed representations
of sentences and documents***
Q. Le and T. Mikolov (2014)

Word2vec can be generalized to paragraphs: instead of predicting the next word from the previous words, keep the word weights w fixed and add the paragraph id as a predictor: the paragraph weights give a vector

representation of each paragraph.

***Topological pattern recognition
for point cloud data***
G. Carlsson (2013)

Gentle introduction to topological data analysis (TDA), with more examples than the other review articles.

To gain insight on the structure of a (contractible) metric space, transform it in some way, e.g., by removing a point, adding a point (1-point compactification, for separated, locally compact, non-compact spaces), removing singular points, removing the “center” (*i.e.*, keeping the “end points”) to identify appendages.

Functional persistence homology is the persistence homology of $f^{-1}(\alpha)$ or $f^{-1}([\alpha, +\infty])$, for some map $f : X \rightarrow \mathbf{R}$ (e.g., the centrality).

Applications include:

- Chemistry: the functional persistence homology barcodes measure how close two molecules (clouds of point/atoms) are;
- Genetics: non-trivial homology of a set of (viral) genetic sequences (for the Hamming distance) reveals horizontal gene transfer;
- Time series: the homology of the set of (centered, normalized) fragments $(x_t, x_{t+1}, \dots, x_{t+k})$ can help identify periodic time series;
- Cosmology: persistence homology (in particular the Euler characteristic) can be used to compare the structure of the universe (galaxies form clusters, filaments, walls) with that from a Gaussian random field.

Introduction to the R package TDA
B.T. Fasy et al.

***Homology and cohomology computation
in finite element modeling***
M. Pellikka et al.

`gmsh` can compute homology and cohomology – for some PDE problems, the boundary only determines the solution within a given cohomology class.

***PREMiuM: an R package for profile regression
mixture models using Dirichlet processes***
S. Liverani et al. (JSS, 2015)

Profile regression is a mixed model in which the groups come from a Dirichlet process mixture clustering.

***GPfit: an R package
for fitting a Gaussian process model
to deterministic simulator outputs***
B. MacDonald et al. (JSS, 2015)

When fitting a Gaussian process on non-noisy data, with a Gaussian correlation function $R_{ij} = \text{Cor}(y_i, y_j) = \prod_k \exp -\theta_k |x_{ik} - x_{jk}|^2$, $\theta_k > 0$, the correlation matrix can be ill-conditioned (some of the points are too close), and the likelihood has local extrema very close to zero. One can replace R with $R + \delta I$, with the smallest nugget δ that makes the matrix well-conditioned, and reparametrize θ as $\theta = \exp \phi$.

Check the R packages `GPfit` (no noise), `tgp` (noise) or `mlegp` (noise, numerically unstable).

Also mentions `lhs::maximinLHS` (random but well-dispersed points).

***Introducing multivalor:
a multivariable emulator***
R.K.S. Hankin

Gaussian processes in higher dimensions.

***Newton's versus Halley's method:
a dynamical systems approach***
G.E. Toberts and J. Horgan-Kobelski (2003)

To solve $f(x) = 0$, Newton's method approximates f with an affine function, Halley's method with a hyperbola.

Pricing composable contracts on the GP-GPU
J. Ahnfelt-Rønne and M.F. Werk (2011)

SPL (stochastic process language) is a Haskell DSL to describe and (efficiently) price derivatives.

***Fractional-parabolic deformations
with sinh-acceleration***
S. Levendorskiĭ

Some integrals can be computed using:

- A fractional-parabolic deformation, *i.e.*, by replacing an integral over \mathbf{R} with an integral over $\sigma \exp[\alpha \log(1 + i\mathbf{R})]$: 
- Sinh acceleration:

$$\begin{aligned} \int_{\mathbf{R}} f(x) dx &= \int_{\mathbf{R}} f(\sinh y) \cosh y dy \\ &\approx \sum_{|n| \leq N} f(\sinh n) \cosh n \end{aligned}$$

***Market timing and return prediction
under model instability***
M.H. Pesaran and A. Timmermann (2002)

To detect structural breaks, apply CUSUM tests to observations reversed in time.

***On the equivalence between quadrature rules
and random features***
F. Bach (2015)

The quadrature problem can be formulated as the problem of approximating an element $i : f \mapsto \int_D f$ of a Hilbert space as a linear combination of well-chosen elements $\text{ev}_x : f \mapsto f(x)$.

It is similar to the kernel approximation problem: finding a low-dimensional embedding ϕ such that $k(x, y) \approx \langle \phi(x), \phi(y) \rangle$.

The CMA evolution strategy: a tutorial
N. Hansen (2011)

CMA-ES is a population-based optimization algorithms that models the current population as a Gaussian, samples from this model, keeps the best candidates and iterates.

Gaussian processes for machine learning
C.E. Rasmussen and C.K.I. Williams (2006)

A Gaussian process is an infinite family of random variables $(X_t)_{t \in \mathbf{R}}$; the mean and covariance functions

$$m(t) = E[X_t], \quad k(s, t) = \text{Cov}(X_s, X_t)$$

suffice to define it. The joint distribution of X_{t_1}, \dots, X_{t_n} is Gaussian, and the conditional distribution $X_{s_1}, \dots, X_{s_m} | X_{t_1}, \dots, X_{t_n}$, obtained in the usual way (Shur complement) is the posterior distribution.

To train a Gaussian process, one can use a hierarchical prior, *i.e.*, posit a parametrization of the mean and covariance functions, *e.g.*,

$$\begin{aligned} m(t) &= at^2 + bt + c \\ k(s, t) &= \sigma_1^2 \exp -\frac{(s-t)^2}{\ell^2} + \sigma_2^2 \delta_{ij} \end{aligned}$$

(the $\sigma_2^2 \delta_{ij}$ term accounts for noisy observations) and select the hyperparameters via log-marginal likelihood.

with general return distributions***
W.T. Shaw

Biased random portfolios.

Algorithms for hyper-parameter optimization
J. Bergstra et al. (2011)

A **Parzen estimator** of a conditional probability distribution $p(x|y)$ is an estimator of the form

$$p(x|y) = \begin{cases} \ell(x) & \text{if } y < y^* \\ g(x) & \text{if } y \geq y^* \end{cases}$$

where ℓ and g are kernel estimators (possibly with a Gaussian, etc. prior) and the threshold y^* is some quantile of the sample data $p(y < y^*) = \gamma$.

The expected improvement (x = parameter, y = loss) is (an increasing function of) $\ell(x)/g(x)$: to get a new candidate solution, one can sample many points from ℓ and take that with the highest $\ell(x)/g(x)$.

The parameter space of hyperparameter optimization problems often has a tree structure: the Parzen estimator can be generalized to a *tree-structured Parzen estimator* (TPE).

Sequential search can be parallelized with the **constant liar** approach: once a candidate point has been chosen, provisionally set its loss to the average loss.

Check the **hyperopt** Python package.

**Sequential model-based optimization
for general algorithm configuration**
F. Hutter et al. (2011)

Gaussian processes (GP) can be generalized to mixed continuous-categorical variables:

$$k(x, y) = \exp \sum_j -\lambda_j d(x_j, y_j)^2,$$

where d is the Euclidean or Hamming distance (note that the coordinates are independent).

Sequential model-based optimization (SMBO, aka Bayesian optimization) can use *random forests* (of regression trees) instead of GPs.

Depending on the problem, you may want to transform the objective function (e.g., replacing the algorithm running time with its logarithm).

Instead of estimating the performance of an algorithm as a sample mean

$$\frac{\text{Mean Performance}(i, \theta)}{i \in \text{Instances}}$$

on a small set of instances, one can learn the mapping (instance, θ) \mapsto performance, using instance features, and use it to estimate $E[\text{Performance}(\cdot, \theta)]$. (You also need a distribution on instance features. SATzilla uses a similar idea to choose the most promising algorithm (DPPL, LP, etc.) for a given instance.)

To maximize the expected improvement (EI), and produce a diverse set of configurations with high EI, use multi-start local search.

**Preliminary evaluation
of hyperopt algorithms on HPOLib**
J. Bergstra et al. (2014)

Testing the hyperopt algorithms on the HPOLib benchmarking suite suggests that vanilla Gaussian processes (with RBF, rather than Matérn kernels) are good enough.

Making a science of model search
J. Bergstra et al. (2013)

TPE is slightly better than random search.

**Time-bounded
sequential parameter optimization**
F. Hutter et al. (2010)

A few improvements on SPO:

- Instead of fitting a *noise-free* Gaussian process to smoothed data (if there are several, contradictory measurements for the same parameter values, you need to somehow reconcile/smooth them), include noise in the model;
- (When minimizing running time) stop the computations early if they take too long: a *censored* running time is still informative;
- Use an approximate Gaussian process, the *projected process* (PP) approximation: instead of considering (inverting) the whole $n \times n$ kernel matrix, select (without replacement) p instances and make do with the $n \times p$ and $p \times p$ submatrices.

**SMAC:
sequential model-based algorithm configuration**

Random-forest-based Bayesian optimization, in Java.

**BayesOpt: a Bayesian optimization library
for nonlinear optimization,
experimental design and bandits**
R. Martinez-Cantin (2014)

Gaussian process Bayesian optimization, in C++.

**Efficient benchmarking
of hyperparameter optimizers via surrogates**
K. Eggenberger et al. (2015)

Comparison of three Bayesian optimization methods:

- Gaussian processes (GP, as implemented in Spearmint);
- Random forests (RF, as implemented in SMAC);
- Tree-structured Parzen density estimators (TPE, as implemented in hyperopt)

on realistic benchmarks, surrogates of real-world problems (real-world problems usually require time, software licenses, and/or specialized hardware, and are therefore hard to reproduce). On low-dimensional continuous problems, GP perform best; on more general problems, RF and TPE perform best.

Optimization: algorithms and applications
R.K. Arora (2015)

Relatively exhaustive list of all optimization-related topics, not too deep, but with examples, exercises and Matlab (?) code.

Tree-structured Gaussian process approximation
T. Bui and R. Turner

Gaussian process estimation can be sped up using a (smaller) pseudo-dataset of (noiseless) pseudo-observations; they can be arranged in a tree (à la Barnes-Hut) and used as a graphical model.

F-Race and iterated F-Race: an overview
M. Birattari et al. (2009)

To minimize an expensive function, e.g., some expected cost, estimated by Monte Carlo simulations: take a set of candidates (e.g., a grid); evaluate them in parallel; regularly test if the (more and more precise) estimated values are significantly different (e.g., with a non-parametric ANOVA test); if so, discard the worst candidate; iterate until only one candidate remains.

This can be combined with CMA-ES: when the number of candidates has been sufficiently reduced, replace them with new, nearby candidates.

ParamILS: an automatic algorithm configuration framework
F. Hutter et al.

Iterated local search (ILS) builds a sequence of local minima: start with a point; use local search to find a nearly local minimum; add some noise to escape its basin of attraction; iterate, keeping the new minimum if it is better (other acceptance criteria are possible).

If the objective function is estimated from a Monte Carlo simulation, there is no need to always use the same number of iterations.

If the objective function is the running time of some algorithm, censored values (“more than x ”, i.e., we stopped after x seconds) are sometimes good enough.

GGA: a gender-based genetic algorithm for the automatic configuration of algorithms
K. Tierney

Gender-based genetic algorithms keep two subpopulations (genders), using different fitness functions. For instance, if the standard fitness is time-consuming to compute, one could use it for one gender and use the other as a “variety store”.

R in Finance 2016

The `ForecastCombinations` package provides various ways of combining predictions:

- Equal-weighted average;

- Precision-weighted average;
- Regression;
- Regression with L^1 loss;
- Constrained regression: $\sum \beta_i = 1$, $\beta_i \geq 0$;
- Average of the best 10% subset regressions;
- BIC-weighted average of all subset regressions.

Stan, a C++-like language to describe Bayesian models, in the spirit of BUGS, is not limited to hierarchical models, but can also be used to model time series: stochastic volatility, mixtures, hidden Markov models, hierarchical stochastic volatility.

Deep learning libraries are no longer limited to Python and Lua: MxNet (a C++ library) can be used from R.

There is now an R package for automatic differentiation (AD): `madness`.

Several talks dealt with portfolio optimization:

- Multi-objective portfolio construction, with NSGA2 (`mco::nsga2`; risk parity, `cccp::rp`, was also mentioned)
- The ROML package provides portfolio optimization functions, a bit like a limited version of disciplined convex optimization, with predefined functions for many objectives. [R finally has a package for disciplined convex optimization: `cvxr`.]
- Portfolio optimization with PortfolioAnalytics and random portfolios

Most talks were about finance:

- Do not use the ADF test to identify trading opportunities: it highlights mean reversion (Ornstein-Uhlenbeck process), while you want oscillations. Try a model of the form

$$x_{t+1} = \beta_0 + \beta_1 \times \text{level}_t + \beta_2 \times \text{slope}_t + \text{noise}_{t+1};$$

filter for $\beta_1 < 0$, $\beta_2 > 0$; keep the best fits. One could also try a Hilbert transform.

- SVM for stock selection (on the S&P100): comparison of 15 different kernels [one could also combine them – this is called multiple kernel learning (MKL)].
- One can measure the connectedness of the bank network by fitting a VAR model (use an adaptive lasso penalty to deal with the large number of banks, and an OHLC-based volatility estimator) and computing the H -step ahead contribution of bank i to bank j .
- Leveraged ETFs give less return than you may think:

$$f(x) = \log_{1p}(k \times \exp_{1p}(x)) \leq k \times x.$$

This becomes more visible when volatility is high, and with compounding:

$$\sum f(x_t) \leq k \sum x_t.$$

- Building an index from GoogleTrends and a list of search terms

A few talks covered data management issues, e.g., `h5`, to read and write hdf5 files (a portable file format to store arrays of numbers, data.frames, etc.), `feather` (to store columnar data and read it from R or Python)

or `ff` to manipulate datasets larger than memory. R can be used in other environments, such as Postgres or Hadoop.

A few talks focused on efficient or extensible computations.

- The **Arborist** package for random forests also provides quantile regression (i.e., the leaves do not only contain the mean, but quantiles) and monotonicity constraints (reject proposals that breach the constraints with probability p – not necessarily 1).
- The **roll** package provides more rolling functions (`mean`, `var`, `sd`, `cor`, `cov`, `lm`, `eigen`, `pcr`, `vif`); the computations use **Rcpp** and are parallelized.
- The **pirls** package re-implementats `glmnet`; it is slower but allows arbitrary link functions.

Many talks showcased Shiny, interactive (Javascript) plots and the use of R to teach finance or options.

There were a few talks about options and stochastic processes:

- The illiquidity of a market can be estimated by comparing the price of an ETF and the NAV of the underlying portfolio; this can be interpreted as a bid-ask spread by noticing that bid and ask prices are American option prices.
- Computation of the returns of the dual moving average (MACD) strategy, under a Brownian motion assumption
- Convertible bonds, divergence swaps, stochastic local volatility model, etc.

A few talks were only remotely related to finance. For instance, the *rearrangement problem* is the problem of finding the intra-column rearrangement of a matrix that minimizes row sum variability (variance, maximum, minus minimum). Here are a few heuristics:

- Pick a column at random and re-order it so that it be in the order opposite to the sum of the columns;
- Idem with a subset of columns versus the others;
- This subset of columns can be chosen so that its sum has as similar a variance as the other columns.

Why should I trust you?

Explaining the predictions of any classifier

M.T. Ribeiro et al. (2015)

To interpret the forecasts of a complex (black box) model, approximate it, locally (as in local regression) with simpler models: sparse linear model (e.g., for a small number of binary features), decision trees, falling rule lists, etc. The explanation is *local*: each observation gets a different explanation. To explain the whole model, provide a diverse, representative set of observations and explanations; it is a (weighted) *set cover problem*: given an instance \times feature binary (or weight) matrix, select a small number of rows that cover as many columns as possible (a greedy algorithm is good enough).

Falling rule lists

F. Wang and C. Rudin (2014)

A *falling rule list* is a set of rules of the form “if patient satisfies condition 1, then risk = $x\%$ else...”, where the risk is decreasing. From a set of candidate conditions B (frequent item set mining: FP-growth, Eclat, Apriori), one can build a Bayesian model (greedily selected decision rules do not perform well).

B : set of candidate rules

λ : expected number of rules

w_j : prior probability of $j \in B$

$\Gamma(\alpha_j, \beta_j)$: prior for the risk of rule j

$\Gamma(\alpha_\infty, \beta_\infty)$: prior for the risk of the default rule

$L \sim \text{Pois}(\lambda)$ number of rules

$c_1 \dots, c_L$: drawn from B , without replacement, with probabilities proportional to w_j

$\gamma_j \sim \Gamma(\alpha_j, \beta_j) \mathbf{1}_{\geq 1}$

$\gamma_\infty \sim \Gamma(\alpha_\infty, \beta_\infty)$

$\text{risk}_j = \sum_{i \geq j} \log \gamma_i$

Interpretable classifiers using rules and Bayesian analysis: building a better stroke prediction model

B. Letham et al. (2015)

Bayesian rule lists generalize falling rule lists to multinomial outcomes.

Scalable Bayesian rule lists

H. Yang et al. (2016)

The alternating decision tree learning algorithm

Y. Freund and L. Mason (1999)

An **alternating decision tree** alternates between prediction nodes and splitting nodes; the value of a leaf is the sum of the predictions on its path; the value of a sample is the sum of the values of the paths leading to it.

They can be learnt by boosting; their performance is similar to boosted decision trees (C5.0), but they are easier to interpret.

**Optimizing the induction
of alternating decision trees**
B. Pfahringer et al.

Alternating decision trees are not scalable: heuristics are needed.

Ensemble samples with affine invariance
J. Goodman and J. Weare (2010)

The affine-invariant Nelder-Mead optimization algorithm motivates an affine-invariant *ensemble* of MCMC samplers, using a “stretch move” (adjust the acceptance probability accordingly)

$$x_k^{\text{candidate}} = x_j + Z(x_k - x_j), \quad j \neq k \text{ random}$$

$$Z \sim p, \quad p(z) \propto \frac{1}{\sqrt{z}} \mathbf{1}_{[1/a, a]}, \quad a = 2$$

Similarly, CMAES suggests a “walk move”,

$$x_k^{\text{candidate}} \sim N(\mu_S, \Sigma_S)$$

where S is a random subset of particles, $|S| \geq 2$, $k \notin S$, and μ_S and Σ_S are their mean and variance.

This is implemented in the `emcee` Python package.

Integration in finite terms
M. Rosenlicht (1972)

Elementary proof of Liouville’s 1834 theorem, which gives a criterion for an indefinite integral to be expressible in closed form. For instance, $\int e^{-x^2} dx$ has no closed form

An invitation to integration in finite terms
E.A. Marchisotto et G.A. Zakeri (1994)

More elementary presentation of Liouville’s theorem.

**Smooth numbers:
computational number theory and beyond**
A. Granville (2008)

Smooth numbers are numbers whose prime factors are small. A number is *y-smooth* if its prime factors are at most y . Let $\psi(x, y)$ be the number of y -smooth integers up to x . Then

$$\frac{\psi(x, x^{1/u})}{x} \xrightarrow{x \rightarrow \infty} \rho(u) > 0$$

where

$$\begin{aligned} \rho(u) &= 1 & u &\in [0, 1] \\ \rho(u) &= 1 - \log u & 1 &\leq u \leq 2 \\ \rho(u) &= \frac{1}{u} \int_{u-1}^u \rho(t) dt & u &> 1. \end{aligned}$$

They play a role in cryptography and computational number theory.

**Generalizing dynamic time warping
to the multidimensional case
requires an adaptive approach**
M. Shokoohi-Yekta et al.

Dependent and independent multidimensional time warp (DTW) give different results. Which is best may be problem-, class- or exemplar-specific, and can be learned.

**Clustering time series
using unsupervised shapelets**
J. Zakaria et al.

(After normalizing the time series) apply clustering algorithms to the matrix of distances between the time series and “shapelets” (shorter time series); a small number of discriminative shapelets suffices.

Foster-Hart optimal portfolios
A. Anand et al.

For a bounded random variable X such that $E[X] > 0$ and $P[X < 0] > 0$, the Foster-Hart risk is the positive number r such that $E \log(1 + X/r) = 0$. It is not coherent, not convex, not time-consistent, not guaranteed to exist.

**Option-implied equity premium predictions
via entropic tilting**
K. Metaxoglou et al. (2016)

Entropy tilting transforms a probability distribution π to change some of its moments g .

$$\begin{aligned} \text{Find} & \quad \pi^* \\ \text{To minimize} & \quad \text{KL}(\pi^* || \pi) = \int \pi^* \log \frac{\pi^*}{\pi} \\ \text{Such that} & \quad \int g(x) \pi^*(x) dx = \bar{g} \end{aligned}$$

Using semantic fingerprinting in finance
F. Ibriyamova et al.

Rather than cosine similarity between bags of words, use vector embeddings (here, Numenta’s “semantic fingerprint”) to identify similar companies.

Pure quintile portfolios
D. Liu

Let r be the vector of stock returns (at a given date), X the matrix of (normalized) factor exposures (stock \times factor); the *factor returns* are $(X'X)^{-1}X'r$; the *factor mimicking portfolios* are the rows of $(X'X)^{-1}X'$. The *factor quintile portfolios* are the minimum variance portfolios subject to the constraints

- (i) $n/5$ stocks, long-only;
- (ii) The exposure to the factor of interest is the same as that of the quintile portfolio;
- (iii) The exposure to the other factors is zero.

***Modeling and forecasting
(un)reliable realized covariances
for more reliable financial decisions***
T. Bollerslev et al. (2016)

The realized covariance is the sum of a (time-dependent but persistent) unobserved variance, and a noise term (market microstructure, Epps effect, non-synchronous observations). Estimating the distribution of this noise term leads to a better (exponentially-weighted) covariance estimator.

***Equivalence
of robust VaR and CVaR optimization***
S. Lotfi and S.A. Zenios (2016)

Robust optimization

$$\underset{\alpha}{\text{Minimize}} \underset{\beta \in B}{\text{Max Loss}}(\alpha, \beta)$$

optimizes the worst case situation, when the values of some parameters are constrained to remain in some box or ellipsoid. Robust CVaR and robust VaR optimization turn out to be equivalent.

An introduction to ROC analysis
T. Fawcett (2005)

Precision-recall curves are affected by class skew; ROC curves are not.

Given a set of classifiers, look at the convex hull of their ROC curves; given two classifiers A and B , the random mixtures $pA + (1-p)B$ form the $[AB]$ segment.

The AUC can be interpreted as the probability, given two observations from the two classes, of correctly distinguishing them.

To estimate the “precision” of a ROC curve, use bootstrapped curves and look at the variation of TP given FP, or (FP, TP) given the score.

For multiclass problems, use $\sum p(c_i) \text{AUC}(c_i)$ or

$$\frac{2}{|C|(|C| - 1)} \sum_{i < j} \text{AUC}(c_i, c_j)$$

***Non-linear dimensionality reduction:
Riemannian metric estimation
and the problem of geometric recovery***
D. Perrault-Joncas and M. Meilă

By inverting the Laplace-Beltrami operator, one can add a Riemannian metric to manifold algorithms, showing how distances, angles and areas are distorted. [One could also try to minimize those distortions.]

***Bayesian model choice and information
criteria in sparse generalized linear models***
R. Foygel and M. Drton

The **extended BIC** uses a prior favouring sparser models.

$$P(J) \propto \binom{p}{|J|}^{-\gamma} |J| \leq q \quad J \subset \llbracket 1, p \rrbracket$$

$$\text{BIC}_\gamma(J) = -2 \log \text{lik}(\hat{\theta}_J) + |J| \log n + 2\gamma |J| \log p$$

***Extended Bayesian information criteria
for model selection with large model spaces***
J. Chen and Z. Chen

Original paper on the eBIC.

***A new method for constructing
networks from binary data***
C.D. van Borkulo et al. (2014)

The structure of a Gaussian Markov random field (MRF, *i.e.*, an undirected graphical model) can be estimated by a graphical lasso (estimate the inverse of the covariance matrix, whose nonzero entries correspond to conditional independencies) and approximated by lasso regressions, one for each variable. This approximation can be generalized to binary MRF (Ising model) and lasso logistic regressions.

***High-dimensional graphical model selection
using ℓ_1 -regularized logistic regression***
M.J. Wainwright et al.

***Confidence bounds of recurrence-based
complexity measures***
S. Schinkel et al. (2009)

Recurrence plots highlight periodic or chaotic behaviour in time series.

$$R_{ij} = \begin{cases} 1 & \text{if } \|x_i - x_j\| \leq \varepsilon \\ 0 & \text{otherwise} \end{cases}$$

Recurrence quantification analysis (RQA) turns those plots into numbers (features):

- Proportion of dark points (recurrence rate);
- Proportion of points in diagonal segments of length at least ℓ_{\min} (determinism);
- Length of the longest diagonal segment;
- Average length of the diagonal segments;
- Similar quantities for vertical segments (laminarity, trapping time).

To compute confidence intervals on those quantities, resample, with replacement, the diagonal (resp. vertical) segments (including those of length one).

***The PP-TSVD algorithm
for image restoration problems***
P.C. Hansen et al.

Besides the penalized

$$\begin{array}{ll} \text{Find} & z \\ \text{To minimize} & \|Az - b\|_2^2 + \lambda \|z\|_2 \end{array}$$

and constrained problems

$$\begin{array}{ll}\text{Find} & z \\ \text{To minimize} & \|Az - b\|_2^2 \\ \text{Such that} & \|z\|_2 \leq c\end{array}$$

one can consider the truncated one

$$\begin{array}{ll}\text{Find} & z \\ \text{To minimize} & \|z\|_2 \\ \text{Such that} & \|Az - b\|_2^2 \leq c.\end{array}$$

As usual, one can replace $\|z\|_2$ with $\|z\|_1$, $\|\nabla^2 z\|_2$, $\|\nabla z\|_2$, $\|\nabla z\|_1$, etc.

***The evolution of popular music:
USA 1960-2010***
M. Mauch et al. (2015)

To study a musical corpus:

- Extract timbre features (12 Mel-frequency cepstral coefficients (MFCC), $\Delta\text{MFCC} = \text{MFCC}_0(t) - \text{MFCC}_0(t-1)$, zero-crossing count) using some Vamp plugin; extract the 12 chroma features from NNLS Chroma, for each frame;
- Apply random sampling (20 frames), PCA, model-based clustering (Gaussian mixture, 35 clusters) to build the timbre lexicon;
- Use the common chord transitions as a harmony lexicon;
- Extract topics with latent Dirichlet allocation (LDA, with the `topicmodels` package).

***An end-to-end neural network
for polyphonic music transcription***
S. Sigtia et al.

Automatic music transcription (AMT) can benefit from the same tools as speech recognition: language models, hidden Markov models, recurrent neural nets, convolutional nets.

Exploiting spillovers to forecast crashes
F. Gresnigt et al. (2015)

Add cross-excitations to Hawkes processes, to model contagion.

fastFM: a library for factorization machines
I. Bayer

Factorization machines

$$y = \alpha + \sum \beta_i x_i + \sum_{i < j} \langle \gamma_i, \gamma_j \rangle x_i x_j$$

are not limited to recommendation systems.

Implementations include `fastFM`, `libFM`, `libffm`, `GraphLab`.

A neural algorithm of artistic style
L.A. Gatys et al.

Compute the correlations between different features in different layers of the CNN and try to match them to those of a “target style” image.

***Compressing neural networks
with the hashing trick***
W. Chen et al.

Use Vowpal Wabbit’s hashing trick for weight sharing in (large) neural nets.

Generalized communities in networks
M.E.J. Newman and T.P. Peixoto

In the stochastic block model, each node belongs to a community, and the link probability only depends on the endpoints’ communities. It can be generalized: each node is assigned a random number, and the link probability only depends on those numbers.

$$\begin{aligned}x_u &\sim U(0, 1) \\ p_{uv} &= \omega(x_u, x_v)\end{aligned}$$

To account for non-Poisson degree distributions, consider instead

$$p_{uv} = \frac{d_u d_v}{2 \times \# \text{edges}} \omega(x_u, x_v).$$

The model can be efficiently estimated (EM with belief propagation, expansion of ω in the basis of Bernstein polynomials – they are nonnegative over $[0, 1]$) and uncovers both community structures and spatial structures.

***Gradient-free Hamiltonian Monte Carlo
with efficient kernel exponential families***
H. Strathmann et al.

Metropolis-Hastings MCMC samples from a probability distribution π , known only up to a multiplicative factor.

$$\begin{aligned}x^* &\sim Q(\cdot|x_t) \text{ proposal distribution} \\ x_{t+1} &\leftarrow x^* \text{ with probability } \min \left\{ 1, \frac{\pi(x^*)}{\pi(x_t)} \frac{Q(x_t|x^*)}{Q(x^*|x_t)} \right\} \\ x_{t+1} &\leftarrow x_t \text{ otherwise}\end{aligned}$$

The proposal distribution is usually Gaussian, with covariance

$$\Sigma_t \propto I = E[(\nabla \log \pi)^2] = -E[\nabla^2 \log \pi].$$

If $\nabla \log \pi$ is intractable, the information matrix can be estimated from the history of the Markov chain, with a kernel embedding if there are nonlinear effects (kernel adaptive MH, KAMH). These ideas can be generalized to Hamiltonian Monte Carlo (HMC).

***A Riemannian framework
for tensor computing***
X. Pennec et al. (2005)

Many algorithms from statistics or numerical analysis can be generalized to the manifold of positive definite matrices S_+ (“tensors”), endowed with the Riemannian structure (Fisher information metric) induced by $\exp : \text{Sym} = T_{\text{Id}} S_+ \rightarrow S_+$, invariant by

$$\begin{cases} \text{GL} \times S_+ \longrightarrow S_+ \\ (X, A) \longmapsto XAX'. \end{cases}$$

For instance:

- Mean: $\sum_i \log_{\bar{x}} x_i = 0$;
- Gradient descent: $x_{t+1} \leftarrow \exp_{x_t}[-\varepsilon \nabla C(x_t)]$;
- Linear interpolation (geodesic):

$$x(t) = \exp_{x_1}[t \overrightarrow{x_1 x_2}] = \exp_{x_1}[t \log_{x_1} x_2]$$

where

$$\begin{aligned} \exp_x(y) &= x^{1/2} \exp(x^{-1/2} y x^{-1/2}) x^{1/2} \\ \log_x(y) &= x^{1/2} \log(x^{-1/2} y x^{-1/2}) x^{1/2}. \end{aligned}$$

***Laplace-Beltrami eigenvalues
and topological features of eigenfunctions
for statistical shape analysis***
M. Reuter et al. (2009)

Use the spectrum (“shape DNA”) of the Laplace operator, and its eigenfunctions (level sets, critical points) as features for shape classification or comparison.

***Geometric understanding of point clouds
using Laplace-Beltrami operator***
J. Liang et al.

The Laplace operator can be approximated, from a cloud of points, using local least squares.

***On the origin of burstiness in human
behavior: the Wikipedia edits case***
Y. Gandica et al. (2016)

For inter-event times, compute the burstiness

$$B = \frac{\sigma - \mu}{\sigma + \mu} \in [-1, 1]$$

(periodic if $\sigma \ll \mu$, bursty if $\sigma \gg \mu$) and the autocorrelation.

What is a paraproduit?
A. Bényi et al. (2010)

A generalization of the operator

$$\Pi_0(f, g)(s) = \int_{-\infty}^s f' g.$$

***Surprising patterns for the call duration
distribution of mobile phone users***
P.O.S. Vaz de Melo et al.

The call duration distribution has heavier tail and head than the log-normal, but can be modeled as a log-logistic,

$$P[X \leq x] = \frac{1}{1 + e^{-z}}, \quad z = \frac{\log x - \mu}{\sigma}.$$

***Fast moment-based estimation
for hierarchical models***
P.O. Perry (2014)

Moment methods can fit large hierarchical models (e.g., a recommender system with 5 predictors, 1000 groups, 100,000 observations).

***Differential geometric least angle regression:
a differential geometric approach
to sparse generalized linear models***
L. Augugliaro and A.M. Mineo (2010)

The GLM L^1 regularization path is not piecewise linear but, on the statistical manifold of an exponential family, the least angle regression algorithm (keep the angle between the “score” of the active variables and the residual tangent vector constant) yields a sparse regularization path. This is implemented in the `dglars` package.

***Convolutional neural networks
for visual recognition***
A. Karpathy and J. Johnson (2016)

Simple classifiers such as k -NN, softmax (multinomial logistic) or multiclass SVM (all with regularization) do not perform well on image classification tasks (MNIST, Cifar-10, ImageNet), though image features (colour histogram, bag of visual words, HOG, SIFT, GIST, LBP, Texton, SSIM, etc.) help: prefer deep convolutional nets, with ReLU units.

To address the vanishing/exploding gradient problem, initialize the weights so that the activations be approximately standard Gaussian: for instance, Xavier initialization suggests `rand()/sqrt(fan-in)`, for linear (or tanh) units and `rand()/sqrt(fan-in/2)` for ReLU. Alternatively, insert *batch normalization layers* to rescale the activations – it is a differentiable operation, therefore amenable to back-propagation. The rescaling is mini-batch-specific: the jittering effect is similar to that of dropout. To use the network, after training, use the (fixed) μ and σ from the whole training set.

To debug your network:

- The initial loss should be $\log(\# \text{classes})$ without regularization, more with
- The unregularized network can overfit a small dataset
- Plot loss and test accuracy versus epoch and weight update; $|\text{weight update}|/\text{weight magnitude}$ should be around 10^{-3}

- Use random hyperparameter search; worry if the best ones are on the boundary.

Among the many optimization algorithms,

- Stochastic gradient descent is slow

$$x += -\alpha dx$$

- Momentum tends to overshoot

$$v = \mu v - \alpha dx$$

$$x += v$$

- Nesterov momentum (aka Nesterov accelerated gradient, NAG) evaluates the gradient after the momentum step
- With Adagrad, the step sizes tend to zero too fast

$$N += (dx)^2$$

$$x += -\alpha dx / \sqrt{N}$$

- RMSprop is similar to Adagrad, but uses an exponential moving average of the second moment instead of a sum;

prefer Adam, which combines momentum and RMSprop, *i.e.*, the first and second moments of the gradients.

Ensembling helps: even if you have a single model, you can simply average some of its snapshots, taken during training, or take an exponential moving average of its weights over training.

Dropout suggests to drop half the neurons at random, at train time, and shrink the activations at test time. Instead, one could drop connections (DropConnect).

Zero-padding is necessary, otherwise the image shrinks at each step, which forbids deep nets. The 1×1 filters make sense – they are actually $1 \times 1 \times \text{depth}$.

Pooling layers are often inserted after some of the convolutional layers: they downsample the image, usually with max pooling (average does not work as well).

Conv nets usually end with a fully connected layer, *e.g.*, a softmax.

Historical convnets include LeNet, AlexNet, ZFNet, VGGNet and, more recently, GoogLeNet (no FC layers), ResNet (152 layers, with skip-layer connections) – pretrained models are available in the Caffe model zoo.

Pre-trained convnets can tackle many computer vision tasks by replacing the “classification head” with another one: localization, detection, etc.

To understand what a convnet does:

- Pick a neuron, see what images excite it;
- Only the first-layer weights are interpretable: they are always Gabor-like features;
- The output of the FC7 layer (last before the classifier) gives a “code” for the image: visualize the cloud of images with t-SNE.

- Occlude a part of the image and check how the probability changes, as a function of the region occluded, to see where the object is;
- Deconv computes the gradient of a specific neuron wrt all the pixels to see what it sees; in guided backprop: ReLU units let the gradient pass if gradient, or both input and gradient are positive (instead of input only) – this gives nicer interpretations of the neurons;
- Choose a neuron and build an image that maximizes its output; regularize with an L^2 penalty or blur the image after each step to avoid accumulation of high-frequency features.

Deep dream starts with an image and tries to amplify the features in a given layer (forward pass until the target layer, set the gradient to the activations, backprop the gradient back to the image, update the image, iterate). *NeuralStyle* (deep art) looks for an image close to the contents of one image (measured by the activations of a layer) and the style of another (measured by the Gram (covariance) matrix of one or several layers).

With *recurrent networks*, do not backprop through the whole sequence, but only 25 characters at a time; to avoid exploding gradients, cut them off. The LSTM or GRU (a slight simplification) equations look complicated: changing them at random does not affect performance

CNNs do not necessarily need a lot of data: take a pre-trained net and freeze all but the last few layers – it becomes a feature extractor and you can forget that the features come from a neural net.

To reduce the number of parameters and increase expressivity,

- Replace large convolutions (5×5 , 7×7) with stacks of 3×3 convolutions;
- Apply a 1×1 convolution to halve the number of filters, then a 3×3 convolution, then a 1×1 to restore the number of filters (bottleneck convolution);
- Replace a 3×3 convolution with a 1×3 followed by a 3×1 .

To increase the training set (data augmentation), use horizontal flips, crops (train the network on crops; use crops at test time and average several crops), or ajitter the colour.

Convolutions can be expressed as matrix multiplications and sped up by linear algebra libraries (to the price of some data duplication); FFT only helps for large filters.

Double precision is not needed: single or half is enough.

Semantic segmentation is the task of labeling each pixel (“cow”, “tree”, “person”, etc.); instance segmentation also distinguishes different instances (first cow, second cow, etc.) Semantic segmentation networks usually end with an upsampling operation, which can be learnt (fractionally-strided convolution, often improperly called “deconvolution”).

For image segmentation, generate a set of proposals (regions of interest, ROI), and refine them (grey out pixels far away and predict which of the remaining pixels are in the region).

For video, detect feature points at different scales; track them using optical flow; extract features (HOG, HOF, MBH) in the corresponding stabilized coordinates. Spatio-temporal convnets use 3-dimensional convolutions, but single-frame CNNs (on just one frame – discard the others) perform well, and video does not add much.

Variational auto-encoders add a Bayesian flavour to auto-encoders: start with data, x ; the encoder generates μ_z, σ_z ; sample $z \sim N(\mu_z, \Sigma_z)$; the decoder generates μ_x, σ_x ; sample $x \sim N(\mu_x, \Sigma_x)$; the loss function combines the reconstruction loss on x and a penalty to ensure that $N(\mu_z, \Sigma_z)$ is close to the prior on z .

Generative adversarial networks train two networks together: the generator turns random noise into a candidate image; the discriminator is given an image and must tell whether it comes from the data or was generated. They work well on simple datasets (MNIST, faces); a multiscale variant also works on more complex ones (CIFAR).

Deep learning for natural language processing R. Socher (Stanford, 2016)

The current trend in natural language processing is to somehow replace words and phrases with vectors, and apply deep learning tools.

For instance, one could take the co-occurrence matrix (from Wikipedia or CommonCrawl), look at the previous and next k words ($k = 5$ to 10 – you can also give more weight to closer words), and reduce the dimension to 25 to 1000, e.g., with SVD. Polysemy, non-symmetry, common words and new words pose problems.

Instead, **Word2vec** tries to predict the previous and next k words

$$P(\text{output} \mid \text{input}) \propto \exp(u'_{\text{output}} v_{\text{input}}).$$

Each word is represented by two vectors, u_w and v_w (concatenate or average them if you want a single one), maximizing the likelihood of the observed data. One can add *negative sampling*: maximize

$$\sigma(u'v) - \sum_k \sigma(-u'_k v)$$

where the u_k are random words, sampled with probability $P(w) \propto U(w)^{3/4}$, where U is the unigram distribution.

The *continuous bag of word* (CBOW) model predicts the center word from the surrounding words.

GloVe uses the (sparse) co-occurrence matrix p and minimizes

$$\sum f(p_{ij})(u'_i v_j - \log p_{ij})^2,$$

where $f(x) = \text{Min}\{x, 100\}$ (to avoid giving too much weight to very common words).

One can predict the sentiment of a word using its context (the vector embedding of $w_{t-2}, w_{t-1}, w_t, w_{t+1}, w_{t+2}$), with a max-margin (hinge) loss, **bidirectional recurrent neural network** (RNN) with LSTM units, clipped gradients,

Use F_1 , the harmonic mean of precision and recall, if the classes are unbalanced.

Recursive neural networks provide embeddings for phrases: their input is the vector embedding of two words (or nodes) and the output is the vector embedding (same dimension) and the score if we merge the two nodes; it can be as simple as one tanh layer, or a different network for each tree depth or phrase type (NP, VP, etc.); it can parse sentences greedily. A PCFG can help reduce the number of candidate trees to examine.

ConvNets are similar to recursive neural nets, but merge all possible trees. Instead of using several layers, use only one, for 2-grams (and 3-gram, 4-grams 5-grams), and add a max-pooling layer, *i.e.*, take the maximum of those n -gram vectors.

DiceKriging, DiceOptim: two R packages for the analysis of computer experiments by Kriging-based metamodeling and optimization O. Roustant et al. (JSS, 2012)

Kriging is another name for Gaussian process modeling (the differences lie in the way the trend is modeled: constant, linear, more complex, known, to be estimated, to be integrated out) but it is often limited to 2 or 3 dimensions and Gaussian kernels, which is unsuitable to Bayesian optimization (“computer experiment” is just another name for blackbox (expensive) function).

DiceKriging::km fits a GP model, **DiceOptim::max_EI** returns the next candidate according to the expected improvement (EI) criterion. These functions can be used with **lhs::optimumLHS** for Latin square designs and **sensitivity::fast99** for **sensitivity analysis**.

Given random variables X_1, \dots, X_n , any (L^2) function $f: \mathbf{R}^n \rightarrow \mathbf{R}$ can be decomposed as

$$\begin{aligned} Y &= f(X_1, \dots, X_n) \\ &= \mu_0 + \sum_i \mu_i(X_i) + \sum_{i < j} \mu_{ij}(X_i, X_j) + \dots \\ &= \sum_{I \subset \llbracket 1, n \rrbracket} \mu_I(X_I) \end{aligned}$$

with $E[\mu_I(X_I) | X_J] = 0$ for $J \subsetneq I$, which gives a variance decomposition $\text{Var } Y = \sum_I \text{Var } \mu_I(X_I)$. The *Sobol indices* are $S_I = \text{Var } \mu_I(X_I) / \text{Var } Y$; S_i and $\sum_{I \ni i} S_I$ are of special interest.

Also check: **BACCO**, **mlegp**, **tgp**.

**Optimal combination forecasts
for hierarchical time series**
R.J. Hyndman et al. (2010)

For an additive hierarchy of time series

$$y_t = \sum_i y_{it}, \quad y_{it} = \sum_j y_{ijt}, \quad y_{ijt} = \sum_k y_{ijk t},$$

independent time series forecasts need not be consistent. They are traditionally reconciled, either in a top-down or a bottom-up fashion. Let Y_t be the vector of all the forecasts and Y_{tK} be that of the low-level ones: $Y_t = SY_{tK}$ (where S is a binary matrix). Existing reconciliation methods are of the form $\hat{Y} = SP\hat{Y}$. The minimum variance reconciled estimator solves the optimization problem

$$\begin{array}{ll} \text{Find} & P \\ \text{To minimize} & SP(\text{Var } \hat{Y})P'S' \\ \text{Such that} & SPS = S. \end{array}$$

Equivalently, one can consider the regression $\hat{Y} = S\beta + \varepsilon$, where β are the (unknown, consistent) low-level forecasts.

**The great time series bake off: an experimental
evaluation of recently proposed algorithms**
A. Bagnall et al.

Comparison of time series classification algorithms:

- 1-NN (nearest neighbour) DTW (dynamic time warp) and weighted variants of the DTW distance, e.g., replacing $(x_i - x_j)^2$ with $w(|i - j|)(x_i - x_j)^2$;
- 1-NN for distances using both the series and their first differences;
- Shapelets, *i.e.*, localized patterns (subsequences) used in a decision tree;
- Random-forest based on simple statistics (mean, standard deviation) on subintervals;
- Ensemble methods, in the time, power spectrum, autocorrelation, shapelet, etc. space.

Ensemble methods (and NN DTW) work best.

**Understanding predictive information criteria
for Bayesian models**
A. Gelman et al. (2013)

The AIC and its variants (deviance information criterion, Watanabe-Akaike information criterion) estimate the out-of-sample performance

$$\begin{aligned} \text{AIC} &= -2 \log P(\text{data} | \hat{\theta}_{\text{MLE}}) + 2k \\ \text{DIC} &= -2 \log P(\text{data} | \hat{\theta}_{\text{Bayes}}) + 2p_{\text{Bayes}} \\ \text{WAIC} &= 2 \log P_{\text{post}}(\text{data}) + 2p_{\text{WAIC}} \end{aligned}$$

where

$$\begin{aligned} \hat{\theta}_{\text{Bayes}} &= E_{\text{post}}[\theta] \\ p_{\text{Bayes}} &= 2(\log P(\text{data} | \hat{\theta}_{\text{Bayes}}) - E_{\text{post}}[P(\text{data})]) \\ \text{or } p_{\text{Bayes}} &= 2 \text{Var}_{\text{post}}[\log P(\text{data} | \theta)] \\ \log P_{\text{post}}(\text{data}) &= \sum_i E_{\text{post}}[p(y_i)] \\ p_{\text{WAIC}} &= 2 \sum_i \log E_{\text{post}} p(y_i) - E_{\text{post}} \log p(y_i) \\ \text{or } p_{\text{WAIC}} &= \sum_i \text{Var}_{\text{post}}[\log p(y_i)] \end{aligned}$$

and $E_{\text{post}}[\cdot] = E_{\text{post}}[\cdot | \theta]$, Var_{post} are computed via simulations. (The BIC, $-2 \log P(\text{data} | \hat{\theta}_{\text{MLE}}) + k \log n$, a more conservative measure, was designed to assess model quality, not forecast quality.)

The effective number of parameters in the DIC and the WAIC recognize that hierarchical models have fewer effective than actual parameters.

**Why ℓ^1 is a good approximation to ℓ^0 :
a geometric explanation**
C. Ramirez et al. (2012)

The ℓ^1 norm is the “best” convex relaxation of the ℓ^0 pseudo-norm (or, rather, ℓ^ε , with $\varepsilon > 0$ small): look at natural, exchangeable, archimedean partial orders on \mathbf{R}^n ; they are determined by $B_{\preceq} = \{x : x \preceq (1, 0, \dots, 0)\}$; notice that the ℓ^1 ball $\{\|x\|_1 \leq 1\}$ is the convex hull of the ℓ^0 ball $\{\|x\|_0 \leq 1\}$.

Local ordinal embedding
Y. Terada and U. von Luxburg (2014)

Local ordinal embedding (LOE) recovers the coordinates of a cloud of points from a set of constraints of the form $d_{ij} \leq d_{k\ell}$, $(i, j, k, \ell) \in \mathcal{A}$, by minimizing (by majorization)

$$\sum_{\mathcal{A}} (\delta + d_{ij} - d_{k\ell})_+^2.$$

Local information is sufficient to recover the data. Contrary to other embeddings (t-SNE, etc.), LOE also recovers the density of the data.

**Towards making high-dimensional distance
metric learning practical**
Q. Qian et al.

Distance metric learning (DML) looks for a metric for which points in the same class are close and points in different classes are far away. For high-dimensional problems, one often uses a low-rank parametrization $M = LL'$ or dimension reduction (PCA, random projection) preliminary step. One could look for a positive semi-definite matrix M satisfying (most of the) triplet constraints: for $x \sim y$ and $x \not\sim z$,

$$(x - y)'M(x - y) + 1 \leq (x - z)'M(x - z)$$

i.e., $d(x, y) + 1 \leq d(x, z)$. To find $M \in S_d$ that minimizes

$$\lambda \|M\|_F^2 + \frac{1}{N} \sum_{\substack{x, y, z \\ x \sim y \\ x \not\sim z}} \text{loss}(M, (x-z)(x-z)' - (x-y)(x-y)'),$$

solve the dual; to reduce the dimension, use a random projection (on the dual); to ensure positive semi-definiteness, project onto the positive semidefinite code only once, at the end.

**FaceNet: a unified embedding
for face recognition and clustering**
F. Schroff et al.

To recognize faces regardless of orientation and lighting, train your neural net to learn an embedding where $\|x_1 - x_2\|^2 + \alpha \leq \|x_1 - x_3\|^2$ for all triplets $x_1 \simeq x_2$, $x_1 \not\simeq x_3$; progressively increase the difficulty of the triplets by selecting those with the largest loss in the current minibatch [not unlike boosting].

**A critical review of recurrent neural networks
for sequence learning**
Z.C. Lipton (2015)

Current neural networks can be trained with:

- Newton: $h = -f''(x)^{-1} f'(x)$;
- Approximate Newton: approximate the Hessian, e.g., by assuming it is diagonal, or by updating it every k steps;
- Truncated Newton (Hessian-free): approximate the inverse $f''(x)^{-1}$, e.g. by running conjugate gradient a (very) small number of steps (this does not require the Hessian, just the map $h \mapsto f''(x) \cdot h$);
- Saddle-free: do not rescale the gradient by $1/\lambda_i$ but $1/|\lambda_i|$

and variants of stochastic gradient descent:

- Momentum: $\text{step}_t \propto \text{gradient} + \alpha \cdot \text{step}_{t-1}$
- Nesterov momentum: idem, but the gradient is taken “half a step” later, i.e., after the momentum step;
- Adagrad: $\text{step}_t \propto \frac{1}{\sqrt{\sum_{k \geq 0} \left| \frac{\partial \text{loss}_{t-k}}{\partial w} \right|^2}}$
- RMSProp: $\text{step}_t \propto \frac{1}{\sqrt{\sum \alpha^k \left| \frac{\partial \text{loss}_{t-k}}{\partial w} \right|^2}}$
- AdaDelta: $\text{step}_t \propto \frac{\sqrt{\sum \alpha^k \|\text{step}_{t-k}\|^2}}{\sqrt{\sum \alpha^k \left| \frac{\partial \text{loss}_{t-k}}{\partial w} \right|^2}}$
- Adam: RMSprop + momentum.

ReLU (restricted linear units) enforce sparsity in the hidden layers.

Recurrent structures are usually of the form:

Bidirectional RNN (BRNN) are of the form:

LSTM (long short term memory) units introduce two changes in the hidden layer, to allow for long memory and avoid vanishing or exploding gradients:

- Self-connected (recurrent) cell with weight 1 (“constant error carousel”);
- Multiplicative nodes, to set or delete the “memory” cell.

**Draw: a recurrent neural network
for image generation**
K. Gregor et al.

Recurrent autoencoders can progressively draw images.

Learning to transduce with unbounded memory
E. Grefenstette et al.

One can devise differentiable analogues of computer elements (e.g., memory cells: LSTM) and data structures (stack, deque, etc.). For instance, a *differentiable stack* is a stack of weighted elements, with weights in $(0, 1)$; the weights decrease when we pop an “element” (but nothing is actually removed); reading the “element on top” returns a weighted sum of the stack elements, with the weights summing to 1, and the higher elements hiding the lower ones as much as possible.

Highway networks
R.K. Srivastava et al.

Use LSTM-like units (gates) in non-recurrent networks to make them deeper but still trainable by SGD: replace $x_{i+1} = H(x_i, w_i)$ with $\lambda = T(x_i, w_i)$, $x_{n+1} = (1 - \lambda)x_i + \lambda H(x_i, w_i)$.

Extremely randomized trees
P. Geurts et al. (2006)

The splits in the trees in a random forest usually come from the data – they can actually be random. [The result can be seen as a smooth and robustified k -NN classifier.]

Deep neural decision forests
P. Kotschieder et al.

Decision trees (and therefore random forests) are amenable to backpropagation: replace the deterministic decision at each node with a stochastic one (a Bernoulli random variable) and define the output of the tree as the expected leaf value.

***Inverse graphics
with probabilistic CAD models***
T.D. Kulkarni et al.

Computer vision is the inverse of computer graphics. It can be approached as a Bayesian inference problem with, as prior, a (random) 3D scene, with lathed objects (using Gaussian processes for their shapes) and human shapes (deformed along their armature), affinely transformed.

Deep convolutional inverse graphics network
T.D. Kulkarni et al.

Computer vision can be seen as the inverse of computer graphics and tackled with an auto-encoder, de-rendering an image into a scene description, and then re-rendering it. The middle layer can be made interpretable by using mini-batches identical except for one aspect (lighting, pose, shape, etc.) and only updating the nodes we want to reflect that aspect.

***Path-SGD: path-normalized optimization
in deep neural networks***
B. Neyshabur et al.

Networks with ReLU units are scale-invariant: multiplying the weights of one layer by λ and dividing those of the next layer by λ leaves the output unchanged. Use scale-invariant optimization algorithms.

Weight uncertainty in neural networks
C. Blundell et al. (2015)

Bayesian neural networks (neural nets whose weights are not numbers but probability distributions) can be seen as a regularization scheme (like early stopping or dropout); in reinforcement learning, they also allow Thompson sampling. A diagonal Gaussian Bayesian neural net (this only doubles the number of parameters) can be trained by back-propagation.

***Evolving neural networks
through augmenting topologies***
K.O. Stanley and R. Miikkulainen (2002)

Genetic algorithms to choose the structure of a neural net.

***MADE:
masked autoencoder for distribution estimation***
M. germain et al. (2015)

An autoencoder can be made autoregressive, *i.e.*, one can ensure that there is no path between input i and output j if $i \geq j$, by using binary mask:

- Connect each hidden node to the first k input nodes, where k is sampled randomly;
- Connect the ℓ th output node to a hidden node if $\ell > k$.

This can be generalized to deeper networks.

***Topological methods
for the analysis of high dimensional data sets
and 3D object recognition***
G. Singh et al. (2007)

Start with a covering $X = \bigcup_{\alpha \in A} U_{\alpha}$; cluster the points in each component, $U_{\alpha} = \bigsqcup_{\beta \in B_{\alpha}} V_{\alpha\beta}$; consider the nerve of the resulting covering $\bar{X} = \bigcup V_{\alpha\beta}$; let the initial covering vary (e.g., balls of radius ε) to have a multiresolution approximation of the dataset.

***Megaman:
manifold learning with millions of points***
J. McQueen et al. (2016)

megaman is an alternative to Scikit-learn's **manifold** submodule, focusing on performance and scalability (sparse matrices, **pyamg**, FLANN, **arpack**, **LOBPCG**, etc.):

- Spectral embedding (Laplacian eigenmaps – fastest);
- Local tangent space adjustment (LTSA)
- Local linear embedding (LLE)
- Isomap
- Diffusion maps

The output also includes an estimate of the distortion.

All those algorithms approximate the manifold with a graph (k -nearest neighbours or, better, ε -radius graphs) and compute its adjacency and/or Laplacian matrix.

***Riemannian preconditioning
for tensor completion***
H. Kasai and B. Mishra

A Tucker decomposition of an order 3 tensor $X \in \mathbf{R}^{n_1 \times n_2 \times n_3}$ is $X = G \times_1 U_1 \times_2 U_2 \times_3 U_3$, where $G \in \mathbf{R}^{r_1 \times r_2 \times r_3}$ and $U_i \in \mathbf{R}^{n_i \times r_i}$ has orthogonal columns. The multilinear rank (r_1, r_2, r_3) of X is the rank of its unfolding matrices (consider X as a cube, cut it into 2-dimensional slices, stack them, and take the rank). Tucker decompositions form a (Stiefel) manifold \mathcal{M} , but they are usually only considered up to rotations: the *Tucker manifold* is $\mathcal{M}/O(r_1) \times O(r_2) \times O(r_3)$.

It can be endowed with a Riemannian metric induced by the Hessian of the loss function of the optimization problem considered, e.g., reconstruction from a small number of entries, under a rank constraint, minimizing the Frobenius norm of the entries available. This is computationally expensive: one can make do with an approximation of the Hessian, assuming that all the entries are available, and only keeping its diagonal blocks.

The usual Riemannian optimization framework then applies.

Fast and guaranteed tensor decomposition via sketching

Y. Wang et al. (2015)

Tensor operations can be sped up by replacing the tensor with a random projection.

Ensemble of exemplar-SVMs for object detection and beyond

T. Malisiewicz

Transfer metadata from the closest exemplar to the observation being classified.

Visualizing large scale and high-dimensional data

J. Tang et al. (2016)

LargeVis is inspired by t-SNE but scales better:

- Compute an approximate k -nearest neighbourhood graph (t-SNE uses an exact one) with a couple of *random projection trees* (pick two points, split the space along their perpendicular bisector hyperplane, iterate) and neighbour exploring (neighbours of neighbours are neighbour candidates) – k -D trees do not work well in high dimensions;
- Use the same weights $p_{j|i} \propto \exp(-\|x_i - x_j\|^2 / 2\sigma_i^2)$ as t-SNE and symmetrize,
- For up to 10^6 points, one can use graph layout algorithms: ForceAtlas2 and Openord are $O(n \log n)$;
- Consider a probabilistic model relating the distance between the points in the low-dimensional projection d_{ij} and the graph weights,

$$\log \text{lik} = \sum_{i-j \text{ edge}} w_{ij} \log f(d_{ij}) - \gamma \sum_{i-j \text{ not edge}} \log(1 - f(d_{ij}))$$

$$f(x) = \frac{1}{1+x^2} \text{ or } \frac{1}{1+e^x}$$

- Replace the $O(n^2)$ negative edges with a smaller number of random edges;
- Optimize with asynchronous stochastic gradient descent.

Unconstrained optimization of real functions in complex variables

L. Sorber et al. (2012)

Traditional optimization algorithms are not directly applicable to real-valued complex functions $\mathbf{C}^n \rightarrow \mathbf{R}$ because they are not (complex) differentiable. Instead of separating the real and complex parts, which would hide some of the structure of the problem, one can use *Wirtinger calculus*, i.e., the complex differentials

$$\frac{\partial}{\partial z} = \frac{\partial}{\partial x} - i \frac{\partial}{\partial y}, \quad \frac{\partial}{\partial \bar{z}} = \frac{\partial}{\partial x} + i \frac{\partial}{\partial y}.$$

Gradient- or Hessian-based algorithms (L-BFGS, CG, Gauss-Newton, Levenberg-Marquardt) then apply.

Recursive decomposition for nonconvex optimization

A.L. Friesen and P. Domingos

Fully decomposable functions, $f(x) = \sum g_i(x_i)$, are easy to minimize, but rare. A function is *globally decomposable* if it can be written $f(x) = g_1(x_0, x_1) + g_2(x_0, x_2)$, where $x = (x_0, x_1, x_2)$ is a partition of the coordinates. A function f is *locally decomposable* if that partition depends on x_0 . It is *approximately locally decomposable* if

$$\|x'_0 - x_0\| \leq \delta \Rightarrow \|f(x') - g_1(x'_0, x'_1) - g_2(x'_0, x'_2)\| \leq \varepsilon.$$

Examples include protein folding (pairwise interactions are negligible if the distance is sufficiently high) or structure from motion (inferring a 3D structure from a set of 2D images). Those problems can be solved by recursive partitioning.

Parallel algebraic modeling for stochastic optimization

J. Huchette et al.

The **StochJuMP** Julia package solves *2-stage stochastic optimization problems with recourse*; contrary to previous implementations, building the model is significantly faster than solving the problem.

Quick introduction to SAT/SMT solvers and symbolic execution

D. Yurichev (2016)

SAT solvers tackle (boolean) satisfiability problems expressed in conjunctive normal form, with ORs ($\bigwedge_i \bigvee_j x_{ij}$, minisat) or XORs ($\bigwedge_i \bigoplus_j x_{ij}$, cryptominisat – XORs are more common than ORs in cryptography).

SMT solvers tackle more general (constraint) satisfiability problems, involving finite sets, integers, reals, arrays, quantifiers. Examples include Z3 (Microsoft, non-free, usable from Python or via a standardized lisp-like language, SMT-LIB), STP, CVC4 (check the SMT competition for a more up-to-date list).

Klee is an LLVM-based symbolic virtual machine, designed to reason about actual programs, generate unit tests, prove code equivalence (e.g., coreutils vs busybox) or correctness, run code backwards – it can also be coaxed into solving more general satisfiability problems.

Klee: unassisted and automatic generation of high-coverage tests for complex systems

D. Dunbar et al.

Symbolic (LLVM) virtual machine, to automatically generate tests or identify bugs.

Faster cover trees

M. Izbicki and C.R. Shelton (2015)

A simplified cover tree (for nearest neighbour queries) is a tree, with one data point in each node, satisfying

$$\begin{aligned}\text{level}(\text{child}) &= \text{level}(\text{parent}) - 1 \\ d(\text{parent}, \text{child}) &\leq 2^{\text{level}(\text{parent})} \\ d(\text{child}, \text{child}_2) &> 2^{\text{level}(\text{child})}\end{aligned}$$

Bloofi: multidimensional Bloom filters

A. Crainiceanu and D. Lemire (2015)

The bitwise OR between Bloom filters (same length, same hash function) is still a Bloom filter. By arranging Bloom filters in a B-tree, one can efficiently find in which Bloom filters an element is.

ZeroDB white paper

M. Egorov and M. Wilkison (2016)

Encrypted databases expose their B-trees to their clients.

A review of homomorphic encryption and software tools for encrypted statistical machine learning **L.J.M. Aslett et al.**

Homomorphic encryption schemes allow some arithmetic operations on the ciphertext, usually additions and multiplications:

$$\text{dec}(\text{enc}(x) \boxplus \text{enc}(y)) = x + y.$$

They currently have the following limitations.

- They typically add noise to a deterministic function, but not too much, to allow for non-ambiguous decryption – but operations on the ciphertext increase that noise. It is possible to reset the level of noise during the computations, but this is complex and slow.
- They are not field morphisms $\mathbf{R} \rightarrow k$; in particular, they do not provide a division: if needed, numerator and denominator can be sent back to the client. Some operations become very expensive: for instance, matrix inversion can be done with cofactors.
- There are no equality or inequality tests: no conditional code flow is possible.
- The ciphertext can be large, – 10,000 times larger than the plaintext. It is possible to use a traditional encryption scheme for the data and homomorphically encrypt the key – but homomorphic AES decryption is very slow.
- Large integers or real numbers have to be encoded, e.g., with the Chinese remainder theorem, or as fractions.

In R, check the `HomomorphicEncryption` package; in C++, check the `HeLib` library.

Encrypted statistical machine learning: new privacy-preserving methods **L.J.M. Aslett (2015)**

The limitations of homomorphic encryption, in particular, the absence of division, exponential and comparisons, requires a redesign of most statistical procedures; the `EncryptedStats` package provides Naives Bayes and extreme random forests. Limited forms of comparison and division are actually available:

- By quantizing the values and replacing them with indicator variables, comparisons such as $x = y$ can be expressed as a scalar product $\sum x_k y_k = 1$; no branching is possible, but $\mathbf{t} ? \mathbf{a} : \mathbf{b}$ can be written $t\mathbf{a} + (1 - t)\mathbf{b}$;
- Approximate division can be performed using (encrypted) random number generation, relying on $X \sim \text{Geom}(p) \implies E[X] = 1/p$.

Smoothing spline ANOVA models: R package gss **C. Gu (JSS, 2014)**

Classical Anova $\mu_{ij} = \mu + \alpha_i + \alpha_j + \varepsilon_{ij}$ can be generalized to functions

$$\begin{aligned}f(x_1, x_2) &= (1 - A_1 + A_1)(1 - A_2 + A_2)f \\ &= A_1 A_2 f + (1 - A_1) A_2 f + (1 - A_2) A_1 f + \\ &\quad (1 - A_1)(1 - A_2)f \\ &= \phi_0 + \phi_1(x_1) + \phi_2(x_2) + \phi_{12}(x_1, x_2)\end{aligned}$$

where A_1 and A_2 are averaging operators, e.g., $(A_1 f)(x_2) = \int_a^b f(x_1, x_2) dx_1 / (b - a)$ and the problem is usually penalized, e.g.,

$$\begin{aligned}\text{Find } & \phi_0, \phi_1, \phi_2, \phi_{12} \\ \text{To minimize } & (\phi_0 - A_1 A_2 f)^2 + \\ & \int (\phi_1 - (1 - A_1) A_2 f)^2 + \\ & \int (\phi_2 - (1 - A_2) A_1 f)^2 + \\ & \iint (\phi_{12} - (1 - A_1)(1 - A_2)f)^2 + \\ & \lambda_1 \int |\phi_1''|^2 + \lambda_2 \int |\phi_2''|^2 + \lambda_{12} \iint \|\phi_{12}''\|^2.\end{aligned}$$

If there are no interactions, this is just a generalized additive model (GAM). The same framework also applies to log-density estimation (with less overfitting than density). In particular, check the `ssanova` and `ssden` functions.

<code>ssanova(y~x)</code>	# Smoothing
<code>ssanova(y~x1+x2)</code>	# GAM
<code>ssanova(y~x1*x2)</code>	# GAM with interactions
<code>ssden(~s)</code>	# Plot with <code>dssden()</code>

Hierarchical archimedean copulae: the HAC package

O. Okhrin and A. Ristig (JSS, 2014)

Archimedean copulas,

$$C_\phi(u_1, \dots, u_d) = \phi(\phi^{-1}(u_1) + \dots + \phi^{-1}(u_d))$$

are exchangeable. By introducing pseudo-variables $C(u_i, u_j)$, one can consider hierarchical archimedean copulas, e.g.,

$$C(u_1, u_2, u_3) \quad C(C(u_1, u_2), C(u_3, u_4)) \quad C(C(C(u_1, u_2), u_3), u_4)$$

The hierarchical structure can be inferred by finding the two closest variables, replacing them with $C(u_i, u_j)$, and iterating; consecutive nodes with a very similar generator ϕ can be collapsed. Check the `estimate.copula` and `[rpd]HAC` functions.

copulaedas: an R package for estimation of distribution algorithms based on copulas
Y. Gonzalez-Fernandez and M. Soto (2014)

EDA (estimation of distribution algorithms, CMA-ES) optimizes a black-box function as follows:

- Start with a random set of candidates
- Improve them by local search;
- Keep the best ones;
- Estimate their distribution;
- Sample more candidates from this distribution
- Iterate.

The distribution is often estimated as a Gaussian, but one can also use copula-based models: independence copula, Gaussian copula, hierarchical archimedean copula, regular vine, etc.

General purpose convolution algorithm in S4 classes by means of FFT
P. Ruckdeschel and M. Kohl (JSS, 2014)

The `distr` package provides operations (+, ×, etc.) on independent random variables, e.g.,

$$X \sim N(0, 3) \text{ and } Y \sim N(0, 4) \implies X + Y \sim N(0, 5)$$

by discretizing and convolving the distributions when no closed form is available.

mediation: R package for causal mediation analysis
D. Tingley et al. (JSS, 2014)

Given random variables T (treatment, binary), M (suspected mediator) and Y (outcome), one can measure how much of a role M plays in the causal process from T to Y

by modeling $M \sim T$ and $Y \sim T + M$ and considering

$$\begin{aligned} \text{Total treatment} \quad & \tau = Y(1, M(1)) + Y(0, M(0)) \\ \text{Causal mediation} \quad & \delta(t) = Y(t, M(1)) + Y(t, M(0)) \\ \text{Direct effect} \quad & \zeta(t) = Y(1, M(t)) + Y(0, M(t)), \end{aligned}$$

which gives decompositions

$$\tau = \delta(t) + \zeta(1 - t), \quad t \in \{0, 1\}.$$

hmm: an R package for hierarchical multinomial marginal models
R. Colombi et al. (JSS, 2014)

Marginal models model the joint distribution of qualitative variables as

$$P(X_1, \dots, X_n) = P(X_1)P(X_2|X_1)P(X_3|X_1, X_2) \cdots P(X_n|X_1, \dots, X_{n-1}),$$

with constraints on some of those factors to enforce conditional independencies (equalities) or stochastic dominance (inequalities) – not unlike graph-less graphical models.

structSSI: simultaneous and selective inference for grouped or hierarchically structured data
K. Sankaran and S. Holmes (JSS, 2014)

Given m p -values $p_1 \leq \dots \leq p_m$, multiple testing procedures usually look at the *family-wise error rate* (FWER), *i.e.*, try to ensure

$$P[\text{at least one false positive}] \leq \alpha$$

- Bonferroni: reject $H_0(k)$ if $p_k \leq \alpha/m$;
- Šidák: reject $H_0(k)$ if $p_k \leq 1 - (1 - \alpha)^{1/m}$;
- Holm–Bonferroni: reject $H_0(k)$ as long as $p_k \leq 1/(m + 1 - k)$;
- Holberg: reject $H_0(k)$ as long as there exists $\ell \geq k$ such that $p_\ell \leq 1/(m + 1 - \ell)$

or the *false discovery rate* (FDR), *i.e.*, try to ensure

$$E \left[\frac{\text{false positives}}{\text{positives}} \right] \leq \alpha$$

- Benjamin–Hochberg (BH): reject $H_0(k)$ as long as $p_k \leq k\alpha/m$;
- BHY: reject $H_0(k)$ as long as $p_k \leq k\alpha / \sum_{i=1}^m (1/i)$.

But they tend to be optimal for independent tests, overly conservative for positively dependent tests, and incorrect for negatively dependent tests – those that remain valid account for an arbitrary dependence structure, but that is too general an assumption.

Some extensions of those tests account for a hierarchical structure:

- Group BH (GBH) estimates the proportion of H_1 's in each group and reweighs the p -values accordingly;
- Hierarchical FDR (HFDR) accepts or rejects the null hypothesis at the group level, and only looks at individual tests in groups whose null hypothesis was rejected.

***LDavis: a method for visualizing
and interpreting topics***
C. Sievert and K.E. Shirley

To find the words most relevant to a given topic, one can rank them according to $P(\text{term}|\text{topic})$ (but this gives too much weight to common, non-discriminative words), or $P(\text{term}|\text{topic})/P(\text{term})$ (lift – but this gives too much weight to rare, non-discriminative words), or, better, a weighted average of their logarithms (“relevance”).

***fitdistrplus:
an R package for fitting distributions***
M.L. Delignette-Muller and C. Dutang (2015)

One can fit a distribution to data using: maximum likelihood (MLE), moment matching, quantile matching, maximum goodness of fit (gof); the gof can be assessed with the Kolmogorov-Smirnov, Cramer-von Mises or Anderson-Darling distance (AD is a variant of CvM with more weight on the tail – there are 1-sided variants, and variants with more weight).

***SDD:
an R package for serial dependence diagrams***
L. Bagnato et al. (JSS, 2015)

The autocorrelation function (ACF) relies on linear correlation. Instead, the *dependogram* uses the independence χ^2 (or its normalization, Cramer’s V) between X and X_{-k} , discretized into n quantile bins, or the Kullback-Leibler divergence between (kernel) density estimators of X , X_{-k} and (X, X_{-k}) .

***Fitting heavy tailed distributions:
the powerLaw package***
C.S. Gillespie (JSS, 2015)

To fit a power law distribution $p(x) \propto x^{-\alpha} \mathbf{1}_{x \geq x_{\min}}$ on the tail of the data, use the maximum likelihood estimator

$$\hat{\alpha} = 1 + n \left/ \sum_{x \geq x_{\min}} \log \frac{x}{x_{\min}} \right/;$$

choose the x_{\min} minimizing the Kolmogorov-Smirnov (KS) distance; bootstrap to estimate the uncertainty on x_{\min} ; to estimate the goodness of fit, look at the distribution of the KS statistic on data sampled from \hat{p} .

***abctools: an R package for tuning
approximate Bayesian computation analyses***
M.A. Nunes and D. Prangle

Approximate Bayesian computation (ABC) is a Bayesian method that uses simulations instead of likelihoods. Rejection ABC proceeds as follows:

- Draw a parameter θ from the prior;
- Simulate data $x \sim p(\cdot|\theta)$; compute statistics $s(x)$;
- If $d(s^{\text{obs}}, s) \leq \varepsilon$, accept θ ;
- Iterate until you have enough samples.

The *abctools* package complements the *abc* package and can help choose the statistics from a set of candidates, e.g., by approximate sufficiency (greedily add the statistics that produce the largest change in the posterior distribution; stop when it becomes insignificant) or by finding the subset minimizing some information criterion (there are also projection methods) and help choose ε .

***ngspatial: a package for fitting the centered
autologistic and sparse spatial generalized
linear mixed models for areal data***
J. Hughes

The autologistic model

$$\log \frac{P[z_i = 1]}{P[z_i = 0]} = x'_i \beta + \eta \sum_{j \in \text{Neigh}(i)} Z_j$$

is confounded; one can center the autocovariate with

$$\log \frac{P[z_i = 1]}{P[z_i = 0]} = x'_i \beta + \eta \sum_{j \in \text{Neigh}(i)} (Z_j - \mu_j)$$

$$\mu_j = (1 + e^{-x_j \beta})^{-1}.$$

***MVN: an R package
for assessing multivariate normality***
S. Korkmaz et al.

To check multivariate normality:

- Look at the 1-dimensional margins: histograms, qq-plots, normality tests;
- Plot the 2-dimensional densities (*persp*, *contour*);
- Plot the sample Mahalanobis distance versus χ^2 quantiles;
- Try multivariate normality tests: Mardia (based on skewness and kurtosis), Henze-Zirkler (combines $\sum e^{-\alpha D_{ij}}$ and $\sum e^{-\beta D_i}$, where $D_{ij} = d_{\text{Mahalanobis}}(x_i, x_j)$ and $D_i = d_{\text{Mahalanobis}}(x_i, \bar{x})$, Royston (Shapiro-Wilk);
- Remove outliers (robust Mahalanobis distance, from minimum covariance determinant estimators instead of sample covariances).

***paircompviz: and R package for visualization
of multiple pairwise comparison test results***
M. Burda

The result of multiple pairwise tests is often represented by a line diagram, or a letter diagram.

Instead, one can consider the relation $T_i \succ T_j$ if i is significantly different from j , hope it is a partial order (this happens surprisingly often) and draw its *Hasse diagram* (i.e., remove the edges that can be inferred

by connectivity) after compressing complete bipartite subgraphs

logcondens: computation related to univariate log-concave density estimation
L. Dümbgen and K. Rufibach

The log-concave density estimator is parameter-free, and log-concavity is a plausible assumption for many datasets: consider using its smoothed version (it is piecewise log-linear and has discontinuities at both ends of the support) instead of a kernel density estimator.

For a multivariate estimator, check LogConcDEAD.

Online graph pruning for pathfinding on grid maps
D. Harabor and A. Grastien

To account for symmetry and avoid examining nodes unnecessarily, path finding algorithms on grids try to recognize rectangular rooms, dead-ends, swamps, neighbours to prune and “jump points”.

Metabolic paths in world economy and crude oil price
F. Picciolo et al. (2015)

Measure paths in the world trade web (WTW) with:

- Trade imbalance $b = \frac{\sum_i \text{Min}(w_{\cdot i}, w_{i \cdot})}{\sum_{ij} w_{ij}}$
- Reciprocity $r = \frac{\sum_{ij} \text{Min}(w_{ij}, w_{ji})}{\sum_{ij} w_{ij}}$
- Cycling index

$$\Gamma^{(s)} = \frac{\sum s_i \Gamma_i^{(s)}}{\sum w_i}$$

$$\Gamma_i^{(s)} = \frac{u_{ii}^{(s)} - 1}{u_{ii}^{(s)}}$$

$$U^s = I + M + M^2 + \dots + M^s$$

$$m_{ij} \propto w_{ij} \text{ (stochastic matrix)}$$

where $\Gamma_i^{(s)}$ is the fraction of trade that goes back to i within s steps.

Look at the corresponding time series, the contribution of each country, the correlation with oil, etc.

Forecasting stock returns during good and bad times
D. Huang et al. (2012)

Log-prices can be modeled as the sum of a random walk (permanent shocks) and an AR(1) process (temporary

shocks)

$$\begin{pmatrix} p_t \\ q_t \\ z_t \end{pmatrix} = \begin{pmatrix} 0 \\ \mu \\ 0 \end{pmatrix} + \begin{pmatrix} 0 & 1 & 1 \\ 0 & 1 & 0 \\ 0 & 0 & \lambda \end{pmatrix} \begin{pmatrix} p_{t-1} \\ q_{t-1} \\ z_{t-1} \end{pmatrix} + \varepsilon$$

$$\text{Var } \varepsilon = \begin{pmatrix} 0 & 0 & 0 \\ 0 & \sigma_1^2 & \rho \sigma_1 \sigma_2 \\ 0 & \rho \sigma_1 \sigma_2 & \sigma_2^2 \end{pmatrix}$$

where the correlation ρ between the random walk and the AR(1) innovations is a market state indicator: $\rho \geq 0$ corresponds to good times, overconfidence, low risk premium, reversal, $\text{Cov}(r_{t+1}, r_t) < 0$. Empirically, use $\text{MRI} = (12\text{-month return} - \mu)/\sigma$, (where μ and σ are the long-term mean and standard deviation of the 12-month return) as momentum, and $\text{IMA} = \mathbf{1}_{\log\text{-price} > \text{MA}(\log\text{-price}, 200d)}$ or $\text{ISR} = \mathbf{1}_{\text{MA}(\text{Sharpe}, 6m) > 30\% \text{ long-term quantile}}$ as market state indicator.

Risk premia: asymmetric tail risks and excess returns
Y. Lempérière et al.

The *ranked PEL skewness* is the area under the curve of the cumulated standardized values, sorted by increasing absolute values (there are other low-moment estimators of skewness, e.g., the normalized mean-minus-median). The risk premium present in many markets seems to be due to skewness rather than volatility – investors do not fear small Gaussian fluctuations, but rather large tail events.

Forecasting the equity risk premium: the role of technical indicators
C.J. Neely et al. (2010)

To forecast index returns, use both macroeconomic variables (dividend yield, robust excess return volatility, term spread) and technical indicators (MACD, momentum, MACD of the signed volume).

Financial volatility and economic activity
F. Fornari and A. Mele (2010)

Volatility (robust MAD estimator, $\sqrt{\frac{\pi}{2}} \langle |\text{ret}_t| \rangle$) and term spread can predict industrial production growth.

Macroeconomic determinants of stock volatility and volatility premiums
V. Corradi et al. (2012)

Conversely, the business cycle can predict volatility.

Short interest and aggregate stock returns
D.E. Rapach (2014)

Aggregate short interest (as a proportion of shares outstanding, detrended) is informative.

The vector algebra war: a historical perspective J.M. Chappell

Different formulations can be used to compactly write Maxwell's field equations:

- Gibbs vectors, *i.e.*, vectors in \mathbf{R}^3 with dot and cross product $(\mathbf{R}, \cdot, \times)$;
- Quaternions \mathbf{H} , a 4-dimensional algebra with $i^2 = j^2 = k^2 = ijk = -1$;
- Clifford algebra, $\mathcal{Cl}(\mathbf{R}^3)$, an 8-dimensional algebra, with $e_i e_j = -e_j e_i$, $e_1^2 = e_2^2 = e_3^2 = +1$, with the natural embedding $e_i \mapsto e_i$ from \mathbf{R}^3 ; the dot and cross product can be recovered as $vw = v \cdot w + e_1 e_2 e_3 v \times w$.

With the Clifford (or geometric) algebra, Maxwell's equations become $\partial(E + jcB) = \rho/\varepsilon - \mu cJ$. [No mention of differential forms or screw calculus.]

Recent results on pattern maximum likelihood J. Acharya et al. (2009)

Given an iid sequence of symbols, e.g., HHTHTTH, where the list of possible symbols is not known, what can we say about the multiset of symbol probabilities? Standard maximum likelihood (estimate the probabilities of each symbol and forget the order) only works well for large samples. *Pattern maximum likelihood* (PML) replaces the symbols by numbers, starting with the most frequent, and reorders them, e.g., ababca \rightarrow 121231 \rightarrow 111223. A pattern probability p is a non-increasing sequence $p_1 \geq p_2 \geq \dots \geq 0$ with $\sum p_i \leq 1$; the remainder $1 - \sum p_i$ is the continuous part of p . The PML of a pattern ψ is

$$\text{PML}(\psi) = \underset{p}{\text{Argmax}} p(\psi).$$

Algebraic computation of pattern maximum likelihood J. Acharya et al. (2011)

The PML can be computed analytically with Gröbner bases. For instance, $\text{PML}(1112234) = (\frac{1}{5}, \frac{1}{5}, \frac{1}{5}, \frac{1}{5}, \frac{1}{5})$.

Analytic combinatorics P. Flajolet and R. Sedgewick (2009)

The traditional approach to combinatorics, to estimate the number a_n of a certain type of objects (e.g., graphs of size n with a certain property) is the following:

- Find a recurrence relation involving a_n (if you can solve it, you are done);
- Consider the generating function $f(x) = \sum a_n x^n$ or (if a grows too fast) $f(x) = \sum a_n x^n / n!$;
- Transform the recurrence relation for a into a functional (or differential) equation for f ;
- Solve the equation or, somehow, use it to infer the asymptotic behaviour of a .

Analytic combinatorics goes directly from the combinatorial description of the problem to the functional equation for the generating function, and uses com-

plex analysis to estimate the asymptotic behaviour of its coefficients.

1. A *combinatorial class* $(\mathcal{A}, |\cdot|)$ is a set \mathcal{A} with a size function $|\cdot| : \mathcal{A} \rightarrow \mathbf{N}$ such that, for all n , $a_n = \#\{x \in \mathcal{A} : |x| = n\}$ is finite. Its *ordinary generating function* is $A(z) = \sum a_n z^n \in \mathbf{R}[[z]]$. The coefficients are denoted $[z^n]A(z) = a_n$.

Simple operations on combinatorial classes translate to their generating functions as follows.

$\mathcal{A} \sqcup \mathcal{B}$	$C(z) = A(z) + B(z)$
$\mathcal{A} \times \mathcal{B}$	$C(z) = A(z)B(z)$
$\text{SEQ } \mathcal{B}$	$C(z) = 1/(1 - B(z))$
$\text{CYC } \mathcal{B}$	$C(z) = \sum_{k \geq 1} \frac{\phi(k)}{k} \log \frac{1}{1 - B(z^k)}$
$\text{MSET } \mathcal{B}$	$C(z) = \prod_{n \geq 1} (1 - z^n)^{-B_n}$
	$= \exp \left(\sum_{k \geq 1} \frac{1}{k} B(z^k) \right)$
$\text{PSET } \mathcal{B}$	$C(z) = \prod_{n \geq 1} (1 + z^n)^{B_n}$
	$= \exp \left(\sum_{k \geq 1} \frac{(-1)^{k-1}}{k} B(z^k) \right)$

The last three formulas are the Pólya logarithm, exponential, and modified exponential. The sequences $\text{SEQ } \mathcal{B} = \{\varepsilon\} \sqcup \mathcal{B} \times \mathcal{B} \times \mathcal{B} \times \dots = \coprod_{n \geq 0} \mathcal{B}^n$ are only defined if $b_0 = 0$; the cycles are $\text{CYC } \mathcal{B} = (\text{SEQ } \mathcal{B} \setminus \{\varepsilon\})/\mathfrak{S}$; the multisets are $\text{MSET } \mathcal{B} = (\text{SEQ } \mathcal{B})/\mathfrak{S}$.

Here are a few examples.

- E : single object of size 0;
- Z : single object of size 1;
- $I = \text{SEQ}_{\geq 1} Z$: non-zero integers;
- $\text{SEQ}(Z \sqcup Z \times Z)$: coverings of $\llbracket 0, n \rrbracket$ by intervals of length 1 or 2 (Fibonacci numbers);
- $T = E \sqcup T \times Z \times T$: triangulations (Catalan numbers);
- $G = Z \times \text{SEQ } G$: rooted plane trees – a tree is a root and a sequence of trees (shifted Catalan numbers shifted);
- $H = Z \times \text{MSET } H$: non-plane (rooted) trees;
- $C = \text{SEQ } I$: compositions (ways of writing an integer as a sum of integers);
- $P = (\text{SEQ } I)/\mathfrak{S} = \text{MSET } I$: partitions;
- $A = mZ$: m -letter alphabet;
- $W = \text{SEQ } A$: words.

The language recognized by a finite automaton has generating function $L(z) = \mathbf{u}'(I - zT)\mathbf{v}$, where T is the incidence matrix (it is not binary because there can be several edges, with different labels, between the same vertices), and \mathbf{u} and \mathbf{v} the indicator vectors of the initial and final states. Rational languages have a rational generating function; context-free languages have an algebraic generating function.

2. A *labelled combinatorial class* is a combinatorial class $(\mathcal{A}, |\cdot|)$ with an action of the symmetric group \mathfrak{S}_n on each $\mathcal{A}_n = \{x \in \mathcal{A} : |x| = n\}$. Informally, think of the elements of \mathcal{A} as graphs (perhaps with some added structure) whose vertex set is $[1, n]$ – the notion of *species of structure* makes this rigorous and unifies the labelled and unlabelled cases. Its *exponential generating function* is $A(z) = \sum a_n x^n / n!$. Operations on labelled combinatorial classes translate to their exponential generating functions.

$$\begin{array}{ll} \mathcal{A} \sqcup \mathcal{B} & C(z) = A(z) + B(z) \\ \mathcal{A} \star \mathcal{B} & C(z) = A(z)B(z) \\ \text{SEQ } \mathcal{B} & C(z) = 1/(1 - B(z)) \\ \text{SET } \mathcal{B} & C(z) = \exp B(z) \\ \text{CYC } \mathcal{B} & C(z) = \log \frac{1}{1 - B(z)} \end{array}$$

Given two labelled objects $\alpha \in \mathcal{A}$, $\beta \in \mathcal{B}$, one can build labelled objects (α', β') by relabelling α and β while keeping their order (there are many such relabelings). The set of all such labelled objects form the *labelled product* $\mathcal{A} \star \mathcal{B}$.

Examples include:

- $R = \text{SEQ SET}_{\geq 1} Z$: surjections;
- $S = \text{SET SEQ}_{\geq 1} Z$: partitions;
- $P = \text{SET CYC} Z$: permutations;
- $I = \text{SET CYC}_{1,2} Z$: permutations;
- $D = \text{SET CYC}_{>1} Z$: derangements;
- $T = Z \star \text{SET } T$, $T(z) = ze^{T(z)}$: a (non-plane) rooted tree is a root and a set of rooted trees;
- $T = U^\bullet$: a rooted tree is a pointed unrooted tree;
- $F = \text{SET CYC } T$, $F(z) = (1 - T(z))^{-1}$: the graph of an endomorphism is a set of cycles, with a tree attached to each element of those cycles.

3. This can be generalized to combinatorial classes with parameters $(\mathcal{A}, |\cdot|, \chi)$, $\chi : \mathcal{A} \rightarrow \mathbf{N}^d$, and multivariate generating functions, $A(z, \mathbf{u}) = \sum a_{n, \mathbf{k}} z^n \mathbf{u}^{\mathbf{k}}$, where $a_{n, \mathbf{k}} = \#\{a \in \mathcal{A} : |a| = n \text{ and } \chi(a) = \mathbf{k}\}$. This leads, for instance, to the expected number of cycles in a permutations of size n , $\mu_n = \sum_{k=1}^n 1/k \sim \log n$.

4. Complex analysis, starting with Cauchy's formula

$$[z^n]f(z) = \frac{1}{2\pi i} \oint_{\Gamma} \frac{f(z)dz}{z^{n+1}},$$

can help study the asymptotic behaviour of those power series.

If f is analytic at 0, with radius of convergence R , then $f_n = [z^n]f(z)$ is of exponential order R^{-n} , $f_n \asymp R^{-n}$, i.e., $\limsup |a_n|^{1/n} = 1/R$.

Saddlepoint bounds are often accurate:

$$[z^n]f(z) \leq \inf_{r \in (0, R)} r^{-n} \sup_{|z|=r} |f(z)|.$$

If f is meromorphic on $[|z| = R]$, then

$$[z^n]f(z) = \sum P_i(n) \alpha_i^{-n} + O(R^{-n}),$$

where α_i are the poles of f on the circle $[|z| = R]$ and P_i are polynomials of degree at most the order of the poles minus 1.

6. If f is meromorphic on $D = [|z| \leq R]$, with radius of convergence R , and dominant singularities (i.e., on the boundary of the convergence disk) ζ_1, \dots, ζ_k , then $g(z) = f(z) - \sum c_i (1 - z/\zeta_i)^{-\alpha_i}$ is holomorphic on a neighbourhood of D , and the asymptotic behaviour of $[z^n]f(z)$ is that of $\sum c_i (1 - z/\zeta_i)^{-\alpha_i}$. For a more precise asymptotic estimate, repeat the process with g .

In particular, if there is only one dominant singularity,

$$f(x) \sim (1 - z/\zeta)^{-\alpha} \implies f_n \sim \frac{1}{\Gamma(\alpha)} \rho^{-n} n^{\alpha-1}.$$

This can be generalized to singularities of the form

$$(1 - z)^{-\alpha} \left(\frac{1}{z} \log \frac{1}{1 - z} \right)^\beta.$$

8. If there are no singularities, or if the closest singularity is essential, the saddle point method can give the asymptotic behaviour of the coefficients.

Given an analytic function f on $\Omega \subset \mathbf{C}$, the surface $z \mapsto |f(z)|$ is not arbitrary: its points are either ordinary ($f \neq 0$, $f' \neq 0$), zeroes ($f = 0$) or saddle points ($f \neq 0$, $f' = 0$) – in particular, the zeroes are the only extrema (this can be used to prove the fundamental theorem of algebra).

A trivial bound for the integral $\int_A^B f(z)dz$ is

$$\left| \int_A^B f(z)dz \right| \leq \text{length}(\Gamma) \times \sup_{\Gamma} |f|.$$

To have a tighter bound, one can choose a path Γ that goes through a saddle point. In particular (if G is analytic at zero, not a polynomial, with nonnegative coefficients and $G(R) = +\infty$),

$$[z^n]G(z) = \frac{1}{2\pi i} \oint \frac{G(z)dz}{z^{n+1}} \leq \frac{G(\zeta)}{\zeta^n}$$

where $\zeta G'(\zeta)/G(\zeta) = n + 1$ (the saddle point, ζ , and the circle of integration depend on n).

The *saddle point method* is a refinement of this bound using the Laplace method: (under a few assumptions)

$$\begin{aligned} [z^n]G(z) &\sim \frac{G(\zeta)}{\zeta^n \sqrt{2\pi b(\zeta)}} \\ b(z) &= z^2 \frac{d^2}{dz^2} \log G(z) + z \frac{d}{dz} \log G(z) \\ \zeta \frac{G'(\zeta)}{G(\zeta)} &= n. \end{aligned}$$

9. The multivariate power series $F(x, u) = \sum f_{n, k} u^k x^n$ can be seen as a deformation of a univariate series $F(x, 1)$. For n fixed, it gives the probability generating function of a discrete distribution

$$f_n^{-1} [x^n] F(x, u) = f_n^{-1} \sum_k f_{n, k} u^k$$

and can help study the limit law, the convergence speed (Berry-Esseen) and the tail probabilities.

[For discrete laws, if $p_n(u) = E[u_n^X]$ pointwise converges to $p(u) = E[u^X]$ for all $u \in \mathbf{C}$, where A has an accumulation point in the open unit disk, then X_n converges to X in distribution. For continuous laws ($\mu_n, \sigma_n \rightarrow \infty$ – rescaling is needed), pointwise convergence of the characteristic function (on \mathbf{R}) or of the Laplace function (on a neighbourhood of 0) implies convergence in distribution.]

Under some conditions (involving the Laplace transform, but reducing to easy-to-check conditions depending on the type of singularity), the distribution is asymptotically Gaussian.

Introduction to the theory of species of structures F. Bergeron et al. (2013)

A *species of structures* is a functor F from the category of finite sets and bijections \mathbf{set} to itself.

To a species F , one can associate formal power series

$$F(x) = \sum_{n \geq 0} \#F[n] \frac{x^n}{n!}$$

$$\tilde{F}(x) = \sum_{n \geq 0} \#(F[n]/\simeq) x^n$$

$$Z_F(x_1, \dots) = \sum_{n \geq 0} \frac{1}{n!} \sum_{\sigma \in \mathfrak{S}_n} \text{fix } F[\sigma] x_1^{\sigma_1} x_2^{\sigma_2} \dots$$

where $[n] = \{1, 2, \dots, n\}$, $\#(F[n]/\simeq) = \#(F[n]/\mathfrak{S}_n)$ is the number of isomorphism classes in $F[n]$, σ_k is the number of cycles of length k in the cycle decomposition of $\sigma \in \mathfrak{S}_n$, $\text{fix } F[\sigma] = \#\{u \in F[n] : \sigma u = u\}$ is the number of points of $F[n]$ fixed by $F[\sigma]$.

The *exponential generating series* $F(x)$ counts (labelled) F -structures; the (isomorphism) *type generating series* $\tilde{F}(x)$ counts isomorphism classes of F -structures, i.e., unlabelled F -structures; the *cycle index series* Z_F contains more information.

Bijections $FU \simeq GU$ for all U (equipotence) do not necessarily define an isomorphism: for instance, the species of linear orders Lin and that of permutations Perm are equipotent, but not isomorphic (the bijections do not form a natural transformation); in particular, $\text{Lin}(x) = \text{Perm}(x)$, but $\widetilde{\text{Lin}}(x) \neq \widetilde{\text{Perm}}(x)$.

The following operations on species correspond to more

or less complex operations on their power series.

Sum	$(F + G)U = FU \sqcup GU$
Product	$(F \cdot G)U = \sum_{U=U_1 \sqcup U_2} FU_1 \times GU_2$
Substitution	$(F \circ G)U = \sum_{\pi \text{ partition of } U} F[\pi] \times \prod_{p \in \pi} G[p]$
Derivative	$F'U = F(U \sqcup \{*\})$
Pointing	$F \bullet U = F[U] \times U$
Superposition	$(F \times G)U = FU \times GU$
Composition	$(F \square G)U = F(GU)$

Here are a few examples.

A permutation can be decomposed into cycles: the cycles of length greater than 1 form a derangement, the cycles of length 1 form a set. This corresponds to a product of species, $\text{Perm} = \text{Der} \cdot U$, where $U : E \mapsto \{*\}$ is the species of sets, and gives $1/(1-x) = \text{Der}(x)e^x$.

$$\text{Perm}(E) = \coprod_{U=E_1 \sqcup E_2} \text{Der}(E_1) \times U(E_2)$$

Since a map is a surjection onto its image, we can relate maps and surjections by $\text{Set}(I, \cdot) = \text{Epi}(I, \cdot) \cdot U$:

$$\text{Set}(I, J) = \coprod_{J=J_1 \sqcup J_2} \text{Epi}(I, J_1) \times U(J_2).$$

A map $E \rightarrow E$ is defined by (iterate the map until you get cycles, and look at the basin of attraction of each element in those cycles):

- A partition π of E ;
- A rooted tree on each block of π ;
- A permutation on the blocks of π .

This is a composition of species, $\text{End} = \text{Perm}(A)$.

A partition of E is:

- A partition π of E ;
- A set structure on each block of π ;
- A set structure on π .

This gives $\text{Partitions} = U(U-1)$, and $\text{Partitions}(x) = \exp(e^x - 1)$ (Bell numbers).

A *weighted species* is a functor $\mathbf{set} \rightarrow R\text{-}\mathbf{set}$, where $R = k((t_1, t_2, \dots))$ is a field of formal power series and $R\text{-}\mathbf{set}$ is the category of R -weighted finite sets. An R -weighted finite set is a set A with a map $w : A \rightarrow R$. One associates power series associated to a weighted species as before, by replacing the size $|A|$ with the inventory $|A|_w = \sum_{a \in A} w(a)$. The usual operations $(+, \cdot, \circ, ', \bullet, \times, \square)$ extend to weighted species. Weighted

species can be used to compute, e.g., the number of rooted trees with a given number of nodes and a given number of leaves.

A k -sort species is a functor $\mathbf{mset}(k) \rightarrow \mathbf{set}$, where $\mathbf{mset}(k)$ is the category of multisets with k sorts of elements (colours), *i.e.*, of k -tuples of sets.

Qu'est-ce qu'une espèce de structures?
Génèse et description
F. Bergeron and G. Labelle (2011)

More elementary introduction to the theory of species of structures.

*Statistical learning with sparsity:
the lasso and its generalizations*

T. Hastie, R. Tibshirani, M. Wainwright (2015)

2. The lasso

$$\begin{array}{ll} \text{Find} & \beta \\ \text{To minimize} & \frac{1}{2N} \|y - X\beta\|_2^2 \\ \text{Such that} & \|\beta\|_1 \leq t \end{array}$$

can be put in *Lagrangian* form

$$\text{Argmin}_{\beta} \frac{1}{2N} \|y - X\beta\|_2^2 + \lambda \|\beta\|_1.$$

The $1/2N$ coefficient makes models of different sizes comparable (e.g., for cross-validation).

For a single predictor, the fit can be obtained by *soft-thresholding* the least squares estimate

$$S_{\lambda}(\beta) = \text{sign}(\beta)(|\beta| - \lambda)_+ = \text{soft}(\beta, \lambda).$$

Cyclical *coordinate descent* updates the coefficients one at a time, keeping the others fixed, by soft-thresholding.

The *degrees of freedom* of an estimator for an additive error model $y_i = f(x_i) + \varepsilon_i$, f unknown, $\varepsilon_i \sim N(0, \sigma^2)$, is

$$\text{df}(\hat{y}) = \frac{1}{\sigma^2} \sum_i \text{Cov}(\hat{y}_i, y_i).$$

One could also consider ℓ^p penalties or constraints, with $0 \leq p < 1$, but the problem would no longer be convex.

3. Generalized linear models (logistic, survival, Poisson, etc.) are estimated by minimizing the log-likelihood; one can simply add an ℓ^1 penalty to them.

Thanks to the ℓ^1 penalty, overspecified models are not a problem: there is no need to encode factors as “contrasts”.

The ℓ^1 regularized SVM path presents jumps: to avoid them, replace the hinge loss with its square; it becomes very similar to logistic regression.

$$\text{Argmin}_{\beta} \frac{1}{N} \sum (1 - y_i f_i(x_i|\beta))_+^2 + \lambda \|\beta\|_1.$$

4. The elastic net combines ℓ^1 and ℓ^2 penalties. An ℓ^1 penalty alone does not work well when there are identical variables (the solution is not unique).

To have groups of variables enter the model or remain unselected in block, the **group lasso** adds their unsquared ℓ^2 norm as a penalty. Larger groups are more likely to be selected: to avoid that, weigh the penalties with the group size, e.g., \sqrt{p} or (better) $\|Z\|_F$ (Frobenius norm of the design matrix of those factors).

To enforce sparsity inside each group, the *sparse group lasso* adds an ℓ^1 penalty in addition to the unsquared ℓ^2 one.

Sometimes, those groups of variables may overlap (e.g., gene pathways). The *overlap group lasso* can also enforce a hierarchical structure, e.g., to allow interactions only if the main effects are already present.

Generalized additive models (GAM) are usually estimated by backfitting, $f_j \leftarrow \text{Smooth}(y - \sum_{k \neq j} \hat{f}_k)$; they solve the optimization problem

$$(\hat{f}_1, \dots, \hat{f}_J) = \text{Argmin}_{f_1, \dots, f_J} E \left[Y - \sum_j f_j(X_j) \right]^2.$$

Sparse GAM (SPAM) adds an unsquared ℓ^2 penalty and uses sparse backfitting:

$$\text{Argmin}_{f_1, \dots, f_J} E \left[Y - \sum_j f_j(X_j) \right]^2 + \lambda \sum_j \|f_j\|_2$$

$$\tilde{f}_j \leftarrow \text{Smooth} \left(y - \sum_{k \neq j} \hat{f}_k \right)$$

$$\hat{f}_j \leftarrow \left(1 - \frac{\lambda}{\|\tilde{f}_j\|_2} \right)_+ \tilde{f}_j$$

The **fused lasso** approximates a time series with a piecewise constant function

$$\text{Argmin}_{\theta} \frac{1}{2} \sum (y_i - \theta_i)^2 + \lambda \sum |\theta_i - \theta_{i-1}|.$$

It can be generalized to images, non-equispaced observations, regression with ordered predictors ($|\beta_i - \beta_{i-1}|$ – nearby predictors tend to have the same coefficient), piecewise affine or piecewise polynomial functions (*trend filtering*), nearly isotonic regression $\|(\Delta\theta)_-\|_1$.

Coordinate descent does not work for the fused lasso. In the 1-dimensional case, one can start with the unpenalized estimate ($\lambda = 0$) and progressively fuse neighboring intervals. One can also solve the dual (lifted) problem or use dynamic programming.

5. The *nuclear norm* (the sum of the singular values) is a generalization of the ℓ^1 norm: $\|\text{diag } x\|_* = \|x\|_1$. It is also a convex relaxation of the rank.

Descent methods are iterative optimization algorithms: choose a direction (usually not far from the gradient, i.e., $\langle \nabla f, \text{dir} \rangle < 0$); make a small step in this direction; iterate. Common direction choices include

$$\begin{aligned}\text{dir} &= -\nabla f && \text{(gradient descent)} \\ \text{dir} &= -D^{-1}\nabla f && \text{for some diagonal matrix } D \\ \text{dir} &= -(\nabla^2 f)^{-1}\nabla f && \text{(Newton).}\end{aligned}$$

The step size is important: estimate it with a 1-dimensional optimization, or with Armijo's rule.

In the presence of constraints, the *projected gradient* method simply projects the solution back onto the feasible set after each step (gradient descent is similar, with $\beta \in \mathbf{R}^n$ instead of $\beta \in C$):

$$\beta_{n+1} = \underset{\beta \in C}{\text{Argmin}} f(\beta_n) + \langle \nabla f(\beta_n), \beta - \beta_n \rangle + \frac{1}{2s} \|\beta - \beta_n\|_2^2.$$

If the objective is a sum of convex functions $f = g + h$, one differentiable, one not, the *generalized gradient update* linearizes g but leaves h as is.

$$\begin{aligned}\beta_{n+1} &= \underset{\beta}{\text{Argmin}} g(\beta_n) + \langle \nabla g(\beta_n), \beta - \beta_n \rangle + \\ &\quad \frac{1}{2s} \|\beta - \beta_n\|_2^2 + h(\beta) \\ &= \text{prox}_{sh}(\beta_n - s\nabla g\beta_n)\end{aligned}$$

The **proximal** map generalizes the projection:

$$\begin{aligned}\text{prox}_h z &= \underset{\theta}{\text{Argmin}} \frac{1}{2} \|z - \theta\|_2^2 + h(\theta) \\ \text{prox}_{I_C} z &= \text{projection of } z \text{ onto } C \\ \text{prox}_{\lambda\|\cdot\|_1} z &= S_\lambda(z) \text{ elementwise soft-thresholding} \\ \text{prox}_{\|\cdot\|_*} Z &= \text{singular value soft-thresholding.}\end{aligned}$$

Convergence is faster if g is strongly convex.

The accelerated gradient descent, e.g., conjugate gradient, or **Nesterov momentum**

$$\begin{aligned}\beta_{n+1} &= \theta_n - s\nabla f(\theta_n) \\ \theta_{n+1} &= \beta_{n+1} + \frac{n}{n+1}(\beta_{n+1} - \beta_n)\end{aligned}$$

is faster (but non-monotonic).

Coordinate descent (optimizing one coordinate at a time) works if the non-differentiable part of f is separable or, more generally if, when the directional derivatives along the axes are non-negative, then so are all the directional derivatives (for a situation where it does not happen, take f on \mathbf{R}^2 with polygonal level curves: coordinate descent cannot escape (acute) corners that remain inside one of the quadrants).

For linear regression, if the variables are centered and standardised, the lasso and the elastic net estimates

can be computed from the OLS estimates by shrinkage and soft-thresholding.

Coordinate descent is faster than the proximal gradient or Nesterov momentum.

Least angle regression (LAR) adds the variables one at a time but, contrary to stepwise regression, it only increases the coefficients until another variable becomes more promising. If the algorithm also removes a variable from the active set when its coefficient drops to zero, it computes the lasso regularization path.

For the alternating direction method of multipliers (ADMM),

$$\begin{aligned}\text{Find} &\quad \beta, \theta \\ \text{To minimize} &\quad f(\beta) + g(\theta) \\ \text{Such that} &\quad A\beta + B\theta = c\end{aligned}$$

the augmented Lagrangian is (with g small)

$$\begin{aligned}L_\rho(\beta, \theta, \mu) &= f(\beta) + g(\theta) + \langle \mu, A\beta + B\theta - c \rangle + \\ &\quad \frac{\rho}{2} \|A\beta + B\theta - c\|_2^2.\end{aligned}$$

It can be solved by iterating

$$\begin{aligned}\beta_{n+1} &= \underset{\beta}{\text{Argmin}} L_\rho(\beta, \theta_n, \mu_n) \\ \theta_{n+1} &= \underset{\theta}{\text{Argmin}} L_\rho(\beta_{n+1}, \theta, \mu_n) \\ \mu_{n+1} &= \mu_n + \rho(A\beta_{n+1} + B\theta_{n+1} - c).\end{aligned}$$

For the lasso

$$\begin{aligned}\text{Find} &\quad \beta, \theta \\ \text{To minimize} &\quad \frac{1}{2} \|y - X\beta\|_2^2 + \lambda \|\theta\|_1 \\ \text{Such that} &\quad \beta - \theta = 0,\end{aligned}$$

β is updated by a ridge regression, θ by soft thresholding and μ linearly.

Minorization-maximization (MM) minimizes a (possibly non-convex) function f by finding a function $\Psi : \mathbf{R}^m \times \mathbf{R}^n \rightarrow \mathbf{R}$ such that

$$\begin{aligned}\forall \beta, \theta \quad f(\beta) &\leq \Psi(\beta, \theta) \\ \forall \beta \quad f(\beta) &= \Psi(\beta, \beta)\end{aligned}$$

and iterating $\beta_{n+1} = \underset{\beta}{\text{Argmin}} \Psi(\beta, \beta_n)$.

The proximal gradient can be seen as a MM (a Lipschitz gradient gives Ψ); in a different context, so can the expectation maximization (EM) algorithm (Ψ comes from Jensen's inequality).

A function $f(\cdot, \cdot)$ is *biconvex* if $f(\cdot, \beta)$ and $f(\alpha, \cdot)$ are convex (for instance, $f(\alpha, \beta) = (1 - \alpha\beta)^2$); a set $C \subset A \times B \subset \mathbf{R}^n$ is biconvex if the sections $C_{\alpha, \cdot}$, $C_{\cdot, \beta}$ are convex. *Alternate convex search* (ACS) successively optimizes each block; the function values will converge, but the solution need not; if it does, it is only to a *partial optimum*. For instance, the maximal singular vectors and values of a matrix can be computed

as (this is a generalization of the power method)

$$\begin{aligned} f(\alpha, \beta, s) &= \|X - s\alpha\beta'\|_F^2 \\ \alpha_{n+1} &= \frac{X\beta_n}{\|X\beta_n\|_2} \\ \beta_{n+1} &= \frac{X'\alpha_n}{\|X'\alpha_n\|_2}. \end{aligned}$$

When there are millions of variables, one can use screening rules (dual polytope projection (DPP), sequential DPP, global string rule, sequential strong rule) to reduce their number; the less conservative rules make mistakes, but they can be corrected by checking the KKT conditions and adding the variables that violate them.

6. It is possible to design statistical tests for the lasso:

- Bayesian (MCMC) simulations, after choosing a prior (for instance, the number of variables in the model is often assumed uniform over $\llbracket 0, k \rrbracket$, with $k \ll p$) [this is unrelated to the fact that the lasso is the posterior model (MAP estimator) for a Laplace prior];
- Bootstrap (even slower, but it scales better);
- **Covariance test:** the change in $\text{Cov}(\hat{y}, y)$ as a variable enters the model is asymptotically $\text{Exp}(1)$; contrary to stepwise regression, adaptivity and shrinkage (asymptotically) compensate each other;
- Exact (finite sample) tests for adaptive models whose selection event can be written $Ay \leq b$ (this includes lasso and stepwise regression)

One can also debias the lasso estimate to compute confidence intervals.

7. The singular value decomposition (SVD) provides the best rank- r approximation of a matrix Z :

$$UD_rV' = \underset{M : \text{rank } M=r}{\text{Argmax}} \|Z - M\|_F$$

but missing values complicate the situation.

The *iterated SVD* (fill in the missing values, compute the rank r approximation from the SVD, iterate) tends to overfit.

The *soft-thresholding iterated SVD* (fill in the missing values, compute $US_\lambda(D)V'$, iterate; you can also let λ decrease at each step) solves the problem

$$\underset{M}{\text{Argmin}} \frac{1}{2} \|Z - M\|_F^2 + \lambda \|M\|_*$$

where the Frobenius norm is taken over the non-missing entries of Z .

The biconvex problem

$$\underset{A,B}{\text{Argmin}} \|Z - AB'\|_F^2 + \lambda(\|A\|_F^2 + \|B\|_F^2)$$

gives a 2-dimensional family of matrix factorizations, indexed by (r, λ) (r is the number of columns of A and B).

A vector-valued regression $Y = X\Theta + E$ can be estimated with the group lasso, which sets whole rows of

Θ to zero, or with a nuclear norm penalty, to make it low rank.

$$\underset{\Theta}{\text{Argmin}} \|Y - X\Theta\|_F^2 + \lambda \|\Theta\|_*$$

These models (matrix completion, low rank regression) can be written $y_i = \text{tr}(X_i'\Theta) + \varepsilon$ for various choices of the matrices X_i , and estimated as

$$\underset{\Theta}{\text{Argmin}} \frac{1}{N} \sum (y_i - \text{tr}(X_i'\Theta))^2 + \lambda \|\Theta\|_*.$$

The penalized SVD,

$$\underset{U,D,V}{\text{Argmin}} \|Z - UDV'\|_F^2 + \lambda_1 \|U\|_1 + \lambda_2 \|V\|_1$$

gives sparse singular vectors (the rank-1 problem is biconvex and can be solved by alternating soft-thresholding; for the rank- r problem, start again with $Z - udv'$).

Additive matrix decompositions express a matrix Z as a sum, e.g., of low-rank, sparse and small (noise) matrices:

$$\underset{L,S}{\text{Argmin}} \|Z - (L + S)\|_F^2 + \lambda_1 \|L\|_* + \lambda_2 \|S\|_1.$$

For row-wise sparsity (*i.e.*, to model row-wise corruption), replace $\|S\|_1$ with $\sum \|S_i\|_2$.

Factor analysis models the data as $y_i = \mu + \Gamma u_i + \varepsilon_i$, $\varepsilon_i \sim N(0, S)$, which gives $\text{Var } y = \Gamma\Gamma' + S$. If S is scalar, principal component analysis (PCA) recovers Γ ; if not, one can use the low rank + sparse + noise decomposition.

8. Most statistical procedures can be formulated as an optimization problem: adding an ℓ^1 penalty (or both ℓ^1 and ℓ^2 penalties) sparsifies them. It may be necessary to reformulate the problem to get a convex, or biconvex, or less nasty problem. Different reformulations give different results.

8a. The first principal component is the direction in which the variance is maximal

$$\underset{v : \|v\|_2=1}{\text{Argmax}} \text{Var } Xv = \underset{v : \|v\|_2=1}{\text{Argmax}} v'X'Xv;$$

it can be sparsified as

$$\begin{aligned} \text{Find} & \quad u, v \\ \text{To maximize} & \quad u'Xv \\ \text{Such that} & \quad \|u\|_2 = \|v\|_2 = 1, \quad \|v\|_1 \leq t \end{aligned}$$

(solvable with SVD and thresholding) or

$$\begin{aligned} \text{Find} & \quad M \succcurlyeq 0 \\ \text{To maximize} & \quad \text{tr}(X'XM) \\ \text{Such that} & \quad \text{tr } M = 1, \quad \text{tr}(|M|E) \leq t^2. \end{aligned}$$

The first principal component can also be defined as the direction minimizing the reconstruction error, and sparsified as

$$\underset{v, \theta : \|\theta\|_2=1}{\text{Argmin}} \frac{1}{N} \sum \|x_i - uv'\theta\|_2^2 + \lambda_1 \|v\|_1 + \lambda_2 \|v\|_2^2.$$

Auto-encoders also minimize the reconstruction error and are easy to sparsify.

For the next principal component, since orthogonality may conflict with sparsity, one may consider

$$\begin{aligned} \text{Find} & \quad u_k, v_k \\ \text{To maximize} & \quad u_k' X v_k \\ \text{such that} & \quad \|v_k\|_2 \leq 1, \quad \|u_k\|_2 \leq 1 \\ & \quad \|v_k\|_1 \leq c \\ & \quad \forall j \in \llbracket 1, k-1 \rrbracket \quad u_k' u_j = 0. \end{aligned}$$

Classical PCA is consistent when $N \rightarrow \infty$, $p/N \rightarrow 0$, but not (at all) if $N, p \rightarrow \infty$, $p/N \rightarrow c > 0$. Thresholding the diagonal of the sample variance matrix and computing the PCA in this lower-dimensional space is actually consistent.

8b. Canonical correlation analysis (CCA) solves the problem

$$\begin{aligned} \text{Find} & \quad \beta, \theta \\ \text{To maximize} & \quad \text{Cov}(X\beta, Y\theta) \\ \text{Such that} & \quad \text{Var } X\beta = \text{Var } Y\theta = 1 \end{aligned}$$

e.g., via SVD or ALS; it can be sparsified by adding ℓ^1 and ℓ^2 constraints and solved by alternating soft-thresholding.

8c. Linear discriminant analysis (LDA) can be presented in three different ways, which can be sparsified as usual:

- Model the classes with Gaussian distributions, with different means but the same variance (the naive Bayes classifier is the special case when the variance matrix is diagonal);
- Fisher: find a low-dimensional projection in which the between-class variance is large wrt the within-class variance, *i.e.*,

$$\text{Argmax}_{\beta} \frac{\beta' \Sigma_b \beta}{\beta' \Sigma_w \beta};$$

- Optimal scoring: LDA with two classes is a linear regression of the binary response; with more classes, it is still a linear regression, provided we assign a number to each class, in an optimal way.

8d. Hierarchical clustering does not work well in the presence of many uninformative variables: *sparse hierarchical clustering* assigns (sparse) weights to the variables and applies the usual clustering algorithms on the resulting weighted dissimilarity matrix.

Convex clustering looks for prototypes, close to the points, and close to one another (with an ℓ^1 loss, so that many are actually equal),

$$\text{Argmin}_{u_1, \dots, u_n} \sum \|x_1 - u_i\|_2^2 + \lambda \sum_{i < j} \|u_i - u_j\|_q, \quad q \in \{1, 2\}.$$

K -means can be sparsified by maximizing the between-

cluster sum of squares

$$\begin{aligned} \text{Find} & \quad \mathcal{C}_1 \sqcup \dots \sqcup \mathcal{C}_K = \llbracket 1, N \rrbracket, \quad w \in \mathbf{R}^p \\ \text{To maximize} & \quad \sum_{j=1}^p w_j \left(\frac{1}{N} \sum_{i,i'=1}^N d_{ii'j} - \sum_k \frac{1}{N_k} \sum_{i,i' \in \mathcal{C}_k} d_{ii'j} \right) \\ \text{Such that} & \quad \|w\|_2 \geq 1, \quad \|w\|_1 \leq s, \quad w \geq 0 \end{aligned}$$

and solved with an alternating algorithm (soft-thresholding and weighted k -means).

9. Undirected graphs can encode dependence properties between random variables (one per vertex) in the following equivalent ways (*Hammersley-Clifford theorem*):

- The joint probability distribution function factorizes over the cliques

$$P(x_1, \dots, x_p) \propto \prod_{C \in \text{Cliques}} \psi_C(x_C);$$

- The random variable X has the Markov property over the graph: for all cut set S separating the graph into connected components A and B , $X_A \perp\!\!\!\perp X_B | X_S$.

For instance, one can model how politicians vote as follows

$$\begin{aligned} X_i &: \text{vote of politician } i \\ \text{sign } \theta_i &: \text{whether } i \text{ is likely to vote yes} \\ \text{sign } \theta_{ij} &: \text{whether } i \text{ and } j \text{ tend to agree} \\ P &\propto \exp\left(\sum \theta_i x_i + \sum \theta_{ij} x_i x_j\right) \end{aligned}$$

(the graph is complete, but only cliques up to size 2 are used).

A multivariate Gaussian model is a graphical model, with only vertex and edge factors; the adjacency matrix of the graph is the sparsity pattern of the concentration (or precision) matrix $\Theta = \Sigma^{-1}$.

The Gaussian likelihood can be penalized (**graphical lasso**)

$$\text{Argmax}_{\Theta \succeq 0} \log \det \Theta - \text{tr } \hat{\Sigma} \Theta - \lambda \rho_1(\Theta)$$

where ρ_1 is the ℓ^1 norm of the off-diagonal elements and $\lambda = 2\sqrt{\frac{\log p}{N}}$. The problem is convex and can be solved efficiently by blockwise coordinate descent (fix everything except a row (and the corresponding column); each step is a lasso regression). If the solution has a block structure, it can be identified before the optimization ($|\hat{\Theta}_{ij}| \leq \lambda$ whenever i and j are in different blocks) and the blocks can be solved independently.

Alternatively, one can estimate the neighbourhood of a random variable as a small set of variables that gives a good prediction, using the lasso (and the AND or OR rule: keep an edge (s, t) if both/either $s \in \mathcal{N}(t)$ and/or $t \in \mathcal{N}(s)$). For discrete variables, use the logistic lasso.

It is possible to mix continuous and discrete variables

$$\begin{aligned} \log P &= \sum \gamma_s x_s - \frac{1}{2} \sum \theta_{st} x_s x_t && \text{continuous} \\ &+ \sum \rho_{sj}(y_j) x_s && \text{mixed} \\ &+ \sum \psi_{jr}(y_j, y_r) && \text{discrete} \end{aligned}$$

through the *pseudo-likelihood* (the product of the neighbourhood likelihoods).

Omitting hidden variables makes a sparse model look dense. In this case, the concentration matrix can be written as a sum $K = \Theta + L$, with Θ sparse and L low rank (from the block inverse formula):

$$\text{Argmin}_{\substack{\Theta, L \\ \Theta - L \succ 0 \\ L \succ 0}} \text{tr} \hat{\Sigma}(\Theta - L) - \log \det(\Theta - L) + \lambda \|\Theta\|_1 + \text{tr} L.$$

10. The best sparse approximation, in an orthonormal basis (Fourier, wavelets) is obtained by keeping the k largest coefficients. One can also combine several bases, e.g., Fourier Φ to capture periodic patterns and smooth changes, and Haar Ψ for sharp changes, with a lasso constraint

$$\begin{aligned} \text{Find} & \quad \alpha, \beta \\ \text{To minimize} & \quad \|\theta - \Phi\alpha - \Psi\beta\|_2 \\ \text{Such that} & \quad \|\alpha\|_1 + \|\beta\|_1 \leq R. \end{aligned}$$

The exact reconstruction problem is even simpler:

$$\begin{aligned} \text{Find} & \quad \alpha, \beta \\ \text{To minimize} & \quad \|\alpha\|_1 + \|\beta\|_1 \\ \text{Such that} & \quad \theta = \Phi\alpha - \Psi\beta, \end{aligned}$$

Compressed sensing reconstructs a sparse signal θ (e.g., the signal of interest, in a basis in which we expect it to be sparse) from a small number of random projections $z'_i \theta$. The random projection matrix can have Gaussian iid entries, Bernoulli ± 1 iid entries, or be a random submatrix of the Fourier matrix $(\exp(2\pi i k \ell / n))_{1 \leq k, \ell \leq n}$.

In R, check the following packages: `glmnet` (GLM), `genlasso` (fused lasso), `monomvn::blasso` (Bayesian lasso, bootstrap), `softImpute` (SVD with missing values), `penalizedLDA`, `sparseLDA`, `cvxcluster` (convex clustering).

Selected applications of convex optimization L. Li (2015)

1. Given the primal problem

$$\begin{aligned} \text{Find} & \quad x \\ \text{To minimize} & \quad f(x) \\ \text{Such that} & \quad \forall i \ g_i(x) \leq 0 \\ & \quad \forall j \ h_j(x) = 0, \end{aligned}$$

define the Lagrangian and the dual function as

$$\begin{aligned} L(x, \alpha, \beta) &= f(x) + \sum \alpha_i g_i(x) + \sum \beta_j h_j(x) \\ q(\alpha, \beta) &= \inf_x L(x, \alpha, \beta); \end{aligned}$$

the dual problem is then

$$\begin{aligned} \text{Find} & \quad \alpha, \beta \\ \text{To maximize} & \quad q(\alpha, \beta) \\ \text{Such that} & \quad \alpha \geq 0. \end{aligned}$$

2. A support vector machine (SVM) can be fit by

$$\begin{aligned} \text{Find} & \quad w, b \\ \text{To maximize} & \quad 1/\|w\|_2^2 \quad (\text{width of the band}) \\ \text{Such that} & \quad \forall i \in L^+ \ w'x_i + b \geq 1 \\ & \quad \forall i \in L^- \ w'x_i + b \leq -1, \end{aligned}$$

which can be written as a convex problem

$$\begin{aligned} \text{Find} & \quad w, b \\ \text{To minimize} & \quad \|w\|_2^2 \\ \text{Such that} & \quad \forall i \ y_i(w'x_i + b) \geq 1 \end{aligned}$$

where $y_i = +1$ if $i \in L^+$ and -1 otherwise. To find the dual problem, write the Lagrangian

$$L(z, b, \alpha) = \frac{1}{2} \|w\|_2^2 - \sum \alpha_i (y_i(w'x_i + b) - 1);$$

use the KKT conditions, $\partial L / \partial w = 0$ and $\partial L / \partial b = 0$, i.e., $w = \sum \alpha_i y_i x_i$ and $\sum \alpha_i y_i = 0$ to compute the dual function $q(\alpha)$:

$$\begin{aligned} \text{Find} & \quad \alpha \\ \text{To maximize} & \quad \sum \alpha_i - \frac{1}{2} \sum \alpha_i \alpha_j y_i y_j x'_i x_j \\ \text{Such that} & \quad \alpha \geq 0 \\ & \quad \sum \alpha_i y_i = 0. \end{aligned}$$

There are many variants, such as the soft-margin SVM

$$\begin{aligned} \text{Find} & \quad w, b, \xi \\ \text{To minimize} & \quad \|w\|_2^2 + c \sum \xi_i^2 \\ \text{Such that} & \quad \forall i \ y_i(w'x_i + b) \geq 1 - \xi_i \\ & \quad \forall i \ \xi_i \geq 0 \end{aligned}$$

or the multiclass SVM (with $t_i = [x_i, 1]$)

$$\begin{aligned} \text{Find} & \quad v_1, \dots, v_k, \xi \\ \text{To minimize} & \quad \frac{1}{2} \sum v'_k v_k + c \sum \xi_i^2 \\ \text{Such that} & \quad \forall i, k \ v'_i t_i - v'_k t_i \geq \delta_{y_i, k} - \xi_i. \end{aligned}$$

Sequential minimal optimization (SMO) tries to reduce memory usage by optimizing two α_i 's at a time.

One can also regularize SVMs, by replacing $\sum \xi_i$ with $\sum \xi_i^2$ (LS-SVM), or by a constraint such as $\sum \xi_i^2 = L\sigma^2$ (Morozov) or $w'w = \pi^2$ (Ivanov).

3. A mixture model

$$\begin{aligned} f(x, \theta) &= \sum \pi_k f(x, \theta_k) \\ z_i(k) &= \mathbf{1}_{x_i \text{ comes from the } k\text{th component}} \end{aligned}$$

can be estimated by expectation maximization (EM):

- E-step: estimate the distribution (not the values – that is a common mistake) of $z_i(k)$ from (π, θ) :

$$\begin{aligned}\gamma_i(k) &= P[x_i \text{ comes from the } k\text{th component}] \\ &= E[z_i(k)] \\ &= \frac{\pi_k f(x_i, \theta_k)}{\sum_j \pi_j f(x_i, \theta_j)}\end{aligned}$$

- M-step: estimate (π, θ) from γ via maximum likelihood.

The general EM algorithm estimates a parameter of interest θ and integrates out nuisance parameters (latent variables or missing values) z , by estimating their posterior distribution $q_i(z_i)$. The log-likelihood can be written

$$\begin{aligned}\log L(\theta) &= \sum_i \log p(x_i, \theta) \\ &= \sum_i \log \sum_{z_i} p(x_i, z_i, \theta) \\ &= \sum_i \log \sum_{z_i} q_i(z_i) \frac{p(x_i, z_i, \theta)}{q_i(z_i)} \\ &\geq \sum_i \sum_{z_i} q_i(z_i) \log \frac{p(x_i, z_i, \theta)}{q_i(z_i)} \quad (\text{Jensen}) \\ &= J(q, \theta)\end{aligned}$$

and maximized by coordinate descent:

- E-step: $q_m = \text{Argmax}_q J(q, \theta_m)$ (we do not estimate the nuisance parameters z_i but their distributions q_i ; after this step, the inequality is actually an equality)
- M-step: $\theta_{m+1} = \text{Argmax}_\theta J(q_m, \theta)$.

The book then gives probabilistic principal component analysis (PCA with missing values) as an example, but they make the common mistake of filling in the missing values.

4. Adding a penalty to the objective, e.g., $\lambda \|x\|_1$, is equivalent to adding a constraint $\|x\|_1 \leq C$, where $C = \|x^*\|_1$ and x^* is the solution of the penalized problem.

6. The SDP (semidefinite programming) relaxation of a non-convex quadratically constrained quadratic program (QCQP, e.g., $x \in \{\pm 1\}$ can be written $x^2 = 1$) is obtained by introducing a matrix $X = xx'$ and relaxing that equality to $X \succcurlyeq xx'$, i.e.,

$$\begin{pmatrix} 1 & x' \\ x & X \end{pmatrix} \succcurlyeq 0.$$

The *reformulation-linearization technique* (RLT) also relaxes $X = xx'$, but start with the inequalities $\ell_i \leq x_i \leq u_i$, i.e., $x_i - \ell_i \geq 0$ and $u_i - x_i \geq 0$, multiplies them, and replaces $x_i x_j$ with x_{ij} .

7. The minimum volume ellipsoid covering n points $x_1, \dots, x_n \in \mathbf{R}^d$ is defined by

$$\begin{array}{ll}\text{Find} & A, \mu \\ \text{To minimize} & \det Q \\ \text{Such that} & \forall i \ (x_i - \mu)' Q^{-1} (x_i - \mu) \leq 1 \\ & Q \succ 0\end{array}$$

and can be recast as a convex problem

$$\begin{array}{ll}\text{Find} & M, m \\ \text{To minimize} & -\log \det M \\ \text{Such that} & \forall i \ (Mx_i - m)'(Mx_i - m) \leq 1 \\ & M \succ 0\end{array}$$

where $M = Q^{-1/2}$ and $m = Q^{-1/2}\mu$.

Parsing algorithms

Recursive descent is the most straightforward top-down parsing algorithm: start with the root of the tree, try the first possible derivation, and continue, backtracking after each failure (it does not work with left recursive (LR) grammars, i.e., those with a rule of the form $S \rightarrow^+ S\alpha$, where \rightarrow^+ means a series of derivations). *Parser combinators* (Parsec, Spirit) are a way to implement recursive descent parsing in functional languages, from simple building blocks (parsers, i.e., functions that convert strings to parse trees) and glue – higher order functions).

Parsing expression grammars (PEG) are an alternative to context-free grammars (CFG): the choice operator $|$ is ordered; the $*$ operator is greedy and does not backtrack after failure; there are $\&$ (AND) and $!$ (NOT) operators (they do not consume any input and allow unlimited look-ahead). *Packrat* is a linear-time recursive descent algorithm with memoization for PEG.

The **Earley** algorithm is similar to recursive descent, but explores the set of possible parse trees breadth-first, not depth-first.

The **CYK** algorithm is a bottom-up dynamic programming based parsing algorithm, building a boolean table in $O(n^3)$: T_{ijk} indicates if $s_{i..j}$ can be derived from rule R_k (it assumes the grammar is in Chomsky normal form (CNF) i.e., the derivation rules are of the form $A \rightarrow \alpha$ or $A \rightarrow BC$).

A grammar is $LL(k)$ if, whenever we hesitate between two derivation rules, we can decide by looking k tokens ahead. An **LL** parser (e.g., ANTLR) precomputes those decisions and puts them in a table (the table is exponential in the worst case, but not in practice).

LR parsers are a bottom-up analogue of the top-down LL parsers: they use a transition table that maps parser state and next token(s) to a next state and an action; the action can be “shift” (consume one token) or “reduce” (do not, but apply one of the rules). Variants include LALR(1) (look-ahead LR(0), yacc/bison), SLR (simple LR), GLR (generalized LR).

QuantifQuantile: an R package for performing quantile regression through optimal quantization
I. Charlier et al. (2015)

Nonparametric quantile regression $Y \sim X$ can be estimated with a variant of the k nearest neighbours:

- Find a set (or grid) γ of N points to minimize $E[|X - X^\gamma|^p]^{1/p}$, where X^γ is the projection of X onto γ (start with a random grid γ and move each grid point towards the average of the observations assigned to it);
- Approximate the conditional quantile of $Y|X$ as

$$\hat{q}_\alpha(y|x) = \underset{a \in \mathbf{R}}{\text{Argmin}} E[\rho_\alpha(Y - a) | X^\gamma = x^\gamma]$$

- Bootstrap to choose N ;
- Bootstrap for a smoother estimate.

***treeClust: an R package
for tree-based clustering dissimilarities***
S.E. Buttrey and L.R. Whitaker

Tree-based distances are insensitive to scaling and provide automatic variable selection: use the proportion of trees (predict each variable with the others) in which the two observations are in the same leaf; refine using tree quality and node distance.

***An R package for the panel approach method
for program evaluation: pampe***
A. Vega-Bayo

To estimate the effect of a policy (“program evaluation”) from observed panel data, with treated and control groups, consider the effect of treatment/non-treatment on the control/treated group as missing values, and model the panel data with a dynamic factor model.

A significance test for the lasso
R. Lockhart et al. (2014)

To test if the inclusion of a variable along the regularization path is significant, use

$$T_k = \frac{\langle y, X\hat{\beta}(\lambda_{k+1}) - X_{A_{k-1}}\tilde{\beta}_{A_{k-1}}(\lambda_{k+1}) \rangle}{\sigma^2} \xrightarrow{d} \text{Exp}(1)$$

where $\hat{\beta}(\lambda)$ is the lasso estimator, A_{k-1} is the set of variables in the model just before λ_k , $\tilde{\beta}_A(\lambda)$ is the lasso estimator on the variables in A .

***Automatically improving accuracy
for floating point expressions***
P. Panchekha (2015)

Herbie is a Racket library that rewrites floating point expressions to improve their precision (e.g., $e^x - e^{-x}$ for x small, or $\log(1 + e^x)$ for x large):

- Sample the possible inputs, uniformly among floating point numbers (not uniformly over some interval of \mathbf{R});
- Estimate the precision of each intermediate result, by comparing it with an arbitrary precision computation (progressively increase the precision until it is sufficient);
- Apply (more than a hundred) rewrite rules (e.g., associativity, but also $\sqrt{x+1} - \sqrt{x} \mapsto 1/(\sqrt{1+x} + \sqrt{x})$); simplify;

- Also try series expansions;
- Choose which rewritten formula to use depending on the values of the inputs.

TOL manual
(2013)

TOL (time-oriented language) is a programming language with predefined types to describe time series:

- Date and Time (confusingly, it is the same type);
- Infinite sets of dates (e.g., the first day of each month), with operations on them (union, intersection, set difference, membership, next-element, restriction, offset);
- Unlimited time series, with a few building blocks (indicator, step function, affine function, random number generator) and operations (+, −, ×, /, coalesce, lag, arima, etc.).

The package repository has a few dozen items, but many are only documented in Spanish.

It is not clear why this DSL was not built on an existing language (Haskell, OCaml, etc.).

Mathematica: a problem-centered approach
R. Hazrat (2010)

Here are a few examples of the syntax of the language.

- Square brackets are used for function arguments, curly braces for lists; matrices are lists of lists;
- Function definitions use `:=`, while `=` creates frozen assignments: compare `x:=Random[]` and `x=Random[]`;
- Function arguments are indicated by `_`, and they can be given an optional name, e.g., `f[n_]:=n^2`;
- Function application can be written `f[x]`, `f@x` or `x//f`; the pipe operator is often used to format the output, e.g., `Inverse[A] // MatrixForm`;
- Anonymous functions end with `&` (it is not always clear where they start) and their arguments are called `#1`, `#2`, etc. (or `#` of there is only one), e.g., `(#^2+1)&[5]` or `5/(#^2)&`;
- The map function is `/@`, e.g., `f /@ Range[5]`; the function is often anonymous, e.g., `#^2& /@ Range[5]`;
- The fold function is `Apply` or `@@`, e.g., `Plus @@ Range[5]` (it actually replaces the head of the rhs with the lhs); its vectorized form, for lists of lists, is `@@@`;
- The `Table` function provides a weak form of list comprehension, e.g., `Table[3n^5+11, {n,1,20}]`;
- The substitution operator is `./`, e.g., `x+y ./ x->2`; `./` applies the rules until nothing changes, e.g., `x+y ./ {x->y,y->z}`;
- It is possible to specify the type and properties of the function arguments or substitution, e.g., `f[x_Integer?EvenQ]:=x/2`; `__` matches a non-empty sequence, `___` a sequence;
- If can be written `/;`, e.g., `f[n_]:=Sqrt[n] /; n>0`.

***A thread-safe arbitrary precision
computation package***
D.H. Bailey (2015)

Implementation details for a multiprecision library – useful for ODEs (e.g., the Lorentz attractor loses 16 digits in each period) and experimental mathematics. Alternatives include: GMP, MPFR (and languages that use it, e.g., Julia), Pari/GP, mpmath (Python), Sage.

Use Newton iteration for square roots $x \leftarrow x + \frac{1}{2}(1 - x^2a)x$, n th roots, inverses $x \leftarrow x + (1 + xb)x$, logarithm $x \leftarrow x - (e^x - a)/e^x$, arcsine; Taylor for exponential (for x small), sine (for x small – use the double angle formula to bring it back to its initial value in $(-\pi/4, \pi/4]$). For multiplication, use the elementary school algorithm (in base 2^{48}) or the FFT (the digits of ab , before accounting for carries, are the convolution of those of a and b).

For much higher precision (thousands to millions of digits), algorithms based on the *arithmetic-geometric mean* (AGM), being quadratically convergent (the number of correct digits doubles at each iteration), become competitive.

Ten problems in experimental mathematics
D.H. Bailey et al. (2006)

Applications of the PSLQ algorithms to situations where the numeric estimation of the number of interest is non-trivial.

***Using integer relation algorithms
for finding relationships among functions***
M. Chamberland (2007)

The PSLQ algorithm can also find integer relations between functions: evaluate them at some random point; apply PSLQ; try another point to make sure.

A=B
M. Petkovšek et al. (1997)

A geometric series is a series $\sum t_n$ in which the ratio of two consecutive terms t_{n+1}/t_n is constant. A **hypergeometric series** is a series $\sum t_n$ in which the ratio of two consecutive terms t_{n+1}/t_n is a rational function of n . If

$$\frac{t_{n+1}}{t_n} = \frac{(n+a_1) \cdots (n+a_p)}{(n+b_1) \cdots (n+b_q)} \frac{x}{n+1},$$

it is usually written

$${}_pF_q \left(\begin{smallmatrix} a_1 \cdots a_p \\ b_1 \cdots b_q \end{smallmatrix}; x \right) = {}_pF_q(\mathbf{a}, \mathbf{b}; x) = \sum_{n \geq 0} t_n.$$

There are lists of hypergeometric identities, but expecting to be able to evaluate arbitrary hypergeometric series from those lists is hopeless.

1. Given a double hypergeometric term $F(n, k)$, *i.e.*, both $F(n+1, k)/F(n, k)$ and $F(n, k+1)/F(n, k)$ are

rational functions, **Sister Celine’s algorithm** looks for a recurrence relation

$$\sum_{i=0}^I \sum_{j=0}^J a_{ij}(n) F(n-j, k-i) = 0$$

as follows: divide the recurrence relation by $F(n, k)$; simplify; only rational functions remain: put them on the same denominator; the numerator is a polynomial in k and its coefficients should be zero: solve the corresponding system; if it does not have any non-trivial solution, increase I and J and try again. By summing over k , we get a recurrence relation for $f(n) = \sum_k F(n, k)$; solve it with the Hyper algorithm.

(The algorithm does not scale well: prefer the equivalent Zeilberger algorithm.)

2. Given a hypergeometric term $(t_k)_k$, *i.e.*, $r_k = t_{k+1}/t_k$ is a rational function of k , **Gosper’s algorithm** looks for another hypergeometric term $(z_k)_k$ such that $\Delta z = t$, *i.e.*, $z_{n+1} - z_n = t_n$; this gives a simple formula for the partial sums $s_n = \sum_{k=0}^{n-1} t_k = z_n - z_0$.

Since it computes an antiderivative of a hypergeometric series, it can be seen as an analogue of the Risch algorithm (differential Galois theory) for hypergeometric series.

The details are technical: write

$$r + n = \frac{a_n}{b_n} \frac{c_n + 1}{c_n}$$

with a, b, c polynomials and $\forall k \gcd(a_n, b_{n+k}) = 1$; find a polynomial x_n , if it exists, such that $a_n x_{n+1} - b_{n-1} x_n = c_n$; let

$$z_n = \frac{b_{n-1} x_n}{c_n} t_n.$$

3. Zeilberger’s algorithm (aka creative telescoping) is a (faster) variant of Sister Celine’s algorithm, to find a telescoping recurrence relation

$$F(n+1, k) - F(n, k) = G(n, k+1) - G(n, k)$$

or, more generally,

$$\sum_{j=0}^J a_j(n) F(n+j, k) = G(n, k+1) - G(n, k).$$

It is guaranteed to exist if F is a proper hypergeometric term:

$$F(n, k) = P(n, k) \frac{\prod_{i=1}^U (a_i n + b_i k + c_i)!}{\prod_{j=1}^V (u_j n + v_j k + w_j)!} x^k,$$

where P is a polynomial, U, V, a_i, b_i, u_j, v_j are integers (c_i and w_j are arbitrary).

Summing over k gives a recurrence relation for $s_n = \sum_k F(n, k)$ (the rhs cancels out if G has finite support in k for all n).

4. To prove hypergeometric identities, e.g., $\sum_k F(n, k) = 1$, the **Wilf-Zeilberger (WZ) algorithm** finds G (with compact support in k for all n) such that $F(n-1, k) - F(n, k) = G(n, k+1) - G(n, k)$, e.g., by applying Gosper's algorithm.

5. The **Hyper algorithm** finds the closed form solution, if it exists, of any recurrence with polynomial coefficients (*holonomic sequence*) by looking for a hypergeometric solution and reducing the problem to finding polynomial solutions of another recurrence (here, "closed form" means sum of hypergeometric series).

Note that the zeroes of the coefficients of the recurrence can make the dimension of the space of solutions larger than expected: checking that two solutions of a recurrence of degree k agree on just k points may not be sufficient to prove they are equal.

There are implementations of those algorithms in Maple (EKHAD) and Mathematica (Gosper, Hyper, WZ).

Deep reinforcement learning with double Q-learning H. van Hasselt et al. (2016)

Imprecise action values lead to overestimated values. Double Q learning, which learns two sets of weights, θ and θ' , randomly updating one of them at each step, and replaces the Q -learning target

$$\begin{aligned} Y_t^Q &= R_{t+1} + \gamma \text{Max}_a Q(S_{t+1}, a; \theta_t) \\ &= R_{t+1} + \gamma Q(S_{t+1}, \text{Argmax}_a Q(S_{t+1}, a, \theta_t), \theta_t) \end{aligned}$$

with $Y_t^Q = R_{t+1} + \gamma Q(S_{t+1}, \text{Argmax}_a Q(S_{t+1}, a, \theta_t), \theta'_t)$,

reduces the problem.

Tensorizing neural networks A. Novikov et al.

To reduce the memory footprint of large neural nets, one can use lower numeric precision, hashing, or low rank tensor approximations such as Tucker, CP or tensor train (TT). A TT decomposition of a tensor \mathcal{A} is a decomposition of each element as a product of matrices (the first and last factors are row and column matrices)

$$\mathcal{A}(j_1, \dots, j_d) = G_{1j_1} G_{2j_2} \cdots G_{dj_d}.$$

Correlation neural networks S. Chandar et al.

Canonical correlation analysis (CCA – for a C++ implementation, check `dlib`) solves the following problem: given two (vector) random variables X, Y , find x and y to maximize $\text{Cor}(x'X, y'Y)$; $x'X$ and $y'Y$ can be seen as a common representation of X and Y . An

auto-encoder can be used for the same purpose,

minimizing the sum of

- Reconstruction error of (X, Y) given (X, Y) ;
- Reconstruction error of (X, Y) given $(X, 0)$;
- Reconstruction error of (X, Y) given $(0, Y)$;
- Minus $\text{Cor}(h(X, 0), h(0, Y))$.

[One could also use a noisy auto-encoder: during training, replace either X or Y with noise.]

Semi-supervised learning with ladder networks A. Rasmus et al.

A *ladder network* is an auto-encoder with skip connections, to preserve details.

Scheduled sampling for sequence prediction with recurrence neural networks S. Bengio et al.

Neural networks outputting a sequence usually predict the next token from the current (hidden) state and the previous token – there may be a discrepancy between training and inference, the former using the true token while the latter only has the precious predicted token. Instead, during training, one can randomly choose to use the true or predicted token, with the probability of the true token decreasing as training progresses.

Learning both weights and connections for efficient neural networks S. Han et al.

For sparse neural nets: train; prune unimportant connections; iterate.

Minimum HGR correlation principle: from marginals to joint distribution F. Farnia et al.

The HGR correlation is

$$\begin{aligned} \rho(X, Y) &= \sup \{ E[f(X)g(Y)] : f, g \text{ measurable such} \\ &\quad \text{that } EfX = EgY = 0 \text{ and} \\ &\quad E(fX)^2 = E(gY)^2 = 1 \}. \end{aligned}$$

It is between 0 and 1, and is 0 (resp. 1) iff X and Y are independent (strictly dependent). The distribution with the minimum HGR correlation for given first and second moments is the Gaussian – this is an analogue of the maximum entropy property of the Gaussian distribution.

**Scalable Bayesian optimization
using deep neural networks**
J. Snoek et al.(2015)

Bayesian neural networks, *i.e.*, distributions over the weights of a neural net (instead of point estimates) are computationally expensive. They can be approximated by *adaptive basis regression*, *i.e.*, neural nets in which only the last, linear layer is Bayesian. Bayesian optimization with Gaussian processes scales cubically in the number of observations; adaptive basis regression is a linear alternative (random forests are another).

**Gradient-based hyperparameter optimization
through reversible learning**
D. Mcclaurin et al.

Backpropagation through the entire learning procedure, back to the hyperparameters, allows the use of gradient-based (instead of gradient-free Bayesian optimization) hyperparameter tuning. Storing all the intermediate results needed to compute the gradients is unreasonable (it would mean remembering all the iterations of the inner loop, on the mini-batches). It is however possible to run the optimization procedure backwards, provided we remember all the bits that fall off in floating point computations.

**Topological data analysis of contagion maps
for examining spreading processes on networks**
D. Taylor et al.

The Watts threshold model (WTM) map is obtained by simulating the WTM (a node becomes infected if the proportion of infected neighbours exceeds some threshold) and using the infection times (for various (singleton) infection seeds) as coordinates; dimension reduction may be needed.

**Compressing neural networks
with the hashing trick**
W. Chen et al.

To reduce the size of a neural net:

- Train a 1-layer net on the log-output of a deep net;
- Do not learn the full weight matrices but low rank approximations;
- Use feature hashing to reduce the weight matrices to a reasonable number of parameters.

**Analyzing big data
with dynamic quantum clustering**
M. Weinstein et al.

The *mean-shift* clustering algorithm starts with a cloud of points, computes a density estimator, moves each point uphill, and iterates. Dynamic quantum clustering (DQC) is a quantum-flavoured variant:

- Start with a cloud of points x_1, \dots, x_n ;
- Consider the density estimator $\phi(x) = \sum \phi(x_i)$,
 $\phi(x_i) = \exp -\frac{1}{2}(x - x_i)'(x - x_i)/\sigma^2$;

- Consider the potential V defined by $H\phi = 0$, where the Hamiltonian operator is

$$H = -\frac{1}{2\sigma^2}\nabla^2 + V(x);$$

- Move the densities towards this potential $\phi_1 \mapsto e^{-i\delta H}\phi_1$;
- Compute the new position of the points;
- Iterate.

**Input warping for Bayesian optimization
of non-stationary functions**
J. Snoek et al.

Gaussian processes (GP) usually model stationary processes: the covariance function $k(x, y)$ only depends on $x - y$. For non-stationary processes, one can use a hierarchical Bayesian model, including a transformation of the input space to make the process stationary. For instance, the cumulative distribution function of the beta distribution can model simple monotonic transformations: use a logarithmic prior on α and β to encode the prior belief in an exponential, logarithmic, linear, sigmoid or logit transformation.

**A sufficient and necessary condition
for global optimization**
D.H. Wu et al. (2010)

If f is Lebesgue-integrable, then

$$\text{essinf } f = \sup\{\alpha : V_{m,f}(\alpha) = 0\},$$

$$V_{m,f}(\alpha) = \int (\alpha - f(x))_+^m d\mu$$

$$V_{m,f}^{(m)}(\alpha) = m!\mu[f(x) \leq \alpha].$$

Use Monte Carlo simulations to estimate those integrals and turn the formula into a global optimization algorithm.

**Chemical equation balancing:
an integer programming approach**
S.K. Sen et al. (2006)

Balancing a chemical equation is a linear optimization problem:

$$\begin{array}{ll} \text{Find} & x \\ \text{To minimize} & x' \mathbf{1} \\ \text{Such that} & Ax = 0, \ x \geq \mathbf{1}, \ x \in \mathbf{Z}^n. \end{array}$$

The quadratic problem

$$\begin{array}{ll} \text{Find} & x \\ \text{To minimize} & x'x \\ \text{Such that} & Ax = 0, \ x \geq \mathbf{1}, \ x \in \mathbf{Z}^n \end{array}$$

may be easier to solve and often has the same solution.

***A new approach
to balancing chemical equations***
I.C. Risteski

Balancing a chemical equation means finding positive vectors, x and y , if they exist, so that $Ax = By$, where A and B have nonnegative entries. Try:

$$\begin{aligned}y &= (I - G^+G)u \\x &= A^+By + (I - A^+A)v \\G &= (I - AA^+)B\end{aligned}$$

for arbitrary vectors u and v . (You need to compute a pseudo inverse in \mathbf{Q} , exactly, or in $\mathbf{Z}/n\mathbf{Z}$, with n sufficiently large.)

***Mastering the game of Go
with deep neural networks and tree search***
D. Silver et al. (2016)

Consider a Go board as a 19×19 image and feed it to two deep convolutional neural nets, for forecast the next move (supervised learning from human games), and to estimate the value of a position; combine with Monte Carlo tree search (MCTS).

Ball arithmetic
J. van der Hoeven (2011)

For reliable computing, consider replacing interval arithmetic with ball arithmetic (sometimes called midpoint-radius arithmetic):

- While interval arithmetic require full precision for both ends of the intervals, ball arithmetic only needs full precision for the centers;
- On \mathbf{C} or $\mathbf{R}^{n \times m}$, intervals tend to grow faster than balls (e.g., $z \mapsto z^2$ around $z = 1 + i$).

Mathemagix if a (C++) software environment for certified numeric computations.

Arb: a C library for ball arithmetic
F. Johansson

Accurate special functions.

Bitcoin and cryptocurrency technologies
A. Narayanan et al. (Princeton & Coursera, 2015)

Non-technical but clear and comprehensive exposition of cryptocurrencies and their applications.

***Curve and surface reconstruction algorithms
with mathematical analysis***
T.K. Dey (2007)

The **skeleton** of a shape (curve, surface) $\Sigma \subset \mathbf{R}^k$ is the set of centers of balls that do not contain any point of Σ and cannot be enlarged while keeping this property. The **medial axis** M_Σ is its closure. It is also the closure of the set of points that have at least two closest points in Σ . [Those notions also

appear in *mathematical morphology*, a branch of image analysis.] The **local feature size** of $x \in \Sigma$ is $f(x) = d(x, M_\Sigma)$. A sample $P \subset \Sigma$ is an ε -sample if $\forall x \in \Sigma \exists p \in P \|x - p\| \leq \varepsilon f(x)$; if $\varepsilon < 1$, the sample is *dense*.

Given an ε -sample P of a closed plane curve Σ whose local feature size is always positive, one can find a piecewise approximation of Σ , as a subset of the Delaunay triangulation, as follows:

- Compute the Voronoi tessellation of P and the voronoi vertices V ; they approximate the median axis;
- Compute the Delaunay triangulation of $P \cup V$; keep the edges connecting two points of P .

Alternatively, link each point $p \in P$ to its nearest neighbour q and its half-neighbour s – the closest point s such that $\angle spq \geq \pi/2$. Both algorithms are $O(n \log n)$ and work if $\varepsilon < 1/5$, resp. $\varepsilon < 1/3$.

One can reconstruct a compact surface (without boundary) $\Sigma \subset \mathbf{R}^3$ from a sample P of points and its Voronoi tessellation:

- The normal at a point $p \in P$ can be approximated by the direction in which the Voronoi cell V_p is elongated; more formally, if V_p is unbounded, use the average direction v_p of the unbounded edges; if it is bounded, take the point $p^+ \in P$ farthest from p , then the point p^- farther from p among the points such that $\angle p^-pp^+ > \pi/2$ and set $v_p = p^- - p$;
- The surface in the neighbourhood of a point $p \in P$ can be approximated by the *cocone*: the complement of the double cone, centered on p , in the direction v_p , of angle $3\pi/8$, restricted to V_p ;
- Take the Voronoi edges that intersect the cocones; their duals are triangles in the Voronoi tessellation (but there are still too many);
- Remove triangles adjacent to “sharp” edges (angle $< 3\pi/2$);
- “Pockets” (blisters) remain on the approximate surface: remove them by walking on the outside.

***Topological anomaly detection performance
with multispectral polarimetric imagery***
M.G. Gartley and W. Basener (2009)

Outliers form the small connected components of the truncated graph.

Return to the Riemann integral
R.G. Bartle (1996)

A *tagged partition* of an interval $[a, b]$ is the datum of

$$a = x_0 < x_1 < \cdots < x_n = b$$

and, for each i , $t_i \in (x_{i-1}, x_i)$. The *Riemann sum* of a function $f : [a, b] \rightarrow \mathbf{R}$ on a tagged partition $((x_i)_i, (t_i)_i)$ is

$$R(f, (x_i)_i, (t_i)_i) = \sum_i f(t_i)(x_i - x_{i-1}).$$

A function f is *Riemann integrable*, of integral S , if

$$\begin{aligned} \forall \varepsilon > 0 \quad \exists \delta > 0 \quad \forall (x_i)_i, (t_i)_i \\ (\forall i \mid |x_i - x_{i-1}| < \delta) \implies |R(f, (x_i)_i, (t_i)_i) - S| < \varepsilon. \end{aligned}$$

The **generalized Riemann integral** replaces δ with a function $\delta : [a, b] \rightarrow \mathbf{R}^{>0}$, evaluated in t_i . The following functions are integrable:

- Riemann integrable functions: $\mathcal{R} \subset \mathcal{R}^*$;
- $\mathbf{1_Q}$;
- Lebesgue-integrable functions:

$$\mathcal{L} = \{f \in \mathcal{R}^* : |f| \in \mathcal{R}^*\};$$

- The derivative of (continuous) functions differentiable except at a countable number of points.

There is no need to add improper integrals: such functions are already integrable.

The convergence theorems from Lebesgue integration (uniform, monotone, dominated convergence) are still valid.

Regulated functions:

Bourbaki's alternative to the Riemann integral
S.K. Berberian (1979)

Another alternative (not a generalization) of the Riemann integral. *Regular functions* are functions with one-sided limits at each point; equivalently, they are uniform limits of step functions. For every regulated function f , there is a function F , differentiable except perhaps at countably many points, with $F' = f$ (the converse is not true). Regulated functions are Riemann integrable.

A friendly introduction to RGP

O. Flasch (2014)

The **rgp** package provides genetic programming (symbolic regression) and typed genetic programming (idem, with higher-order functions); it can be used with **emoa** for multiobjective optimization and **SPOT** for hyperparameter tuning. Alternatives include **ECJ** (Java), **GPTIPS** (Matlab) and, on the commercial side, **Data-Modeler**, **Discipulus** and **Eureqa**.

Gradient boosting machines, a tutorial

A. Natekin and A. Knoll (2013)

Boosting builds an ensemble model by fitting simplistic models (base learners, weak learners) to the data, with more weight on the observations currently misclassified by the ensemble. **Gradient boosting** gives an interpretation of this algorithm as a gradient descent, not

in parameter space, but in function space, *i.e.*, we do not look at

$$\sum_i \frac{\partial \text{Loss}(y_i, h(x_i, \theta))}{\partial \theta} \quad \text{but} \quad \sum_i \frac{\partial \text{Loss}(y, \hat{y})}{\partial \hat{y}} \bigg|_{\substack{y=y_i \\ \hat{y}=f(x_i)}}.$$

More precisely, we iterate:

$$\begin{aligned} (\rho_t, \theta_t) &= \underset{\rho, \theta}{\text{Argmin}} \sum_i \left[-\frac{\partial \text{Loss}(y, \hat{y})}{\partial \hat{y}} \bigg|_{\substack{y=y_i \\ \hat{y}=f_{t-1}(x_i)}} - \rho h(x_i, \theta) \right]^2 \\ f_t &\leftarrow f_{t-1} + \rho_t h(\cdot, \theta_t) \end{aligned}$$

The weak learners can be: linear regression, ridge regression, mixed model, splines, radial basis functions, GAM, tree stumps, trees with a maximum interaction depth (5 is good enough), wavelets (Viola-Jones face detection algorithm), etc.

The loss function can be: L^2 , L^1 , Huber, quantile loss, binomial loss $\log(1 - e^{-y\hat{y}})$, Adaboost loss $e^{-y\hat{y}}$, etc.

Generalizations include:

- If there are many variables, fit the base learners on a random subset of the variables, several times, and keep the best fit – this gives a sparser model;
- Subsampling (bagging);
- Shrinkage: $f_t \leftarrow f_{t-1} + \lambda \rho_t h(\cdot, \theta_t)$;
- Early stopping – this is needed; the optimal number of iterations depends on the step size λ and can be estimated by cross-validation.

Laplacian eigenmaps for dimensionality reduction and data representation

M. Belkin and P. Niyogi (2002)

Given a cloud of points x_1, \dots, x_N , build a graph, with those points as vertices, and an edge when the distance between two points is below some threshold, or when one is among the k nearest neighbours of the other; use 1 or $w_{ij} = \exp - \|x_i - x_j\|^2 / t$ as weights (similarities).

Spectral dimension reduction solves the generalized eigenvalue problem $Lf = \lambda Df$, where $D = \text{diag}(W\mathbf{1})$ and $L = D - W$,

$$Lf_i = \lambda_i Df_i \quad 0 = \lambda_0 \leq \lambda_1 \leq \dots \leq \lambda_m,$$

and uses f_1, \dots, f_m as coordinates.

In dimension 1 (Fiedler vector), this can be justified as follows: we want a 1-dimensional embedding $(y_1, \dots, y_N) \in \mathbf{R}^N$ so that points that should be close (W_{ij} large) be close, e.g., by minimizing $\sum_{ij} (y_i - y_j)^2 W_{ij}$, with some normalization constraint, e.g., $\|y\|^2 = 1$ or $y'Dy = 1$ (in order to avoid the trivial solution $y = \mathbf{1}$, we also add $y \perp \mathbf{1}$, *i.e.*, $y'D\mathbf{1} = 0$ – this will give the smallest eigenvalue, skipping zero). Noticing that $\sum (y_i - y_j)^2 W_{ij} = y'Ly$, the optimization problem becomes

$$\begin{aligned} \text{Find} \quad & y \in \mathbf{R}^N \\ \text{To minimize} \quad & y'Ly \\ \text{Such that} \quad & y'Dy = 1 \text{ and } y'D\mathbf{1} = 0 \end{aligned}$$

and can be solved with Lagrange multipliers

$$\begin{aligned} f(y) &= y'Ly \\ g(y) &= y'Dy \\ \nabla f &= \lambda \nabla g, \end{aligned}$$

i.e., $Ly = \lambda Dy$ – a generalized eigenvalue problem.

This interpretation remains valid in a continuous setting, *i.e.*, if we replace the cloud of points with a compact manifold M :

$$\begin{aligned} \text{Find} \quad & f : M \rightarrow \mathbf{R}, \mathcal{C}^2 \\ \text{To minimize} \quad & \int \|\nabla f\|^2 \\ \text{Such that} \quad & \|f\|^2 := \int_M f^2 = 1 \\ & \langle f, 1 \rangle := \int_M f = 0 \end{aligned}$$

where $\|\nabla f\|$ estimates how far apart f maps nearby points. The objective can be written $\int \|\nabla f\|^2 = \int \langle \nabla f, \nabla f \rangle = \int \langle \nabla^* \nabla f, f \rangle = \int \mathcal{L} f \cdot f$, where $\mathcal{L} = \nabla^* \nabla = -\operatorname{div} \nabla$ is the Laplace-Beltrami operator (that is the name of the Laplace operator on a Riemannian manifold); it is positive semidefinite and (if M is compact) its spectrum is discrete $0 = \lambda_0 \leq \lambda_1 \leq \dots$. The first eigenvalues give a low-dimensional embedding.

To find two clusters in a weighted graph, one can try to find a partition $V = A \amalg B$ that minimizes

$$\operatorname{Cut}(A, B) = \sum_{\substack{u \in A \\ v \in B}} W_{uv},$$

but this tends to cut off weakly-connected outliers. Instead, one can minimize the normalized cut

$$\operatorname{NCut}(A, B) = \operatorname{Cut}(A, B) \left(\frac{1}{\operatorname{vol} A} + \frac{1}{\operatorname{vol} B} \right),$$

where $\operatorname{vol} A = \sum_{\substack{u \in A \\ v \in V}} W_{uv}$. By setting

$$x_1 = \begin{cases} 1/\operatorname{vol} A & \text{if } i \in A \\ 1/\operatorname{vol} B & \text{if } i \in B, \end{cases}$$

one can see that

$$\begin{aligned} \operatorname{NCut}(A, B) &= \frac{x' L x}{x' D x} \\ x' D \mathbf{1} &= 0; \end{aligned}$$

the relaxed minimum normalized cut problem, aka **spectral clustering**, is a generalized eigenvalue problem.

The local linear embedding (LLE) algorithm builds an unweighted graph from a cloud of points; the barycentric coordinates W_{ij} minimize $\sum_i \|x_1 - \sum_j W_{ij} x_j\|^2$, and are normalized by $\forall i \sum_j W_{ij} = 1$; the embedding is given by the k lowest eigenvalues of $E = (I - W)'(I - W)$. One can see that $E \approx \frac{1}{2} L^2$ (under some conditions); the eigenvectors are the same as those of L .

Constructing Laplace operator from point clouds in \mathbf{R}^d M. Belkin et al.

One can approximate the Laplace operator L on a submanifold $M \subset \mathbf{R}^d$ of (known) dimension k from a finite sample of points $P \subset M$ as follows:

- Approximate the tangent space at $p \in P$, for instance by the k plane Q^* through p best fitting $P_r = P \cap B(p, r)$, *i.e.*, minimizing the 1-sided Hausdorff distance $d_H(P_r, Q^*) = \sup_{p \in P_r} \inf_{q \in Q^*} d(p, q)$; an approximation \hat{T}_p of Q^* is sufficient;
- Build the Delaunay triangulation K_δ of the projection $\pi(P_\delta)$ or P_δ on \hat{T}_p ;
- For a function $f : P \rightarrow \mathbf{R}$, set $Lf(p)$ to

$$\sum_{\substack{\sigma: k\text{-dim} \\ \text{face of } K_\delta}} \frac{\operatorname{vol} \sigma}{k+1} \sum_{q \in V(\sigma)} [f(p) - f(\pi^{-1}q)] e^{-\frac{\|f(p) - f(\pi^{-1}q)\|^2}{4t}}.$$

Contrary to other implementations (e.g., the adjacency matrix with Gaussian weights), it does not assume that the points are drawn uniformly from M and does not require a global mesh (given a mesh, one can use the same formula, with the whole mesh instead of K_δ , and the tangent space is not needed ($\pi = \operatorname{id}$) – this is the **mesh-Laplace operator**).

Convergence, stability and discrete approximation of Laplace spectra T.K. Dey et al.

The mesh-Laplace operator gives a good approximation of the Laplace operator (pointwise convergence) and a good (accurate, robust) approximation of its spectrum.

The spectrum of the Laplacian gives some information on the manifold, e.g., its volume (Weyl's law: $\lambda_n \sim 4\pi n / \operatorname{Vol} M$) or its total curvature.

Differential representation for mesh processing O. Sorkine (2006)

The graph Laplacian of a mesh in \mathbf{R}^3 can be interpreted as the linear transformation from coordinates

to δ -coordinates (useful, e.g., for mesh editing)

$$\begin{aligned} L : v_i &\mapsto \delta_i = v_i - \frac{1}{|N(i)|} \sum_{j \in N(i)} v_j \\ &= \frac{1}{|N(i)|} \sum_{j \in N(i)} v_i - v_j, \end{aligned}$$

i.e., $L = I - D^{-1}A$, symmetrized $L_{\text{sym}} = DL = D - A$, $L_{\text{sym}}x = D\delta_x$. There are many variants, e.g.,

$$\begin{aligned} \delta_i &= \frac{1}{|\Omega_i|} \sum_j \frac{1}{2} (\cot \alpha_{ij} + \cot \beta_{ij}) (v_i - v_j) \\ \delta_i &= \frac{1}{|\Omega_i|} \sum_j \frac{\tan(\theta_{ij}^1/2) + \tan(\theta_{ij}^2/2)}{\|v_i - v_j\|} (v_i - v_j) \end{aligned}$$

where $|\Omega_i|$ is the volume of the Voronoi cell of i , α_{ij} , β_{ij} are the angles opposite the edge (ij) , θ_{ij}^1 , θ_{ij}^2 are the angles at i along (ij) .

Reconstructing the coordinates from the δ -coordinates (with a few positional “constraints” on some of the vertices) can be approached as a least squares problem.

If the mesh is known (e.g., a character in a video game – the mesh is just deformed as it moves), we can use the eigenfunctions of the Laplacian to encode the coordinates (it is not really necessary to compute the eigenfunctions: the reconstruction can also be reduced to a least squares problem).

Distilling the knowledge in a neural network **G. Hinton et al.**

To transfer the information in a complex model to a smaller model (model compression, model distillation), one often trains the smaller model to reproduce the output of the complex one on a very large (unlabeled) dataset. In the case of a multiclass classification problem, since there is information in the low probabilities, one can, instead of reproducing the output classes of the complex model, reproduce its probabilities or, rather, their logits. Even better, one can increase the temperature in the learning phase (to help learn smaller probabilities), and set it back to 1 afterwards.

A SQP method for general nonlinear programs using only equality constrained subproblems **P. Spellucci**

The `donlp2` algorithm solves a nonlinear program with equality and inequality constraints by taking a second order approximation of the objective, linearizing the constraints, replacing some inequalities with equalities and discarding the others. The subtleties reside in the choice of the inequalities to keep as equalities (those violated or near-active) or to discard, and how to deal with inconsistent quadratic programs.

Q-learning and SARSA: a comparison between two intelligent stochastic control approaches to financial trading **M. Corazza and A. Sangalli**

Misguided attempt to apply reinforcement learning (RL) to trading, using the past returns as state: they use the *past* Sharpe ratios as rewards – by construction, this will give a momentum strategy.

Universal value function approximators **T. Schaul et al. (2015)**

The value function approximator $V(s; \theta)$ learnt in reinforcement learning can be generalized to account for various goals (e.g., a single desired final state), $V(s, g; \theta)$, and used for planning (do not try to get to the final goal from the start; try to reach intermediate milestones first).

Weighted Voronoi stippling **A. Secord (2002)**

Stippling (non-photorealistic rendering) with weighted *centroidal Voronoi diagrams*, i.e., Voronoi diagrams in which the generators are the centroids of their cell.

Modern C **J. Gustedt (2015)**

Long presentation of C11.

Abstract tensor systems and diagrammatic representations **J. Lazovskis (2012)**

Formalization of Penrose’s diagrammatic tensor calculus, with a focus on Lie algebras.

Sampling for inference in probabilistic models with fast Bayesian quadrature **T. Gunter et al.**

Bayesian quadrature is a faster variant of MCMC. For positive integrands (e.g., a likelihood), use a Gaussian process prior on its square root or its logarithm.

Probabilistic line searches for stochastic optimization **M. Mahsereci and P. Hennig**

Stochastic gradient descent (SGD) has two problems:

- The gradient (even if it were not noisy) is not the best direction: use momentum, AdaGrad, etc.;
- One must choose the learning rate or resort to an expensive line search: instead of a line search, try Bayesian optimization.

Sequential Bayesian prediction in the presence of changepoints and faults **R. Garnett (2009)**

List of covariance structures to detect change points with Gaussian processes (GP):

- Drastic changepoint: the observations before and after are independent – the result is discontinuous;
- Continuous drastic changepoint: the observations before and after are independent conditionally on the value at the changepoint;
- Change in input and/or output scales,

$$K(x, y) = \lambda_{\text{out}}^2 \kappa \left(\frac{|y - x|}{\sigma_{\text{in}}} \right);$$

- Faults: bias, stuck value, drift, etc.

RRegrs: an R package for computer-aided model selection with multiple regression models
G. Tsiliki et al. (2015)

To estimate, compare and choose between 10 regression models: linear, lasso, elastic net, SVM, neural net, random forest, recursive feature elimination (fit the full model, rank the features, take the top k , re-fit the model, keep the best of those smaller models), etc., via `caret`.

Bellman's GAP: a 2nd generation language and system for algebraic dynamic programming
G. Sauthoff (2011)

Textbook dynamic programming (DP) is straightforward, but real-life DP can involve more tables, more recurrence relations, more indices (for instance, sequence alignment with affine gap penalty requires several tables). Algebraic dynamic programming (ADP) simplifies DP by describing the search space (e.g., the set of all possible alignments) with a grammar – this removes all the indices. “Bellman’s GAP” is a Java-like programming language for ADP. Alternatives include Haskell- or Ocaml-based DSLs and/or code generators and may not scale well.

Categorification of persistent homology
P. Bubenik and J.A. Scott (2014)

Persistent homology can be expressed in categorical terms. An ε -interleaving between $F, G : (\mathbf{R}, \leq) \rightarrow \mathcal{D}$ is a pair of natural transformations

$$\begin{array}{ccc} (\mathbf{R}, \leq) & & (\mathbf{R}, \leq) \\ \downarrow T_\varepsilon & \searrow F & \searrow G \\ (\mathbf{R}, \leq) & \xrightarrow{G} & \mathcal{D} \\ \downarrow T_\varepsilon & \searrow F & \searrow G \\ (\mathbf{R}, \leq) & \xrightarrow{G} & \mathcal{D} \end{array}$$

where T_ε is the translation, such that

$$\begin{array}{ccccc} F(a) & & & & F(b) \\ & \searrow & & \swarrow & \\ & G(a + \varepsilon) & \longrightarrow & G(b + \varepsilon) & \\ & \swarrow & & \searrow & \\ F(a + 2\varepsilon) & & & & F(b + 2\varepsilon) \\ & \searrow & & \swarrow & \\ & G(a + 3\varepsilon) & \longrightarrow & G(b + 3\varepsilon) & \end{array}$$

This defines an *interleaving distance*

$$d(F, G) = \inf \{ \varepsilon : F, G \text{ } \varepsilon\text{-interleaved} \}.$$

For any functor H , $d(HF, HG) \leq d(F, G)$. In $\mathcal{V}\text{ec}^{(\mathbf{R}, \leq)}$, *tame* diagrams (constant on a neighbourhood of each $t \in \mathbf{R}$, except a finite number of them) are of *finite type*; they can be described as *barcodes*. The *bottleneck distance* on barcodes defines an isometric embedding $\{\text{barcodes}\} \hookrightarrow \mathcal{V}\text{ec}^{(\mathbf{R}, \leq)}$. Given $f, g : X \rightarrow \mathbf{R}$ (not necessarily continuous), consider their lower level sets $F, G : (\mathbf{R}, \leq) \rightarrow \mathcal{T}\text{op}$; let $H : \mathcal{T}\text{op} \rightarrow \mathcal{D}$ be a functor; then, $d(HF, HG) \leq \|f - g\|_\infty$, i.e., H is stable to perturbations; this applies to persistent homology or relative homology. If \mathcal{D} is abelian, the category of ε -interleavings of diagrams $(\mathbf{R}, \leq) \rightarrow \mathcal{D}$ is also abelian.

Econometrics: methods and applications
P.H. Frances et al. (Coursera, 2015)

Linear models assume that the predictive variables are not stochastic. In the model $Y = X_1\beta_1 + X_2\beta_2 + \varepsilon$, the predictive variable X_1 is **endogenous** if $\text{Cor}(X_1, \varepsilon) \neq 0$: the ordinary least squares estimate $\hat{\beta}_1$ is then inconsistent. This can happen if a variable correlated with X_1 has been omitted, if there is a feedback mechanism between the predictive variables (e.g., when predicting sales from price and demand, it may seem that higher prices are good for sales, but higher prices may just come from higher demand), or if there are measurement errors (we do not observe X_1 but $X_1 + \eta$).

To address endogeneity, **2-stage least squares** (2SLS) looks for **instrumental variables** (IV) Z , i.e., variables Z that affect y only through X : $\text{Cor}(Z, X) \neq 0$, $\text{Cor}(Z, \varepsilon) = 0$ and uses them to find β : $\text{Cov}(Z, y) = \text{Cov}(Z, X)\beta$. The computations can also be done using two linear regressions ($X \sim Z$, then $y \sim \hat{X}$).

The method is consistent if $\frac{1}{n}Z'\varepsilon \rightarrow 0$ (Z and ε are uncorrelated), $\lim \frac{1}{n}Z'Z$ invertible (Z is not multicollinear), $\lim \frac{1}{n}Z'X$ has rank k (the number of variables – Z and X are sufficiently correlated). In particular, you need at least as many instruments as predictive variables (use the intercept and the exogenous variables as instruments: there will be fewer to find).

The **Sargan test** checks if $H_0 : \text{Cor}(Z, \varepsilon) = 0$ by approximating the residuals using 2SLS: estimate $\hat{X} = Z(Z'Z)^{-1}Z'X$ (1S), estimate $b = (\hat{X}'\hat{X})^{-1}\hat{X}'y$ (2S), compute the residuals $e = y - Xb$ (this is X , not \hat{X}), compute the R^2 of $e \sim Z$: under the null hypothesis, it is small, and $nR^2 \sim \chi^2(m - k)$ (where m is the number of instruments and k the number of variables in X).

The **Hausmann test** for “ $H_0 : X_1$ is actually exogenous” uses the R^2 of $\text{res}(y \sim X) \sim X + \text{res}(X_1 \sim Z)$: it should be small and $nR^2 \sim \chi^2(k_1)$.

The course also covered variable selection (forward or backward, using T or F tests, AIC, BIC, L^2 (RMSE) or L^1 (MAE) norm of the residuals), pseudo- R^2 for logistic regression (McFadden, Nagelkerke), time series (ARMA, unit roots, cointegration, Granger causality) and many regression tests:

- Regression specification (RESET): add the powers of

the fitted values $y_1 = x'_i\beta + \sum_{j=1}^p \gamma_j \hat{y}_i^{j+1} + \varepsilon_i$ (instead of the powers of x) and perform an F test for $H_0 : \forall j \gamma_j = 0$ (it is approximate because the \hat{y}_i are not fixed predictors);

- Chow break test: split the data in two, at a potential break point, and use an F test for $H_0 : \beta_{\text{before}} = \beta_{\text{after}}$;
- Chow forecast test: linear before the break, perfect fit after: $y_i = x'_i\beta + \sum_{j=n_1+1}^{n_1+n_2} \gamma_j \delta_{ji} + \varepsilon_i$, $H_0 : \forall j \gamma_j = 0$;
- Jarque-Bera normality test (for the residuals): some combination of the sample skewness and kurtosis of a Gaussian variable is approximately $\chi(2)$ -distributed.

Integer relation detection **D.H. Bailey (2000)**

Given x_1, \dots, x_n (high-precision) floating-point numbers, the **PSLQ** algorithm looks for integers k_1, \dots, k_n , not all zero, so that $\sum_i k_i x_i = 0$. Given a number α of interest, apply it to:

- $1, \alpha, \alpha^2, \dots, \alpha^n$ to show that α is a root of a simple polynomial;
- $\alpha, \zeta(1), \zeta(2), \dots, \log 2, \log 3, \dots, \pi, \pi^2, \dots, \text{Li}_k(\ell), \pi^k \zeta(\ell)$, etc. to find interesting relations.

It was also used to find a base-16 expansion of π .

For n numbers and integer coefficients with at most d digits, you need at least nd significant digits.

The LLL algorithm has similar applications.

It is available in a C++ library, in GAP, perhaps also from SAGE via `mpmath` and/or `GMP`.

The decompositional approach to matrix computation **G.W. Stewart (2000)**

The “big six” matrix decompositions are:

- Cholesky: $A = RR'$ (or $A = LDL'$), where A is positive definite and R upper-triangular; used to solve $A'x = b$ or compute $x'A^{-1}x$;
- LU: $P'AQ = LU$, where A is square, L lower-triangular, U upper-triangular, P and Q permutations; used to solve $Ax = b$;
- QR: $A = QR$, where Q is orthogonal and R upper-triangular with non-negative diagonal elements; used in least-squares estimation: QQ' is the projection on $\text{Im } A$;
- Spectral decomposition: $A = V\Lambda V'$, where A is symmetric, V orthogonal and Λ diagonal;
- Schur: $A = UTU^*$, where A is square, U unitary, T upper-triangular; sometimes an intermediate step in eigenvalue problems;
- SVD: $A = U\Sigma V'$, where U and V have orthogonal columns and Σ is diagonal.

Using multi-complex variables for automatic computation of high-order derivatives **G. Lantoin et al (2012)**

The first derivative of an analytic function $f : \mathbf{R} \rightarrow \mathbf{R}$ can be approximated as $f'(x) = \text{Im} \frac{f(x+ih)}{h} + o(h)$. For higher derivatives, use **multicomplex numbers**,

$$\mathbf{C}_n = \frac{\mathbf{R}[i_1, \dots, i_n]}{(i_1^2 + 1, \dots, i_n^2 + 1)}$$

$$f^{(n)}(x_0) \approx \text{Im}_{1,2,\dots,n} \frac{f(x_0 + hi_1 + \dots + hi_n)}{h^n}$$

For higher derivatives, some have also suggested to use Cauchy’s formula,

$$\oint_C \frac{f(z)}{z - z_0} dz = 2\pi i f(z_0),$$

which generalized to

$$f^{(n)}(z_0) = \frac{n!}{2\pi i} \oint_C \frac{f(z)}{(z - z_0)^n} dz.$$

Learning to discover efficient mathematical identities **W. Zaremba et al.**

The set of equivalent reformulations of a mathematical expression (e.g., `sum((A*B)^6)`, where A and B are matrices) form a graph, with edges corresponding to valid transformations. Computer algebra systems (Maple, Mathematica) use a set of heuristic rules to explore this graph and return a simpler expression (either a shorter one, or one with a lower algorithmic complexity). One can also use random exploration.

Instead, machine learning (e.g., n -grams, or RNN) can guide the exploration.

A contextual-bandit approach to personalized news article recommendation **L. Li et al.**

There are 3 classes of bandit algorithms:

- ε -greedy (with decaying ε);
- Upper confidence bounds (UCB);
- Bayesian approaches (Gittins index).

LinUCB generalizes UCB to contextual bandits: if the reward is linear, i.e., $E[r_a|x_a] = x'_a \theta_a$, θ_a unknown, a = arm, a confidence interval can be computed in closed form.

Frequentism and Bayesianism: a Python-driven primer **J. VanderPlas (2014)**

Frequentist confidence intervals can be problematic: for instance, for the truncated exponential $P(x|\theta) = e^{\theta-x} \mathbf{1}_{x>\theta}$ and the observed data $\{10, 12, 15\}$, the 95% confidence interval is $(10.2, 12.2)$, even though we know that $\theta < 10$ – the corresponding bayesian **credible interval** is $(9.0, 10.0)$.

The paper also details Bayesian linear regression, with `emcee` (affine invariant ensemble MCMC), `PyMC` (Metropolis-Hastings) and `PyStan` (Hamiltonian

MCMC), and explains how to choose an uninformative prior: we want it to be invariant under the transformations $(x, y) \mapsto (y, x)$ and $(x, y) \mapsto (\lambda x, \lambda y)$ – this second transformation gives the **Jeffreys prior** for the variance, $P(\sigma) \propto 1/\sigma$.

**An object-oriented framework
for robust multivariate analysis**
V. Todorov and P. Filzmoser (2009)

The **rrcov** package provides robust estimators of scale and location:

- **Minimum covariance determinant (MCD)**: mean and variance of the k observations whose covariance matrix has the smallest determinant (heuristically: start with k points, compute $\hat{\mu}$ and \hat{V} , $d_i^2 = (x_i - \hat{\mu})' \hat{V}^{-1} (x_i - \hat{\mu})$, take the k points with the smallest distance, iterate);
- **Minimum volume ellipsoid (MVE)** that contains at least half the data;
- **Stahel-Donoho**: weighted mean and covariance,

$$w_i = \text{Min} \left\{ 1, \left(\frac{c}{r_i} \right)^2 \right\}$$

$$r_i = \text{Max}_a r(x_i, a) \quad \text{outlyingness}$$

$$r_i(x_i, a) = \frac{|x_i' a - m(a' X)|}{s(a' X)} \quad \text{outlyingness in direction } a$$

m, s : robust 1-dimensional location and scale;

- **Orthogonalized Gnanadesikan-Kettenring (OGK)**: given a robust 1-dimensional scale σ , define robust covariances

$$s_{ij} = \frac{1}{4} \left[\sigma \left(\frac{X_i}{\sigma X_i} + \frac{X_j}{\sigma X_j} \right)^2 - \sigma \left(\frac{X_i}{\sigma X_i} - \frac{X_j}{\sigma X_j} \right)^2 \right]$$

and tweak the resulting covariance matrix to make it positive semidefinite;

- **S-estimator**: solution of the optimization problem

$$\begin{array}{ll} \text{Find} & \mu, V \\ \text{To minimize} & \sigma(d_1, \dots, d_n) \\ \text{Such that} & \det V = 1 \end{array}$$

where $d_i = (x_i - \mu)' V^{-1} (x_i - \mu)$, and σ is an M-estimator of scale, *i.e.*, $\frac{1}{n} \sum \rho(z/\sigma) = \delta$, $\delta \in (0, 1)$, $\rho : \mathbf{R}_+ \rightarrow [0, 1]$ increasing from 0 to 1.

It also provides **robust PCA**:

- PCA using a robust variance matrix;
- Projection pursuit, *i.e.*, finding the direction in which some quantity (a robust 1-dimensional estimator of scale) is maximal;
- Huber's method: consider all the directions defined by pairs of points, and project the data on those directions; for each point and each of those directions, compute the normalized distance to the center, using 1-dimensional robust estimators of location and scale; use the k points with the lowest distance.

Robust principal component analysis?
E.J. Candès (2009)

If a matrix is the sum of a (dense) low-rank and a sparse matrix, $M = L + S$, the components can be recovered by solving the convex optimization problem

$$\begin{array}{ll} \text{Find} & L, S \\ \text{To minimize} & \|L\|_* + \lambda \|S\|_1 \\ \text{Such that} & L + S = M, \end{array}$$

where $\|\cdot\|_*$ is the nuclear norm (sum of the singular values). Depending on the application, L or S may be of interest.

**Introduction to numerical methods
in differential equations**
M.H. Holmes (2007)

1. To solve an *initial-value problem* (IVP), *i.e.*, an ordinary differential equation (ODE) of the form $y' = f(y, x)$, $y(0) = \alpha$, one can discretize the derivative. There are many ways of doing that (forward Euler, backward Euler, centered, leapfrog, etc.) and the resulting numeric schemes have different stability properties.

A numeric scheme is **A-stable** if the numeric solution of $y' = -ry$, $y(0) = \alpha$ remains bounded (the exact solution decays exponentially). This equation is chosen because, near a stable (constant) solution, all ODEs look like that. A scheme is *conditionally A-stable* if it is stable when the step size is sufficiently small. It is *strictly A-stable* if the solution converges to zero. It is *monotone A-stable* if the solution is monotonic. The forward (Euler) scheme is conditionally (monotone) A-stable and explicit; the backward scheme is (monotone) A-stable but implicit; the leapfrog method is unstable.

One can also integrate the equation, $y_{i+1} - y_i = \int_{t_i}^{t_{i+1}} f(y, t) dt$ and use numeric integration, *e.g.*, left box, right box, midpoint, trapezoidal rule (implicit, A-stable, $O(h^2)$, conditionally monotone), Simpson's rule, etc. The Adams method approximates f with a function that can be integrated exactly (for instance, a quadratic approximation gives Simpson's rule).

The trapezoidal method is $O(h^2)$, but it is implicit.

$$\begin{aligned} y_{i+1} &= y_i + \frac{1}{2} h (f_i + f_{i+1}) \\ f_i &= f(t_i, y_i) \\ f_{i+1} &= f(t_{i+1}, y_{i+1}). \end{aligned}$$

It can be turned into an explicit method by replacing f_{i+1} , which we do not know yet, by its Euler approximation: the second order *Runge-Kutta* (RK) method (Heun) is $O(h^2)$, explicit, conditionally A-stable.

$$\begin{aligned} y_{i+1} &= y_i + \frac{1}{2} (k_1 + k_2) \\ k_1 &= h f(t_i, y_i) \\ k_2 &= h f(t_{i+1}, y_i + k_1) \end{aligned}$$

The popular RK4 method uses a similar idea, with Simpson's rule.

Newton's equation, $my'' = F(y)$, conserves energy, $H(t) = \frac{1}{2}my'^2 + V(y)$, where $V'(y) = -F(y)$, but not all numeric schemes do. The trapezoidal method does, but it is implicit. The *velocity Verlet method* simply replaces it with its Euler approximation (it is preferred to RK4 in physics). It does not exactly conserve energy, but almost: it is *symplectic*.

2. A *boundary value problem* (BVP) is an ODE of the form $y'' = f(x)$, $y(0) = \alpha$, $y(1) = \beta$.

If the equation is linear, $y'' + p(x)y' + q(x)y = f(x)$, the centered approximations of y' and y'' give a tridiagonal system (choose a step size $h < 2/\|p\|_\infty$). If the condition number is 10^n (it is $O(N^2)$, where N is the number of steps), do not expect more than $15 - n$ significant digits.

The discretization of non-linear BVP gives a non-linear system of equations, which can be solved by Newton's method (the Jacobian is tridiagonal); the solution need not be unique.

Residual methods look for solutions of the form $y(x) = \sum a_k \phi_k(x)$, for some basis functions ϕ_k (B-splines, Fourier) so that the residual be zero on a grid (*collocation*) or minimal in L^2 norm (least squares).

Shooting methods solve the IVP $y(0) = \alpha$, $y'(0) = s$, and adjust s so that $y(1) = \beta$, hoping the problem is not ill-conditioned.

3. The heat equation

$$\begin{aligned} D \frac{\partial^2 u}{\partial x^2} &= \frac{\partial u}{\partial t} \\ u(0, t) &= u_{\text{left}}(t) \\ u(1, t) &= u_{\text{right}}(t) \\ u(x, 0) &= g(x) \end{aligned}$$

is a parabolic equation: it is a *diffusion* (it tends to smooth the initial condition – g need to be continuous, but u will), it satisfies the *maximum principle* (the maximum and minimum of u are on the boundary) and has the *instant messaging* property (even if $u(\cdot, 0)$ is zero on some interval, it immediately becomes non-zero).

The explicit method (forward difference for time, centered for space), with *stencil*

does not satisfy the instant messaging property and has stability problems as t increases. (PDEs have ad hoc notions of stability, e.g., by looking at how an oscillatory initial condition evolves; the explicit method requires $k = O(h^2)$, where k is the time step and h the space step.) The implicit method (backward dif-

ference)

has the instant messaging property and is stable. Numerical simulations suggest that the exact solution often lies between the explicit and implicit ones. The *theta method* mixes a proportion θ of explicit and $1 - \theta$ of implicit.

For $\theta = \frac{1}{2}$ (Crank-Nicolson – the most widely used method for parabolic equations), the error is $O(h^2) + O(k^2)$ (instead of $O(h^2) + O(k)$). The trapezoidal rule (for time) also gives the Crank-Nicolson method. It is not robust to the presence of jumps.

The *method of lines* discretizes only the space: this gives a family of coupled ODEs.

Residual methods, approximating the solution as $u(x, t) = \sum q_k(t)B_k(x)$, can also be used.

4. The advection equation is

$$\frac{\partial u}{\partial t} + a \frac{\partial u}{\partial x} = 0, \quad u(x, 0) = g(x), \quad a > 0.$$

It can be solved exactly with a change of variables: $u(x, y) = g(x - at)$. Contrary to the heat equation, jumps in the initial condition g are preserved (strictly speaking, this is a weak solution). The upwind and downwind explicit schemes (forward difference in time, backward or forward in space)

have different *domains of dependence*.

The downwind scheme will not work. For the upwind one, the exact domain of dependence is included in the numeric one (Courant-Friedrichs-Lewy (CFL) condition – this did not happen with the heat equation) if $ak/h \leq 1$. More generally, one could look at methods of the form $u_{i,j+1} = Au_{i+1,j} + Bu_{i,j} + Cu_{i-1,j}$, compute a Taylor expansion of the error and set to zero as many terms as possible. Implicit methods tend to have an infinite domain of dependence, which is not desirable for advection equations.

5. The wave equation is

$$\begin{aligned} c^2 \frac{\partial^2 u}{\partial x^2} &= \frac{\partial^2 u}{\partial t^2} \\ u(0, t) &= u(1, t) = 0 \\ u(x, 0) &= f(x) \\ u_t(x, 0) &= g(x). \end{aligned}$$

It can be solved by separation of variables (Fourier series) or by a change of variable. Jumps in the initial conditions are preseved. The domain of dependence is

To study the stability of hyperbolic equations (or of their discretizations), look for solutions of the form $u(x, t) = e^{i(kx - \omega t)}$. For the wave equation, this gives $\omega = \pm ct$. For other equations (Klein-Gordon, $c^2 u_{xx} = u_{tt}$; modified advection, $u_t + au_x + bu = 0$; beam, $u_{xxxx} + u_{tt} = 0$; advection-diffusion, $Du_{xx} = u_t + au_x$; etc.), it may be complex, $u(x, t) = e^{at} e^{i(kx - bt)}$. The equation is *stable* if $\text{Im } \omega \leq 0$ (for all k), *non-dispersive* if $\text{Re } \omega \propto k$ (the speed of the wave does not depend on the wavelength), *non-dissipative* if $\text{Im } \omega = 0$ (for all k). The explicit method (centered differences)

satisfies the CFL condition if $\lambda = ck/h \leq 1$; it is non dissipative for $\lambda \leq 1$ but dispersive for $\lambda < 1$ (problematic for short wave lengths).

6. The Laplace equation $\Delta u = 0$, the prototypal elliptic PDE, is the steady state of the wave equation: it has similar smoothing properties. It can be solved, with a finite difference approximation (centered differ-

ences: 5-point scheme).

The resulting matrix has the following sparsity pattern, where T is tridiagonal and D diagonal.

$$\begin{pmatrix} T & D & 0 \\ D & & \\ 0 & D & T \end{pmatrix}$$

One can solve $Ax = b$, without inverting A , if A is symmetric positive definite, by gradient descent, minimizing $F(x) = \frac{1}{2}x'Ax - bx$:

$$\begin{aligned} x_{k+1} &\leftarrow x_k + \alpha_k d_k \\ d_k &: \text{descent direction} \\ r_k &= b - Ax_k = r_{k-1} - \alpha_{k-1} q_{k-1} \\ q_k &= Ad_k \\ \alpha_k &= \underset{\alpha}{\text{Argmin}} F(x_k + \alpha d_k) = \frac{d_k \cdot r_k}{d_k \cdot q_k}. \end{aligned}$$

Steepest descent, $d_k = -\nabla F(x_k) = r_k$, may converge very slowly if the level surfaces of F are eccentric ellipsoids, *i.e.*, $\text{cond } A \gg 1$ (but $\text{cond } A \approx 4N^2/\pi^2 \gg 1$). *Conjugate gradient* addresses this problem by using $d_k = r_k + \beta_{k-1} d_{k-1}$, where β is such that $\forall i \neq j$, $r_i \perp r_j$, *i.e.*, $\beta = \|r_{k+1}\|^2 / \|r_k\|^2$; the solution is reached in (at most) N steps.

To address the conditioning problem, find B invertible such that $\text{cond } BA \approx 1$ and solve $BAx = Bb$. To apply the conjugate gradient method, we need a symmetric (positive definite) matrix: just rewrite the equation as $(BAB')B'^{-1}x = Bb$. Popular choices for this *preconditioner* include $M = B^{-1}B'^{-1} = \text{diag } A$, $\text{tridiag } A$ and $(D+L)D^{-1}(D+U)$ where $A = D+L+U$, D diagonal, L and U strictly upper and lower triangular.

**Probabilistic numerics
and uncertainty in computations**
P. Hennig et al. (2015)

Many numeric (non-probabilistic) algorithms can be given a Bayesian flavour: Bayesian optimization is the best known, but not the only one.

In **Bayesian quadrature**, to estimate an integral, e.g., $\int_0^1 f$, one models the integrand as a Gaussian process $f \sim \text{GP}$: since integration is linear, $(\int_0^1 f, f(t_1), \dots, f(t_n))$ is Gaussian, and one can estimate the conditional distribution $\int_0^1 f \mid f(t_1), \dots, f(t_n)$. This gives an estimate of the integral and of its precision – but it depends a lot on (the smoothness of) the prior. One can also choose the point where to evaluate the function next to increase the precision the most. The prior (the covariance function of the Gaussian process) specifies the smoothness of the integrand (usually \mathcal{C}^∞) and perhaps other properties (e.g., the sign – but the distributions would no longer be Gaussian). Different priors lead to different quadrature rules.

$$f \sim \text{GP}(m, C) \implies \int f \sim N(\int m, \int \int C)$$

Bayesian quadrature can be generalized to **Bayesian ODEs** or PDEs.

Bayesian decision theory uses Bayesian quadrature to estimate and maximize expected utility. (Bayesian optimization uses Bayesian decision theory to choose the next point to evaluate.)

Bayesian linear algebra tries to solve $Ax = b$ where A is too large to be inverted, using the value of some products $As_1 = y_1, \dots, As_n = y_n$ to gain some knowledge about A^{-1} and $A^{-1}b$. The inverse A^{-1} is not known but can be modeled as a Gaussian variable; $(A^{-1}b, A^{-1}y_1, \dots, A^{-1}y_n)$ is then Gaussian, and so is the conditional distribution $A^{-1}b \mid s_1 = A^{-1}y_1, \dots, s_n = A^{-1}y_n$.

**Sampling for inference in probabilistic models
with fast Bayesian quadrature**

T. Gunter et al.

Bayesian quadrature, to estimate expectations $E[\ell] = \int \ell(x)\pi(x)dx$, with a Gaussian process (GP) prior on the integrand ℓ , is problematic when ℓ is a likelihood: the prior does not enforce non-negativity, and struggles to model the high dynamic range of most likelihoods. A Gaussian prior on the log-likelihood is better, but the integral is far from Gaussian. A square root transform, $\ell(x) = \alpha_f(x)^2$, $f \sim \text{GP}$, is a good compromise; the integral is not Gaussian but can be approximated by a Gaussian, either by linearization or moment matching (warped sequential active Bayesian integration, WS-ABI).

Projection pursuit
P.J. Huber (1985)

Given a random variable $X \sim f$ on \mathbf{R}^n , **projection pursuit** looks for a projection $X \mapsto AX$ on a low-dimensional subspace (dimension 1, 2 or 3) that maximizes (or minimizes) some *projection index* $Q(AX)$. This projection index may be:

- Equivariant (mean or some other measure of location);
- Location-invariant and scale-equivariant (standard deviation or some other measure of dispersion – this gives PCA and robust PCA);
- Affine-invariant, e.g., normality test statistics (uninteresting projections tend to be more Gaussian than those with idiosyncrasies): |skewness|, excess kurtosis (or other standardized absolute cumulants – but they tend to be very outlier-sensitive), standardized Fisher information

$$Q(X) = \sigma^2(X) \int \left(\frac{f'}{f} - \frac{\phi'}{\phi} \right)^2 f,$$

standardized negative Shannon entropy

$$Q(X) = - \int \log \left(\frac{\phi}{f} \right) f,$$

Kolmogorov-Smirnov, Durbin-Watson, etc. (this is now called independent component analysis, ICA).

The k -dimensional projection can be approximated in a greedy (stepwise) fashion (if you want a more precise result, use *backfitting*: once you have a k -dimensional projection, remove one vector, find its optimal replacement, and iterate until convergence).

Given two random variables X, Y in \mathbf{R}^n , a discriminating hyperplane can be found by using the T -statistic as a projection index, or

$$\frac{\text{ave}[a'X] - \text{ave}[a'Y]}{\text{sd}[a'(X \cup Y)]}$$

or

$$\frac{\text{med}[a'X] - \text{med}[a'Y]}{\text{mad}[a'(X \cup Y)]}.$$

The same idea gives a measure of outlyingness

$$r_i = \sum_a \frac{a'x_i - \text{med}[a'X]}{\text{mad}[a'X]}$$

which can be used to define weights and robust (weighted) estimators of location and scale.

Regression is the estimation of $f(x) = E[Y|X = x]$. **Projection pursuit regression** (PPR) estimates it as a sum of *ridge functions*

$$f(x) \approx \sum g_j(a'_j x)$$

(note that the ridge functions are constant on hyperplanes). The ridge functions can be estimated greedily:

- Compute the residuals $r_i = y_i - \sum_1^{m-1} g_j(a'_j x_i)$;
- Smooth the scatterplot $r_i \sim a'x_i$:

$$r_i = g(a'x_i) + \text{noise}$$

(this depends on a);

- Find the projection a that minimizes

$$\sum_i (r_i - g(a'x_i))^2;$$

- Iterate.

Not all functions can be represented exactly as a finite sum of ridge functions (but they can be approximated – and, even if it is possible, the decomposition need not be unique).

Projection pursuit density approximation (PPDA) uses the same idea to approximate probability distribution functions, with a multiplicative decomposition (to ensure non-negativity)

$$f(x) \approx f_0(x) \prod_1^k h_j(a'_j x),$$

for some reference distribution f_0 . One can either look for

$$f_k(x) = f_0(x) \prod_1^k h_j(a'_j x) \xrightarrow[k \rightarrow \infty]{} f(x)$$

or, dually,

$$f_{-k}(x) = f(x) \prod_1^k h_j(a'_j x) \xrightarrow[k \rightarrow \infty]{} f_0(x)$$

(this removes the features of f , one by one, until we are only left with the reference (featureless) f_0). The quality of the approximation can be measured with the *relative entropy* $E(f, g) = \int \log(f/g)$, the *Hellinger distance* $H(f, g) = \int (\sqrt{f} - \sqrt{g})^2$, the Prohorov distance

$$\pi(\mu, \nu) = \inf\{\varepsilon > 0 : \forall A \quad \mu(A) \leq \nu(A_\varepsilon) \text{ and } \nu(A) \leq \mu(A_\varepsilon)\},$$

the bounded Lipschitz metric

$$d(\mu, \nu) = \sup \left\{ \left| \int f d\mu - \int f d\nu \right| : f \in \mathcal{C}^0, \sup |f| \leq 1, \sup_{x \neq y} \left| \frac{f(x) - f(y)}{x - y} \right| \leq 1 \right\},$$

etc. One can proceed iteratively: find a minimizing $E(f_a, g_a)$ (where f_a and g_a are the marginal distributions and $g = f_0$); replace f with $f g_a / f_a$ (resp. g with $g f_a / g_a$); iterate.

Projection pursuit density estimation (PPDE) applies the same idea to density estimation (from samples):

- Standardize, using robust location and dispersion estimates;
- Choose f_0 with fat tails; fit it to the cloud of points;
- Proceed as above; if the marginal densities are too time-consuming to estimate, use sample-based estimates.

(Only use when there is not enough data or too many dimensions for a kernel estimator.)

Deconvolution tries to recover a signal x from a convolution $y = f * x$ with an unknown filter f . *Minimum entropy deconvolution* considers segments of length d , (y_t, \dots, y_{t+d-1}) , as points of \mathbf{R}^d , and finds the least Gaussian 1-dimensional projection $q' \cdot y_{t:t+d-1}$: q is an estimate of f^{-1} .

If a time series X_t is a sum of periodic signals with independent periods, they can be recovered by finding p maximizing

- $Q(p) = \text{ave}_t[Z_{p,t}^2]$, where $Z_{p,t} = \text{ave}_k[X_{t+kp}]$;
- Or $|C(p)|^2 = |\text{ave}_t[e^{2\pi i t/p} X_t]|^2$.

Reinforcement Learning D. Silver (2015)

1. Reinforcement learning (RL) is the search for the optimal policy for a Markov decision process (MDL) observed only through its history (past states, actions and rewards). A RL agent can model one or several of:

- The MDP itself;
- The value of each state;
- The policy.

Planning refers to the special case where the MDP is known.

2. A **Markov reward process** is a Markov process (a Markov chain) with rewards. The value of a state is

$$v(s) = E[R_{t+1} + \gamma v(S_{t+1}) \mid S_t = s],$$

i.e., $v = R + \gamma P v$.

A **Markov decision process** (MDP) adds actions. We still have $v = R + \gamma P v$, but v , R and P depend on the policy π . The value of a state, or of a state-action pair, for the optimal strategy (there exists an optimal deterministic strategy) satisfies the Bellman equation:

$$v_*(s) = \text{Max}_a q_*(s, a)$$

$$q_*(s, a) = R_s^a + \gamma \sum_{s'} P_{ss'}^a v_*(s').$$

3. To find the optimal strategy for a known MDP (planning), **policy iteration** starts with an arbitrary policy, evaluates the values of the states for this policy, computes the greedy policy for those values, and iterates. Each step improves the policy and, in the limit, the Bellman equation is satisfied: it converges to the optimal policy.

Value iteration is a variant in which we do not compute the values exactly, but just iterate $v \leftarrow R + \gamma P v$ once. There is actually no need to keep track of the policy, it suffices to iterate on the values:

$$v(s) \leftarrow \text{Max}_a R_s^a + \gamma \sum_{s'} P_{ss'}^a v(s).$$

There are many variants:

- Update the states one at a time, in a random order;
- Only update the most promising states;
- Use a sample of the transition matrix;
- Focus on states close to the agent.

4. To estimate the value function of a given policy on an unknown MDP (*prediction*), **Monte Carlo RL** uses the average return (the sum of the discounted rewards) from complete episodes (*i.e.*, you have to let the MDP run until it reaches a final state to know the return). **Temporal difference learning** (TD) uses incomplete episodes:

$$\text{MC: } v(s_t) \leftarrow v(s_t) + \alpha(G_t - v(s_t))$$

$$\text{TD: } v(s_t) \leftarrow v(s_t) + \alpha(R_{t+1} + \gamma v(s_{t+1}) - v(s_t)).$$

MC is unbiased but has high variance; TD is biased but has lower variance. Instead of looking one step ahead, we can look n steps ahead and replace G_t with

$$G_t^{(n)} = R_{t+1} + \gamma R_{t+2} + \dots + \gamma^{n-1} R_{t+n} + \gamma^n v(s_{t+n}).$$

Forward-view TD(λ) combines them all:

$$G_t^\lambda = (1 - \lambda) \sum_{n \geq 1} \lambda^{n-1} G_t^{(n)} \quad (\lambda\text{-return})$$

$$v(s_t) \leftarrow v(s_t) + \alpha(G_t^\lambda - v(s_t)).$$

Backward-view TD(λ) only uses information from the past, by assigning credit for the reward to the most recent and frequent states, using **eligibility traces**.

$$E_0(s) = 0$$

$$E_t(s) = \gamma \lambda E_{t-1}(s) + \mathbf{1}_{s_t=s}$$

$$\delta_t = R_{t+1} + \gamma v(s_{t+1}) - v(s_t) \quad \text{1-step-ahead error}$$

$$v(s) \leftarrow v(s) + \alpha \delta_t E_t(s)$$

Backward- and forward-view TD(λ) are equivalent.

5. *Control* looks for the optimal value (or policy) of an unknown MDP. It can be *on-policy* (learn about the optimal policy while following it) or *off-policy* (learn about the optimal policy while following another one). Since the model is unknown, the *q-value function* is more useful than the value function to compute the policy.

$$\pi(s) = \underset{a}{\text{Argmax}} R_s^a + P_{ss'}^a v(s') \quad (P \text{ is unknown})$$

$$\pi(s) = \underset{a}{\text{Argmax}} q(s, a)$$

MC- ε -greedy control uses MC to evaluate the *q*-value function and ε -greedy exploration (with probability

$1 - \varepsilon$, choose the greedy (optimal) policy; with probability ε , act at random; update the strategy at the end of each episode).

SARSA control uses SARSA (TD for the *q*-value function) and ε -greedy exploration

$$q(s, a) \leftarrow q(s, a) + \alpha(R + \gamma q(s', a') - q(s, a)).$$

As before, these can be generalized to forward-view SARSA(λ)

$$q_t^{(n)} = R_{t+1} + \gamma R_{t+2} + \dots + \gamma^{n-1} R_{t+n} + \gamma^n v(s_{t+n})$$

$$q_t^\lambda = (1 - \lambda) \sum \lambda^{n-1} q_t^{(n)}$$

$$q(s_t, a_t) \leftarrow q(s_t, a_t) + \alpha(q_t^\lambda - q(s_t, a_t))$$

and backward-view SARSA(λ)

$$E_0(s, a) = 0$$

$$E_t(s, a) = \gamma \lambda E_{t-1}(s, a) + \mathbf{1}_{s_t=s, a_t=a}$$

$$\delta_t = R_{t+1} + \gamma q(s_{t+1}, a_{t+1}) - q(s_t, a_t)$$

$$q(s, a) \leftarrow q(s, a) + \alpha \delta_t E_t(s, a)$$

The step sizes usually decrease, but not too quickly (Robbins-Monro sequence: $\sum \alpha_t = \infty$, $\sum \alpha_t^2 < \infty$).

Off-policy algorithms learn about a policy π while following another policy μ . **Importance sampling MC**

$$G_t^{\pi/\mu} = \frac{\pi(a_t|s_t)}{\mu(a_t|s_t)} \frac{\pi(a_{t+1}|s_{t+1})}{\mu(a_{t+1}|s_{t+1})} \dots \frac{\pi(a_T|s_T)}{\mu(a_T|s_T)} G_t$$

$$v(s_t) \leftarrow v(s_t) + \alpha(G_t^{\pi/\mu} - v(s_t))$$

has a high variance.

For **importance sampling TD**,

$$v(s_t) \leftarrow v(s_t) + \alpha \left(\frac{\pi(a_t|s_t)}{\mu(a_t|s_t)} (R_{t+1} + \gamma v(s_{t+1})) - v(s_t) \right),$$

the variance remains reasonable.

Q-learning does not use importance sampling, but uses π (not μ) in the target

$$q(a_t, s_t) \leftarrow q(a_t, s_t) + \alpha(R_{t+1} + \gamma q(s_{t+1}, a') - q(s_t, a_t))$$

where a' comes from π and a_{t+1} from μ . In particular, when $\pi = \text{greedy}$ and $\mu = \varepsilon\text{-greedy}$, this becomes **SARSAMAX** (or “Q-learning”):

$$q(s, a) \leftarrow q(s, a) + \alpha(R + \gamma \text{Max}_{a'} q(s', a') - q(s, a)).$$

Algorithm	Model	Policy	Aim	on-/off-policy
Policy iteration Value iteration	known	unknown	π^*	
MC TD(λ)	unknown	known	v or q	on
MC + ε -greedy TD(λ) + ε -greedy	unknown	unknown	q^*	on
IS MC or TD Q-learning				off

6. If the number of states is large, we cannot use a table lookup to model the value function $v(s)$ or $q(s, a)$: one can summarize the state as a set of features and use them in a linear (or nonlinear) model. This model attempts to minimize

$$J(w) = E_{\pi}(v_{\pi}(s) - v(s, w))^2,$$

e.g., with stochastic gradient descent (SGD),

$$\Delta w = \alpha(v_{\pi}(s) - v(s, w))\nabla J(w),$$

where, for a linear model $v(s, w) = x(s)'w$ with features $x(s)$, the gradient is $\nabla J(w) = x(s)$, i.e.,

$$\Delta w = \text{step size} \times \text{prediction error} \times \text{feature value}.$$

Since $v_{\pi}(s)$ is unknown, we use a target instead: the return G_t for MC, $R_{t+1} + \gamma v(s_{t+1}, w)$ for TD(0), the forward or backward λ -return G_t^{λ} for TD(λ).

Deep Q-networks (e.g., those that play Atari games) keep all the history and replay it (random mini-batches); they compute the Q-learning targets with some old, fixed (slowly updated) estimate of the q -function.

7. Instead of the value function, one can directly learn a parametrized policy $\pi_{\theta}(s, a)$ = probability of taking action a in state s . This allows stochastic policies. The *policy gradient theorem* links the gradient of the loss function to the *score function* of the policy, $\nabla \log \pi$:

$$\nabla J(\theta) = E_{\pi_{\theta}}[\nabla_{\theta} \log \pi_{\theta}(s, a) q^{\pi_{\theta}}(s, a)].$$

For instance, for a softmax,

$$\begin{aligned}\pi_{\theta}(s, a) &\propto \exp(\phi(s, a)' \theta) \\ \nabla \log \pi &= \phi(s, a) - E_{\pi_{\theta}}[\phi(s, \cdot)]\end{aligned}$$

and for a Gaussian policy

$$\begin{aligned}a &\sim N(\mu(s), \sigma^2), \quad \mu(s) = \phi(s)' \theta \\ \nabla_{\theta} \log \pi &= \frac{(a - \mu(s)) \phi(s)}{\sigma^2}.\end{aligned}$$

The **Monte Carlo policy gradient** (“REINFORCE”) algorithm estimates this expectation using one MC sample, i.e., $q^{\pi_{\theta}}(s, a) \approx r_t$.

The **actor-critic** method learns both the action-value function and the policy (it may be biased, but reduces

the variance)

$$\begin{aligned}q_w(s, a) &\quad \text{critic} \\ \pi_{\theta}(s, a) &\quad \text{actor} \\ \Delta w &= \text{as above} \\ \Delta \theta &= \alpha \nabla_{\theta} \log \pi_{\theta}(s, a) q_w(s, a).\end{aligned}$$

The **advantage function** critic replaces $q_v(s, a)$ with the advantage function

$$A^{\pi_{\theta}}(s, a) = q^{\pi_{\theta}}(s, a) - v^{\pi_{\theta}}(s)$$

(this does not change the expectation but reduces the variance). The **TD error** is an unbiased estimate of the advantage function

$$\delta = r + \gamma V_v(s') - V_v(s)$$

that only requires an estimate of v instead of q . (As before, you can replace the TD(0) target $r + \gamma v(s')$ with the return (MC target), the λ -return (TD(λ) target) or use eligibility traces (backward-view TD(λ)).)

8. Model-based reinforcement learning learns the model (an MDP: the state and action spaces are known, the reward $(s, a) \mapsto r$ is a regression problem, the transitions $(s, a) \mapsto s'$ a density estimation problem, possibly with a Bayesian prior) and uses it to estimate the value function or policy.

Dyna learns the model from experience and the value function from both real experience and simulated experience.

Forward search focuses on the sub-MDP starting at the current state. In particular, **Monte Carlo tree search** (MCTS) applies MC control to simulated experience (at first, we do not know the $Q(s, a)$, so we act at random until the end; this gives an estimate of some of the $Q(s, a)$; iterate with more and more paths – this is how computers play go).

TD search applies SARSA to the sub-MDP starting at the current state.

Dyna2 uses two sets of weights, long-term (TD learning, from real experience) and short-term (TD search), and adds them.

9. A **multi-arm bandit** is a 1-state, 1-step MDP.

action value	$q(a) = E[R \mid A = a]$
optimal value	$v^* = \text{Max}_a q(a)$ (unknown)
regret	$\ell_t = E[v^* - q(A_t)]$
total regret	$L_t = E\left[\sum_{\tau \leq t} v^* - q(A_\tau)\right]$
gap	$\Delta_a = v^* - q(a)$ (unknown)

We want to play the arms (actions) with a low gap more often. For the *greedy* (no exploration) and ε -*greedy* strategies, the loss L_t is linear in t . *Optimistic initialization* initializes $q(a)$ to a high value; it is still linear. *Decaying ε -greedy* is sublinear, but choosing the schedule requires knowledge of the gaps.

“Optimism in the face of uncertainty” uses an upper bound on $q(a)$: $q(a) \leq \hat{q}_t(a) + \hat{u}_t(a)$ with high probability. For instance, **UCB1** uses *Hoeffding’s inequality* (which assumes q bounded):

$$a_t = \underset{a}{\text{Argmax}} \hat{q}_t(a) + \sqrt{\frac{2 \log t}{N_t(a)}}.$$

Bayesian bandits put a prior on q and use some quantile of the posterior, e.g., $\hat{q}(a) + c\sigma(a)$.

Probability matching tries to estimate

$$P[\forall a' q(a) > q(a')]$$

from the posterior. **Thompson sampling** crudely estimates this probability by sampling from $q(a)$ (once for each action) and choosing the best action.

Information state search extends the state space to include all the information so far: the bandit becomes an MDP (with an infinite state space). For instance, a Bernoulli bandit gives an infinite tree of Beta distributions, and the values can be computed exactly (Gittins index) or with MCTS.

A **contextual bandit** is a 1-step MDP (with several states).

For MDPs, UCB is trickier: try optimistic initialization or the information state approach (with MCTS).

10. Let us consider 2-player zero-sum, perfect information (“Markov”) games. Nash equilibria (*joint* strategies) exist (provided you allow mixed strategies) but need not be unique. **Minimax** (depth-first) search

$$\begin{aligned} \pi &= \langle \pi_1, \pi_2 \rangle \\ v_\pi(s) &= E_\pi[G_t \mid S_t = s] \\ v_*(s) &= \text{Max}_{\pi_1} \text{Min}_{\pi_2} v_\pi(s) \end{aligned}$$

explores the tree of possible actions – usually truncated, with the leaf values estimated with some evaluation function.

Simple TD learns the value function with TD and uses it with minimax search. **TD root** uses the minimax value (of the root of the tree) as the target. **TD**

leaf does not update the root but the leaf of the search tree (run a search from s_t , take a decision, end up in s_{t+1} , run a search from s_{t+1} , update the leaf of the first search towards the value of the second search). **Treestrap** updates all the values in the search (not just the root or the leaf), *i.e.*, updates a shallow search from a deep one. MCTS (simulate games until the end, from the current state, and apply RL to those self-play games) works well. UCB can be generalized (UCT).

Phase plots of complex functions: a journey in illustration

E. Wegert and G. Semmler (2011)

To plot a function f of a complex variable, one often considers the surface $z \mapsto |f(z)|$ (or $\log |f(z)|$), sometimes with a colour for the phase $f(z)/|f(z)| \in \mathbf{S}^1$. *Phase plots* only plot the phase, as a colour in the plane (one can also change the brightness, using a sawtooth function of $\log |f(z)|$ or $f(z)/|f(z)|$ or a product of them). Most of the information is still visible, sometimes more clearly than with the surface:

- Zeroes and poles are clearly visible: the colours changes on a simple loop give the difference between the number of zeroes and poles (counted with multiplicity) inside the loop;
- The zeroes of f' (that are not zeroes of f) are “colour saddle points”, *i.e.*, intersections of isochromatic lines;
- Essential singularities are obvious;
- Some results have a striking illustration, e.g., the zeroes of the partial sums of a converging power series with finite convergence radius R cluster at every point on $|z| = R$.

```
## Error in loadNamespace(x): there is no
package called 'elliptic'
```

**Introducing *elliptic*, an R package
for elliptic and modular functions**

R.K.S. Hankin

The **elliptic** R package provides tools to deal with (and plot) complex functions, in particular elliptic functions (doubly periodic meromorphic functions) such as Weierstrass's \wp and related $(\zeta' = -\wp, \sigma'/\sigma = \zeta)$ functions.

**Topology and data
G. Carlsson (2009)**

1. Topological data analysis estimates the **Betti numbers** $\beta_k(X, F) = \dim H_k(X, F)$ of a topological (or metric) space X (often, a subspace of \mathbf{R}^n), over a field F (often \mathbf{F}_2), from a finite number of points sampled from X .

An abstract *simplicial complex* is a pair (V, Σ) , where V is a finite set and $\Sigma \subset \mathcal{P}(V)$ such that $\sigma \in \Sigma, \tau \subset \sigma \implies \tau \in \Sigma$. Its topological realization is

$$\bigcup_{\sigma \in \Sigma} \text{chull}(\{e_i : i \in \sigma\})$$

where $(e_i)_{i \in V}$ is the canonical basis of \mathbf{R}^V .

The *homology* of a simplicial complex $X = (V, \Sigma)$ is

defined as

$$\Sigma_k = \{\sigma \in \Sigma : \#\sigma = k + 1\} \quad k\text{-simplices}$$

$$C_k = \mathbf{Z}^{\Sigma_k} \quad k\text{-chains}$$

$$(V, \leq) \quad \text{total order}$$

$$d_i(\sigma) = \sigma \setminus i\text{th element of } \sigma$$

$$d_i : \Sigma_k \longrightarrow \Sigma_{k-1}$$

$$\partial_k = \sum (-1)^i d_i : C_k \longrightarrow C_k$$

$$\partial_k \circ \partial_{k+1} = 0, \text{ therefore } \text{Im } \partial_{k+1} \subset \ker \partial_k$$

$$H_k(X, \mathbf{Z}) = \frac{\ker \partial_k}{\text{Im } \partial_{k+1}}.$$

Let $\mathcal{U} = (U_\alpha)_{\alpha \in A}$ be an open covering of a topological space X . The **nerve** $N\mathcal{U}$ is the abstract simplicial complex (A, Σ) where $\sigma = \{\alpha_0, \dots, \alpha_k\} \in \Sigma$ iff $\bigcap_{\alpha \in \sigma} U_\alpha \neq \emptyset$. If all intersections of elements of \mathcal{U} are empty or contractible, it is homotopy equivalent to X .

The **Čech complex** $\check{C}(V, \varepsilon)$ is the nerve of the covering of X with balls of radius ε with centers in a finite subset $V \subset X$. If X is compact, Riemannian, ε sufficiently small and V well chosen, then $\check{C}(V, \varepsilon)$ is homotopy equivalent to X .

The **Vietoris-Rips complex** $\text{VR}(V, \varepsilon)$ is (V, Σ) , with $\sigma = \{x_0, \dots, x_k\} \in \Sigma$ iff $\forall i, j, d(x_i, x_j) \leq \varepsilon$, i.e., all (x_i, x_j) span a Čech 1-simplex. (Its 1-skeleton is the “truncated graph” from the distance matrix.)

The **Delaunay complex** is the nerve of the covering by Voronoi cells

$$V_\lambda = \{x \in X : x \text{ closer to } \lambda \text{ than to any other } \lambda' \in V\}.$$

The **strong witness complex** of X , wrt a finite set of points (landmarks) $\mathcal{L} \subset X$, is a fattening of the Delaunay complex, $W^s(X, \mathcal{L}, \varepsilon) = (\mathcal{L}, \Sigma)$ with $\{\ell_0, \dots, \ell_k\} \in \Sigma$ iff

$$\exists x \in X : \forall i, d(x, \ell_i) \leq d(x, \mathcal{L}) + \varepsilon.$$

The **weak witness complex** $W^w(X, \mathcal{L}, \varepsilon)$ is (\mathcal{L}, Σ) with $\{\ell_0, \dots, \ell_k\} \in \Sigma$ iff

$$\forall \Lambda \subset \{\ell_0, \dots, \ell_k\} \quad \exists x \in X \quad \forall \ell \in \mathcal{L} \setminus \Lambda \quad \forall \ell_i \in \Lambda \\ d(x, \ell) + \varepsilon \geq d(x, \ell_i).$$

There are Vietoris-Rips variants W_{VR}^s and W_{VR}^w .

All those complexes are *functorial* in ε : the inequality $\varepsilon \leq \varepsilon'$ induces an inclusion $\check{C}(V, \varepsilon) \hookrightarrow \check{C}(V, \varepsilon')$, which in turn induces a morphism of homology groups $H_k \check{C}(V, \varepsilon) \longrightarrow H_k \check{C}(V, \varepsilon')$.

The **R-persistence homology** is the functor

$$\left\{ \begin{array}{ccc} (\mathbf{R}_+^{>0}, \leq) & \longrightarrow & \mathfrak{Mod} \mathbf{Z} \\ \varepsilon & \longmapsto & H_k \check{C}(V, \varepsilon). \end{array} \right.$$

R-persistence \mathbf{Z} -modules are complicated objects, but there is a classification theorem for finitely-generated **N-persistence** F -vector spaces,

$$(V_n)_{n \in \mathbf{N}} \equiv \bigoplus_{i=0}^N U(m_i, n_i),$$

where

$$U(m, n)_t = \begin{cases} F & \text{if } m \leq y \leq n \\ 0 & \text{otherwise} \end{cases}$$

and $U(m, n)_s \rightarrow U(m, n)_t$ is the identity for $m \leq s \leq t \leq n$. Note that $\text{---} \neq \text{---}$ even though all the dimensions are the same.

The \mathbf{N} -persistence F -homology of a finite set X (choose a subset $\{\varepsilon_n, n \in \mathbf{N}\} \subset \mathbf{R}$) can be represented as a **barcode**.

The actual computations require linear algebra (diagonalizing ∂ – Smith normal form) over the principal ideal domain $F[t]$ (\mathbf{N} -persistence vector spaces are equivalent to graded $F[t]$ -modules).

2. Those ideas have been applied to image data:

- Consider 3×3 patches (points in \mathbf{R}^9); only keep those with high contrast (top 20%);
- Center and normalize (points in \mathbf{S}^7); sub-sample;
- Estimate the density with the distance to the nearest neighbours ($k = 15$) and keep the top $T\%$ densest points ($T = 20\%$);
- Build the witness complex on 50 landmark points chosen by **archetypal analysis**.

The barcodes suggest $\beta_0 = 1$, $\beta_1 = 5$, which can be realized as the union of 3 circles,

corresponding to edges (or gradients), horizontal lines and vertical lines (consistent with the presence of horizontal and vertical artefacts: horizon, buildings, people, trees, etc.). Looking at β_2 suggests (unconvincingly) that those circles may be embedded in a Klein bottle.

For datasets in which one observation is a cloud of points (e.g., a few statistics estimated on a moving window – say, the number of spikes for the 5 neurons firing the most, in brain activity data), you can use

Betti numbers (or the most frequent Betti signatures) as features.

3. Given a map $\rho : X \rightarrow Z$ and a covering \mathcal{U} of Z (with $Z = \mathbf{R}$ or \mathbf{R}^n or \mathbf{S}^1), $\rho^*\mathcal{U}$ is a covering of X ; consider the Čech complex of its connected components $\check{C}^{\pi_0}(\rho^*\mathcal{U})$, e.g., for $\mathcal{U} = \mathcal{U}[R, e] = \{[kR - e, (k_1)R + e], k \in \mathbf{Z}\}$. For point clouds, replace the connected components π_0 with single linkage clustering: points less than ε apart are in the same component (these are the Vietoris-Rips connected components). The map ρ could be a density estimator, data depth

$$\rho_p(x) = \frac{1}{|X|} \sum_{y \in X} d(x, y)^p$$

or eigenvectors of the graph Laplacian of the 1-skeleton of the Vietoris-Rips complex, seen as (eigen) functions. To avoid choosing ε , consider the simplicial complex $SS(X, \rho, \mathcal{U})$ whose vertices are (α, I) , with $\alpha \in A$ and $I = (\varepsilon_i, \varepsilon_{i+1})$ a (maximal) interval on which the barcode of $H_0\check{C}(\rho^{-1}U_\alpha, \varepsilon)_\varepsilon$ does not change and whose k -simplices are the $\{(\alpha_0, I_0), \dots, (\alpha_k, I_k)\}$ such that $A_{\alpha_0} \cap \dots \cap A_{\alpha_k} \neq \emptyset$ and $I_0 \cap \dots \cap I_k \neq \emptyset$. Choose a section of the projection, $s : \check{C}\mathcal{U} \rightarrow SS$, $s(\alpha) = (\alpha, I_\alpha)$, and choose $\varepsilon_\alpha \in I_\alpha$. [The results are similar to Isomap. I am not convinced this is significantly different from a minimum spanning tree.]

4. Persistent homology can be generalized to other index posets. For instance, $\text{VR}(X[T], \varepsilon)_{\varepsilon, T}$ where $X[T] = \{x \in X : \phi(x) \geq T\}$ and ϕ is a density estimator on the finite set X (or some other function – this is *Morse theory*), gives $\mathbf{R} \times \mathbf{R}$ - (or $\mathbf{N} \times \mathbf{N}$ -) persistent homology. It can be described with multigraded modules over $k[X_1, \dots, X_n]$ (here, $n = 2$). The classification of those modules is too complex to be useful (but may be amenable to *Gröbner bases*), but simpler invariants are more accessible, e.g., $\dim M_{t_1, \dots, t_n}$ or

$$\text{rank}(M_{t_1, \dots, t_n} \rightarrow M_{t'_1, \dots, t'_n})$$

(for $n = 1$, the ranks contain all the information).

Zigzag diagrams (*quiver representations*) appear in the following situations:

- Pairwise comparisons of subsamples (bootstrap)

- Samples from a moving window;
- Upper level sets ($T\%$) of a density estimators with varying bandwidths ε_i

- Witness complexes as the set of landmarks change

There is a classification theory for finite zigzag persistence vector spaces: the elementary blocks are of the form

5. The paper ends with a discussion of functorial clustering algorithms (functors from the category of finite metric spaces with isometries, embeddings, non-increasing embeddings, non-increasing maps, to the category of sets.)

Barcodes: the persistent topology of data
R. Ghrist (2008)

Another (shorter) clear review article.

Computational topology for point data: Betti numbers of α -shapes
V. Robins (2002)

To estimate the Betti numbers (intuitively, $\beta_k(X)$ is the number of k -dimensional holes in X) of $X \subset \mathbf{R}^d$ from a finite set of points $S \subset X$, attach spheres of increasing radius α at each point:

$$S_\alpha = \bigcup_{x \in X} B(x, \alpha)$$

$$\beta_k^\alpha(S) = \dim H_k(S_\alpha)$$

for $\alpha \geq d_{\text{Hausdorff}}(S, X)$. The persistent Betti number $\beta_k^{\alpha, \beta}(S) = \text{rank}(i_* : H_k(S_\alpha) \rightarrow H_k(S_\beta))$, for $\alpha \leq \beta$ and $i : S_\alpha \hookrightarrow S_\beta$, is, intuitively, the number of k -dimensional holes in S_α that are not filled in S_β .

The number of connected components $\beta_0^\alpha(S)$ can be obtained from the minimum spanning tree of S . Higher Betti numbers can be computed from the Delaunay complex of S_α in S (the dual of the Voronoi complex of S_α in S).

JavaPlex tutorial
H. Adams and A. Tausz (2015)

JavaPlex is a Java/Matlab library to compute the persistent homology of filtered simplicial complexes. The tutorial ends with the 3-circle structure of image patches.

A roadmap for the computation of persistent homology
N. Otter et al. (2015)

Comparison of software to compute persistent homology: JavaPlex (well documented), Dionysus (C++/Python, documented), Dipha (C++, MPI, command line interface, fast), Gudhi (C++, fast), Perseus, Simpers, jHoles, pHat, CHomP.

Three examples of applied and computational homology
R. Ghrist (2008)

Concrete applications of algebraic topology include:

- *Euler characteristic integration* (constructible sheaves) to aggregate sensor data: the Euler characteristic is a measure since, under some circumstances, $\chi(A \cup B) = \chi(A) + \chi(B) - \chi(A \cap B)$;
- *Persistent homology* to understand the shape of and identify the structures in high-dimensional datasets, e.g., natural images or brain activity;
- *Conley index theory* (a generalization of Morse theory) to distinguish between chaotic and noisy (experimental or simulated) data.

How to write a 21st century proof
L. Lamport (2012)

Advocacy for the replacement of “informal proofs” (which we have been writing since the 17th century) with “structured proofs”: sequences of statements, each with a proof (itself structured, if needed). It is still too early for mathematicians to write formal (computer-verified) proofs, but familiarity with them can be helpful; the appendix shows a proof in TLA^+ .

An extensible SAT-solver
N. Eén and N. Sörensson (2004)

Walk through the MiniSAT code – should you want to implement your own SAT solver

Conflict-driven clause learning SAT solvers
J. Marques-Silva et al. (2008)

DPLL is the basic SAT solving algorithm:

- Write the formula as $\bigwedge_i \bigvee_j x_{ij}$;
- If one of the clauses has only one term, set it to true;
- If one of the variables always appears with the same sign, e.g., always x , or always $\neg x$, set it to true (or false);
- When you can no longer apply the previous steps, choose a value for one of the variables; backtrack when needed.

But this is suboptimal: when we reach a contradiction, we backtrack and try another value for some variable, but if it is unrelated to the contradiction, nothing will change, and we will explore the same tree again and again. *Clause learning* identifies the cause of the contradiction and adds it as a new clause, to help prune the search tree.

To find one (or several) clauses to add, represent the current state of the exploration as a graph, whose nodes are the possible values of the variables and with the clauses used for the deductions as arrows (all inbound edges have the same label), and find a cut between the latest decision variable and the conflict node.

Practical applications of Boolean satisfiability

J. Marques-Silva

SAT applications include:

- Hardware verification: checking that two circuits are equivalent;
- Circuit testing: automatic test generation, for boolean circuits, assuming the failure is that of a single value stuck at 0 or 1;
- Planning: checking if a state is reachable in k steps, in a deterministic transition system, with several transition functions, corresponding to the decisions; temporal logic;
- Bioinformatics, e.g., inferring haplotypes from genotypes: a genotype is a string over the alphabet $\{0, 1, 2\}$ (wild, mutant, heterozygous); a haplotype is a string over $\{0, 1\}$; each genotype comes from two haplotypes; the genotypes are known but the haplotypes are not; we want the minimum number of haplotypes to explain the genotypes.

Bayesian structural time series models

S.L. Scott (2015)

Structural models (level, trend and seasonality) can be put in state-space form and used for ad campaign effectiveness measurement. The model can be extended to allow non-Gaussian innovations (by expressing them as an (infinite) mixture of Gaussians) and long-term trends (by using a mean-reverting AR(1) slope instead of a random walk).

In R, check the `bsts` and `CausalImpact` packages.

Experiments in the internet age: a modern look at the multi-armed bandit

S.L. Scott (2014)

Planning an experiment and running it until the end is suboptimal (in terms of regret): you spend a lot of time estimating precisely options that are suboptimal. In the 2-arm bandit setup, $P(\theta_1 > \theta_2)$ can be estimated analytically, or estimated by sampling from the posteriors of θ_1 and θ_2 : *Thompson sampling* uses a single sample and works well. Full factorial experiments are rarely possible, but one can design fractional factorial experiments to estimate the coefficients as precisely as possible [this is not unlike Bayesian optimization].

Big data, statistics and the internet

S.L. Scott (2014)

Gibbs sampling (sample from $\beta|\mu, V$; sample from $\mu, V|\beta$; iterate) cannot be directly, efficiently implemented with MapReduce (there is too much communication and virtually no CPU usage – the complexity

of most MapReduce algorithms is the volume of communications, not the computations). Instead, **consensus Monte Carlo** gives different bits of data to various workers, which work independently (sample from $\beta|\mu, V, \text{data}_w$; sample from $\mu, V|\beta, \text{data}_w$; iterate) and the results are combined. Contrary to distributed optimization (ADMM) or horizontal strategies for stochastic optimization (progressive hedging), it is a simple consensus – there are no increasing penalties to force convergence.

This can be applied to hierarchical Bayesian Poisson regression (2×10^7 observations, 10^4 groups, 10 variables).

Introduction to RKHS and some simple kernel algorithms

A. Gretton (2015)

Given a kernel $k : X \times X \rightarrow \mathbf{R}$ on a finite set X , one can consider the Hilbert space

$$H = \text{Span}\{k(x, \cdot), x \in X\} \subset \mathcal{F}(X, \mathbf{R})$$

$$\left\langle \sum_x \alpha_x k(x, \cdot), \sum_y \beta_y k(y, \cdot) \right\rangle := \sum_{x,y} \alpha_x \beta_y k(x, y).$$

It satisfies:

$$H \subset \mathcal{F}(X, \mathbf{R})$$

$$\forall x \in X \quad k(x, \cdot) \in H$$

$$\forall x \in X \quad \forall f \in H \quad \langle f, k(x, \cdot) \rangle = f(x)$$

$$\|\delta_x\| = k(x, x)^{1/2} < \infty,$$

where

$$\delta_x : \begin{cases} H & \longrightarrow \mathbf{R} \\ f & \longmapsto f(x) \end{cases}$$

is the evaluation function.

Those results generalize to infinite X , and H is called a *reproducible kernel Hilbert space* (RKHS) for k .

Scalable Bayesian optimization using deep neural networks

J. Snoek et al. (2015)

Gaussian-process-based optimization scales cubically with the number of observations. Instead, one can train a neural net on the data

$$\text{input} \xrightarrow{\tanh} \dots \xrightarrow{\tanh} \phi_1 \dots \phi_D \xrightarrow{\text{linear}} \text{output}$$

(prefer tanh to ReLU) and fit a Bayesian linear model using the last layer $y = \sum \beta_i \phi_i + \varepsilon$ (*adaptive basis regression*).

Fast exact summation using small and large superaccumulators

R.M. Neal (2015)

Naive computation of long sums can lead to rounding error accumulation. There are approximate algorithms (Kahan-Babuška), but it is actually possible to compute those sums exactly, by using a “superaccumulator”, i.e., 4096 64-bit numbers, one for each possible

exponent (all but one bit overlap: carry propagation is rarely needed). For small sums, a smaller number of 64-bit numbers (e.g., with 32-bit overlaps) is sufficient. The overhead is twofold. [A big fixpoint number, with no overlap, looks simpler, but would force us to reimplement addition and could end up slower.]

Quantifying creativity in art networks
A. Elgammal and B. Saleh (2015)

To measure creativity (originality and influence):

- Build a graph of paintings, with a directed edge between two paintings if the first precedes the second, weighted by similarity;
- Subtract some reference value from the weights;
- Invert the negative edges;
- Compute the eigenvector centrality (PageRank).

An R package flare for high dimensional linear regression and precision matrix estimation
X. Li et al.

Variants of the lasso where the square loss is replaced with the absolute value, the L^2 norm (not its square), or more generally the L^p norm, $1 \leq p \leq 2$, and applications to sparse precision matrix estimation (TIGER, CLIME).

Tiger: a tuning-insensitive approach for optimally estimating Gaussian graphical models
H. Liu and L. Wang (2012)

Fitting a Gaussian graphical model, *i.e.*, estimating a sparse precision matrix, can be done column by column, with sparse regressions $X_i \sim X_{\setminus i}$: the lasso and many variants (Dantzig selector, scaled lasso, etc.) have been suggested, but the optimal tuning parameters cannot be computed in practice. The **sqrt lasso** (minimize $\|\text{residuals}\|_2 + \lambda \|\beta\|_1$ – this is the L^2 norm, not its square) is tuning-insensitive.

In R, check the **bigmatrix** and **flare** packages.

Identification of structured dynamical systems in tensor product reproducing kernel Hilbert spaces
M. Signoretto and J.A.K. Suykens

Factorization machines (or tensor machines) with a low rank constraint: add a “multilinear spectral penalty”, built from the SVDs of the unfoldings of the model parameters.

Improving distributional similarity with lessons learned from word embeddings
O. Levy et al.

Traditional and neural word embeddings use the same bag-of-contexts representation:

- Positive pointwise mutual information;

$$\text{PPMI}(\text{word}, \text{context}) = \left(\log \frac{\hat{P}(\text{word}, \text{context})}{\hat{P}(\text{word})\hat{P}(\text{context})} \right)_{+}$$

- Its SVD-based low-rank approximation;
- Skipgram with negative sampling (SGNS, wordvec): maximize $s(\text{word} \cdot \text{context})$ and minimize $s(\text{word} \cdot \text{corrupted context})$, where s is the sigmoid function and \cdot the scalar product – this can be seen as a matrix factorization $\text{PMI} \approx \text{Words} \cdot \text{Contexts}' + \log k$, with a robust (sigmoid) loss;
- Global vectors (GloVe), a factorization $M \approx \text{Words} \cdot \text{Contexts}' + b_w \cdot \mathbf{1}' + \mathbf{1} \cdot b_c'$, where $M_{w,c} = \log \#(w, c)$.

The difference in performance is mostly due to better (or learned) hyperparameters in the “neural” networks.

Auto-WEKA: combined selection and hyperparameter optimization of classification algorithms
C. Thornton et al.

Use Bayesian optimization, e.g., SMAC (random-forest-based Bayesian optimization) or TPE (tree-structured Parzen estimators), to choose both algorithm and hyperparameters in Weka.

Real-time prediction and post-mortem analysis of the Shanghai 2015 stock market bubble
D. Sornette et al. (2015)

- Fit the log-periodic power law (LPPL) model on several windows, from 750 to 125 trading days;
- Filter the results (they give a long list of empirical conditions the model should satisfy);
- The “confidence” is the proportion of models (*i.e.*, window sizes) that pass those filters; it estimates crash risk;
- The “trust” is a resampling-based variant of that goodness-of-fit test: resample the residuals, add them to the fit, re-estimate the model, check if it still passes the filters;
- Compute the probability distribution function of the crash time, or of the bubble start time.

Generative adversarial nets
I.J. Goodfellow et al.

Generative adversarial nets simultaneously learn two models

generator G : noise \mapsto data
discriminator D : noise or data \mapsto true or false

via the minimax game with value

$$V(D, G) = E_{x \sim \text{data}} \log D(x) + E_{x \sim \text{noise}} \log(1 - DG(x))$$

$$\text{value}(\text{game}) = \min_G \max_D V(D, G).$$

Conditional generative adversarial nets

M. Mirza and S. Osindero

GANs can be generalized to conditional models (models of $x|y$ instead of x).

Deep generative image models using a Laplacian pyramid of adversarial networks

E. Denton et al.

Stack GANs to generate finer and finer images.

A neural conversational model

O. Vinyals and Q.V. Le

Build a conversational model with a sequence-to-sequence (seq2seq) RNN-LSTM network, trained on IT helpdesk chats or movie subtitles.

Learning to understand phrases by embedding the dictionary

F. Hill et al.

Train a RNN with LSTM to map dictionary definitions to word vector representations (word2vec) and use as a crossword solver (or a reverse dictionary, *i.e.*, to find the word on the tip of your tongue from its definition).

A simple way to initialize recurrent networks of rectified linear units

Q.V. Le et al.

To avoid the vanishing/exploding gradient problems when training recurrent neural networks (RNN) with stochastic gradient descent (SGD):

- Use Hessian-free optimization instead of SGD;
- Or use SGD, with momentum, careful initialization, and clipped gradients;
- Or use a LSTM network (the model is complicated, but its gradients well-behaved);
- Or use ReLU and careful initialization.

Towards large-scale continuous EDA: a random matrix theory perspective

A. Kabán et al.

In high dimension, one can still use CMA-ES after imposing some structure on the covariance matrix (e.g., diagonal). Instead, one can apply CMA-ES on random (low-dimensional) subspaces and combine the resulting subpopulations. (EDA, “estimation of distribution algorithms”, refers to CMA-ES-like evolutionary algorithms.)

Centrality of the supply chain

L. Wu

Supplier and consumer centralities (HITS algorithm).

Discovering hidden factors of variation in deep networks

B. Cheung et al.

Train a semi-supervised auto-encoder

(we want a latent representation (z, y) of x , where y is known, and z should be as independent of y as possible) with a penalty on the average squared covariance $\langle \text{Cov}(z_i, y_i)^2 \rangle$.

A MiniZinc tutorial

K. Marriott and P.J. Stuckey

MiniZinc is a discrete optimization modeling language: it translates the problem to feed it to various optimizers (constraint propagation, linear programming, etc.) and provides global constraints (alldifferent, etc.).

Modeling discrete optimization

P.J. Stuckey and C. Coffrin (Coursera, 2015)

Another MiniZinc tutorial, with exercises.

The Wiener-Askey polynomial chaos for stochastic differential equations

D. Xiu and G.E. Karniadakis (2001)

The **polynomial chaos** expansion of a stochastic process (with finite variance) is the approximation

$$X_t = a_0(t)H_0 + \sum_{i_1 \geq 0} a_{i_1}(t)H_1(X_{i_1}) + \sum_{i_1, i_2 \geq 0} a_{i_1 i_2}(t)H_2(X_{i_1}, X_{i_2}) + \dots$$

where X_1, X_2, \dots are $N(0, 1)$ iid,

$$H_n(x_1, \dots, x_n) = e^{-\frac{1}{2}x'x} (-1)^n \frac{\partial^n}{\partial x_1 \dots \partial x_n} e^{-\frac{1}{2}x'x}$$

are Hermite polynomials and a_{i_1, \dots, i_k} are functions to be determined. It can be generalized to other families of orthogonal polynomials and non-Gaussian random variables. These expansions can be used to solve SDEs, in the same way one would use power series with ODEs.

Time-dependent polynomial chaos

P. Vos

Worked out examples showing how to numerically solve stochastic ODEs (ODEs with random variables in their

coefficients or their initial conditions) with generalized polynomial chaos (gPC) expansions and to circumvent numeric instability (by reinitializing the expansion from time to time).

Polynomial chaos: a tutorial and critique from a statistician's perspective
A. O'Hagan (2013)

Polynomial chaos (PC) describes a random variable X as $X \stackrel{d}{=} f(\Xi)$ (equality in distribution), where Ξ is a random variable following a known, simple distribution. Such a function f is not unique: one can look for it in the finite-dimensional space of polynomials (of degree at most n) orthogonal wrt the probability distribution function of Ξ (Legendre for $U(-1, 1)$, Hermite for $N(0, 1)$, Laguerre for $\text{Exp}(1)$ – choose depending on the boundedness of X). Typically, Ξ has dimension at least that of X . The Karhunen-Loève expansion is a degree-1 PC expansion.

Random geometry on the sphere
J.F. Le Gall (2014)

To obtain a random metric on the sphere, draw a random planar graph on the sphere, consider the graph distance (suitably rescaled), refine it by adding more nodes and edges until, in the limit, you have a metric on the whole sphere. More precisely, the “random graphs” are defined as follows:

- Consider *planar maps*, i.e., embeddings of graphs into the sphere \mathbf{S}^2 , up to homeomorphism;
- Consider only p -angulations (i.e., the faces have p edges);
- Sample uniformly from

$$M_n^p = \{p\text{-angulations with } n \text{ faces}\},$$

for $p = 3$ or 4 and n large.

For the limit, notice that a planar map is an element of

$$K = \{\text{compact metric spaces}\}/\text{isometries},$$

which is complete when equipped with the Gromov-Hausdorff distance

$$\begin{aligned} d(E_1, E_2) &= \inf\{d_H(\psi_1 E_1, \psi_2 E_2) : \\ &\quad \psi_i : E_i \hookrightarrow E \text{ isometric embeddings}\} \\ d_H(X, Y) &= \text{Max}\left\{\sup_{x \in X} \inf_{y \in Y} d(x, y), \sup_{y \in Y} \inf_{x \in X} d(x, y)\right\} \\ &= \inf\{\varepsilon \geq 0 : X \subset Y_\varepsilon \text{ and } Y \subset X_\varepsilon\} \end{aligned}$$

where X_ε is the ε -enlargement of X .

The **Brownian map** is the random variable, with values in K , obtained in the limit; it is a sphere, but it has Hausdorff dimension 4 (a.s.).

Quadrangulations can be described as *well-labeled trees* (Schaeffer's bijection).

A **continuous random tree** (CRT) is obtained from a *Brownian excursion* (a Brownian motion B such that

$B_0 = B_1 = 0$ and $\forall t \ B_t \geq 0$), as $[0, 1]/\sim$ where $s \sim t$ if $d(s, t) = 0$ and

$$d(s, t) = B_s + B_t - 2 \min_{u \in [s, t]} B_u;$$

is a distance on the tree. Schaeffer's construction can be applied to a CRT with Brownian labels (there are two levels of randomness: in the tree, and in the labels).

Aspects of random maps
G. Miermont (2014)

All the details on the Brownian map.

A relation between Brownian bridge and Brownian excursion
W. Vervaat (1979)

A **Brownian excursion** is a Brownian motion E on $[0, 1]$ conditioned by $E_0 = E_1 = 0$ and $\forall s \in [0, 1], E_s \geq 0$. It can be built from a Brownian bridge by finding its minimum and shifting it (modulo 1) to start and end at that minimum:

$$\begin{aligned} W_t & \quad \text{Brownian motion} \\ B_t = W_t - tW_1 & \quad \text{Brownian bridge} \\ \tau = \underset{t}{\text{Argmin}} B_t & \\ E_t = B_{\tau+t \bmod 1} - B_\tau & \quad \text{Brownian excursion.} \end{aligned}$$

Automatic construction and natural language description of nonparametric regression models
J.R. Lloyd et al.

The **automatic statistician** models time series as Gaussian processes (GP) whose kernel is described via a formal language, using elements such as WN (white noise), C (constant), Lin (linear), SE (square exponential), Per (periodic), CP (change points) and $+$ and \times operators. The models are not unlike *symbolic regression* and include linear regression ($C + \text{Lin} + \text{WN}$), GP smoothing ($\text{SE} + \text{WN}$), cyclical decomposition ($\sum \text{SE} + \sum \text{Per} + \text{WN}$), Fourier decomposition ($C + \sum \cos + \text{WN}$), etc.

Intelligible models for classification and regression
Y. Lou et al. (2012)

Comparison of variants of GAM: the shape functions can be splines (in R: `mgcv`), regression trees, tree ensembles (bagged, boosted, or both) with a fixed or adaptive depth; the model can be learnt via penalized least squares (wiggleness penalty, $\int |f''|^2$), gradient boosting or backfitting (learn f_k on the residuals $y - \sum_{i \neq k} f_i(x_i)$, iterate until convergence): boosted bagged trees, preferably with adaptive depth, perform better.

***Accurate intelligible models
with pairwise interactions***
Y. Lou et al. (2013)

Interactions can easily be added to GAMs (GA²M), but since the number of pairs of variables can be huge, some form of feature selection is needed. For instance, one can greedily add the most promising interaction to the model, using

- Anova (p -value of a test comparing the model with no interactions and the model with the (x_i, x_j) interaction);
- Independence χ^2 test between the sign of the GAM residuals and $(x_i > a_i, x_j > a_j)$, $a_i = \text{median}(x_i)$;
- Comparison of the RMSE of a full model (e.g., a random forest) $y \sim \text{rf}(x_1, \dots, x_n)$ with a model without the (x_i, x_j) interaction, $y \sim \text{rf}(x_1, \dots, \hat{x}_i, \dots, x_n) + \text{rf}(x_1, \dots, \hat{x}_j, \dots, x_n)$;
- RSS of the best split for (x_i, x_j) – it can be computed efficiently.

Convexifying the set of matrices of bounded rank: applications to the quasiconvexification and convexification of the rank function
J.B. Hiriart-Urruty and H.Y. Le (2011)

The convex hull of

$$\{M : \text{rank } M \leq k \text{ and } \|M\| \leq 1\}$$

is

$$\{M : \|M\|_* \leq k \text{ and } \|M\| \leq 1\}$$

where $\|M\| = \sum_{x \neq 0} \|Mx\|_2 / \|x\|_2 = \sigma_1(M)$ is the spectral (operator) norm and $\|M\|_* = \sum_i \sigma_i(M)$ is the nuclear (trace) norm (those norms are dual).

This generalizes a similar result for the ℓ^0 pseudo-norm: the convex hull of $\{x : \|x\|_0 \leq k \text{ and } \|x\|_\infty \leq 1\}$ is $\{x : \|x\|_1 \leq k \text{ and } \|x\|_\infty \leq 1\}$ and $\|\cdot\|_1$ and $\|\cdot\|_\infty$ are dual.

A function f is **quasi-convex** if its sublevel sets $[f \leq \alpha]$ are convex. The *(quasi-)convex hull* of a function is the largest (quasi-)convex function minorizing it. The restricted rank is

$$\text{rank}_r : M \mapsto \begin{cases} \text{rank } M & \text{if } \|M\| \leq r \\ +\infty & \text{otherwise.} \end{cases}$$

Its quasi-convex hull is

$$M \mapsto \begin{cases} \lceil \frac{1}{r} \|M\|_* \rceil & \text{if } \|M\| \leq r \\ +\infty & \text{otherwise} \end{cases}$$

and its convex hull is

$$M \mapsto \begin{cases} \frac{1}{r} \|M\|_* & \text{if } \|M\| \leq r \\ +\infty & \text{otherwise.} \end{cases}$$

In other words, the spectral norm $\|\cdot\|_*$ (sum of the singular values) is a convex relaxation of the rank. For instance, the non-convex **robust PCA** problem

$$\begin{aligned} &\text{Find} && L, S, N \\ &\text{To minimize} && \text{rank } L + \lambda \|S\|_0 \\ &\text{Such that} && \|N\|_F \leq \varepsilon \\ &\text{and} && X = L + S + N \end{aligned}$$

can be relaxed to

$$\begin{aligned} &\text{Find} && L, S, N \\ &\text{To minimize} && \|L\| + * + \lambda \|S\|_1 \\ &\text{Such that} && \|N\|_F \leq \varepsilon \\ &\text{and} && X = L + S + N. \end{aligned}$$

Robust models often look for a decomposition

$$\begin{aligned} \text{data} &= \text{model} + \text{outliers} + \text{noise} \\ &= \text{low rank} + \text{sparse} + \text{small}. \end{aligned}$$

***Robust rotation synchronization
via low-rank and sparse matrix decomposition***
F. Arrigoni et al. (2015)

Robust PCA and matrix completion are both low-rank approximations: they can be combined.

Rotation matrices $R_1, \dots, R_n \in \text{SO}(3)$ can be recovered from noisy relative alignments $R_{ij} = R_i R_j^{-1} + \text{noise}$ by minimizing

$$\sum_{R_{ij} \text{ available}} \|R_{ij} - R_i R_j^{-1}\|_F^2.$$

Letting $X = \begin{pmatrix} 1 & R_{12} & \cdots & R_{1n} \\ R_{21} & & & \vdots \\ \vdots & & & \\ R_{n1} & \cdots & & 1 \end{pmatrix}$, the problem becomes

$$\begin{aligned} &\text{Find} && R = \begin{pmatrix} R_1 \\ \vdots \\ R_n \end{pmatrix} \in \text{SO}(3)^n \\ &\text{To minimize} && \|p(X - RR')\|_F^2 \end{aligned}$$

where p is the projection on the available coordinates. Since $R \in \text{SO}(3)^n$, we can add the constraints $\text{rank } X \leq 3$ and $X \succcurlyeq 0$.

***Efficient computation of sparse Hessians
using coloring and automatic differentiation***
A.H. Gebremedhin et al. (2009)

To recover a sparse, symmetric matrix A , from its sparsity structure and a small number of products Ax_1, \dots, Ax_n , one can use a colouring of the graph whose adjacency matrix is the sparsity structure to define $S = (\mathbf{1}_{\text{node } i \text{ has colour } j})_{ij}$; for a *star-colouring* (each 4-vertex path has at least 3 colours; consequently, the subgraph induced by 2 colours is a collection of stars), one can efficiently recover A from AS .

***Compressed sensing recovery
via nonconvex shrinkage penalties***
J. Woodworth and R. Chartrand (2015)

Compressed sensing, *i.e.*, ℓ^0 minimization

$$\begin{array}{ll}\text{Find} & w \\ \text{To minimize} & \|w\|_0 \\ \text{Such that} & Aw = b\end{array}$$

is often relaxed to ℓ^1 minimization, and many algorithms rely on the *proximal mapping* of the ℓ^1 norm

$$S(x) = \text{Argmin}_w \lambda \|w\|_1 + \frac{1}{2} \|w - x\|_2^2.$$

The ℓ^p quasi-norms, $0 < p < 1$, are a better approximation of the ℓ^0 penalty, but their proximal mapping has no known closed form expression. Instead, one can start with a proximal mapping (in closed form), *e.g.*,

and derive the corresponding penalty .

Entropy-based financial asset pricing
M. Ormos and S. Zibriczky (2014)

In portfolio construction, one can use entropy instead of the standard deviation as a risk measure (it requires a density estimator): one can compute and plot efficient portfolios in the entropy \times return space and decompose the entropy into systematic (mutual information) and specific (conditional entropy) components.

***Permutation-information-theory approach
to unveil delay dynamics
from time series analysis***
L. Zunino et al. (2010)

Given a probability distribution p on $\llbracket 1, N \rrbracket$, one can define the normalized entropy H_S and the complexity C_{JS} as (here, p_e denotes the uniform distribution)

$$\begin{aligned} S[p] &= - \sum p_i \log p_i \\ S[p_e] &= \log N \\ H_S[p] &= \frac{S[p]}{S[p_e]} \\ J(p|p_e) &= S[\tfrac{1}{2}(p + p_e)] - \tfrac{1}{2}S[p] - \tfrac{1}{2}S[p_e] \\ \max_p J(p|p_e) &= \log 2N - (N + 1) \log(N + 1) \\ Q_J(p|p_e) &= \frac{J(p|p_e)}{\max_q J(q|p_e)} \\ C_{JS}[p] &= Q_J(p|p_e) H_S[p] \end{aligned}$$

To transform a time series into a discrete distribution, choose

- an embedding dimension $D > 1$;

- an embedding delay τ

and consider the permutation defined by

$$(x_t, x_{t+\tau}, \dots, x_{t+(D-1)\tau}).$$

This defines a discrete distribution on \mathfrak{S}_D (D should not be too large: $D! \ll n$.) The corresponding entropy and complexity are the *permutation entropy* and the *permutation statistical complexity*.

As an example, one can look at the Mackey-Glass oscillator

$$\begin{aligned} \dot{x} &= -x + \frac{ax(t - \tau_0)}{1 + x^c(t - \tau_0)} \\ a &= 2, \quad c = 10, \quad \tau_0 = 60 \end{aligned}$$

in the (H_S, C_{JS}) space, as τ_0 varies.

***Data manipulation detection
via permutation information theory quantifiers***
A.F. Bariviera (2015)

Application to financial time series.

***Representing numeric data in 32 bits
while preserving 64-bit precision***
R.M. Neal (2015)

Storing data as decimals (rather than floating point) is space-efficient, but a time-consuming conversion is usually needed to use the data. Instead, one can use a table lookup (implemented in pqR).

***A generalized
Kahan-Babuška-summation algorithm***
A. Klein (2005)

When naively computing a (long) sum of floating point numbers, the rounding errors accumulate. It is possible to compensate for them, *e.g.*, by re-ordering the terms (if they are all positive, use the Huffman code order, starting with the smallest numbers – unfortunately, with arbitrary signs, finding the optimal order is an NP-hard problem) or by estimating the error and correcting for it: the Kahan algorithm estimates the error and corrects it immediately; the more accurate Kahan-Babuška-Neumaier (KBN) algorithm corrects it at the end. There are dozens of variants of those algorithms.

***Printing floating-point numbers quickly
and accurately with integers***
F. Loitsch (2010)

Printing floating-point numbers (*i.e.*, converting them to decimal) is not a trivial task. The previous algorithm, Dragon4, required arbitrary-precision arithmetic. Grisu, only requires integer arithmetic (but occasionally needs to fall back to Dragon4).

***Kylrix: a sparse allreduce
for commodity clusters***
H. Zhao and J. Canny

The all-reduce pattern usually involves a tree network

In a *bufferfly* network, the nodes are arranged in a hypercube; in step k , the nodes communicate with their neighbours along dimension k .

***Edge compression techniques
for visualization of dense directed graphs***
T. Dwyer et al. (2013)

To display a directed graph with a lot of edges (e.g., the dependencies between software components), one can try to group them into modules, with edges between modules instead of between nodes:

- One can find, in linear time (via hashing), nodes that have the same set of neighbours, and group them (the nodes inside a module are either disconnected or form a clique, depending on whether we include a node in its neighbourhood);
- One can also allow for some internal structure in the modules (but the algorithm is trickier);
- One can also allow for some module-crossing edges (powergraph), e.g., with a greedy algorithm: compute a hierarchical clustering of the nodes, for some node similarity measure; for each potential cluster, compute the number of edges that would be removed; choose the modules greedily. The results were compared with the optimal minimizer of

$$\#modules + w_1 \times \#edges + w_2 \times \#crossings,$$

computed using MiniZinc – the greedy solution is far from optimal but, in psychological tests (“how much of the graph do you remember?” “Can you find the shortest path from A to B ?”), it is an improvement on traditional layout algorithms.

***Improved optimal and approximate
power graph compression
for clearer visualization of dense graphs***
T. Dwyer et al. (2013)

Finding the optimal *powergraph compression* of a graph (i.e., a module decomposition that reduce the number of edges) using general optimization methods (integer propagation, integer programming) is too time-consuming.

The following heuristic is faster, and gives decent results:

- Arrange the set of possible solutions into a tree, with the initial graph (1-node modules) as the root, and children obtained by merging two modules in the parent;
- Use best-first-search or, better, *beam search*: at each iteration (i.e., for each depth in the tree), keep the k best solutions ($k = 1$ is greedy-best-first search).

It is actually reasonable to explore the whole tree, with backtracking, after judicious pruning.

***A generic algorithm
for layout of biological networks***
F, Schreiber et al. (2009)

The algorithm begins *dunnart* (for constrained graph layout): start with a feasible but partial layout, find a locally optimal partial layout, extend it into a full layout.

***Google matrix analysis
of the multiproduct world trade network***
L. Ermann and D.L. Shepelyansky (2015)

In the graph whose vertices are country \times product pairs, also consider the *Chei-rank* (the PageRank of the opposite graph); use a personalized variant of PageRank to account for imbalance between products (e.g., oil vs furs) or countries; and compute the correlations

$$\kappa = \sum_{c,p} p_{cp} p_{cp}^* - 1$$

$$\kappa_{p_1, p_2} = N_C \sum_c \frac{p_{cp_1} p_{cp_2}^*}{\sum_{c_1} p_{c_1 p_1} \sum_{c_2} p_{c_2 p_2}} - 1$$

where p_{cp} (resp. p_{cp}^*) are the PageRank (Chei-rank) scores (eigenvectors for $\lambda = 1$, normalized so that $p' \mathbf{1} = p'^* \mathbf{1} = 1$).

***Randomizing bipartite networks:
the case of the world trade web***
F. Saracco et al. (2015)

The common graph metrics can be generalized to bipartite graphs:

- Assortativity: $\text{Cor}(\deg X, \deg Y \mid \text{edge } X-Y)$;
- Complexity and fitness are PageRank analogues – they can be used to reorder the rows and columns of the adjacency matrix;
- As a replacement for the clustering coefficient (there are no odd cycles), one can count motifs, e.g., and
- Nestedness: count the number of products (countries) two countries (products) have in common; sum; normalize.

To construct statistical tests on a graph, use some maximal entropy distribution on the set of graphs (e.g., assuming the degree distribution is known).

***On the modular dynamics
of financial market networks***
F.N. Silva et al. (2015)

Let G be a graph (undirected, no self-loops, no multiple edges), $A(G)$ its adjacency matrix, $\Delta(G)$ its degree matrix (diagonal), $L(G) = \Delta(G) - A(G)$ its Laplacian, $\rho(G) = L(G)/\text{tr } \Delta(G)$ its density matrix, $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_n$ the eigenvalues of $\rho(G)$. The **Von Neumann entropy** of G is

$$S(G) = - \sum_i \lambda_i \log_2 \lambda_i.$$

One can look at how graph metrics or community metrics (modularity, average shortest path length, average betweenness, degree assortativity, transitivity, von Neumann entropy) vary over time (for a network built from the correlation matrix of asset returns, estimated on a moving window).

With a model-based community detection algorithm, one can generate random graphs from the fitted community model, and look at the distribution of graph metrics.

***A note on the von Neumann entropy
of random graphs***
W. Du et al. (2010)

***Dynamic multi-factor clustering
of financial networks***
G.J. Ross (2015)

To measure how much a qualitative variable (sector, country, etc.) influences a hierarchical clustering (from stock return correlations): for each pair of points i, j in the same class, find their closest common ancestor k , count the proportion of points in this class among the descendants of k ; average over all pairs.

Identifying states in a financial market
M.C. Münnix et al. (2012)

To identify market states:

- Compute the correlation matrix, for daily (or hourly) returns, on a 2-month moving window;
- Compute the normalized L^1 distance (alternatively, the difference between the largest eigenvalues) between those correlation matrices, and cluster them (hierarchical clustering or k -means) – alternatively, fit some regime-switching model.

***Forecasting financial extremes: a network
degree measure of super-exponential growth***
W. Yan et al. (2015)

Use the degree of the *visibility graph* of the log-price (or its opposite) to identify super-exponential growth (or decay); this is similar to the LPPL pattern recognition indicator.

***A practical approach to financial crisis
indicator based on random matrices***
A. Kornprobst and R. Douady (2015)

The **Hellinger distance** between two probability distributions is

$$\text{Hellinger}(p, q) = \int (\sqrt{p} - \sqrt{q})^2.$$

To detect market instability, look at the following indicators:

- Hellinger distance between the Marcenko-Pastur distribution and the distribution of the eigenvalues of the correlation matrix (low eigenvalues are not informative: discard everything below the tenth of the maximum theoretical eigenvalue);
- Hellinger distance with the spectrum of the sample correlation of a constant correlation Gaussian (or Student, with 2 degrees of freedom);
- Maximum eigenvalue of $\text{Var } X$ (spectral radius);
- $\text{tr } \text{Var } X$;
- $\text{Max Spec Cor } X$, with capitalization-weighted and volume-weighted variants (apply a moving average filter if too noisy).

Kernel spectral clustering and applications
R. Langone et al. (2015)

To cluster data with PCA (or kernel PCA, or spectral methods – kPCA on a graph Laplacian), binarize the transformed data ($\text{sign PC}_1, \text{sign PC}_2, \dots$) and use the most frequent binary codes as clusters.

***Scale up nonlinear component analysis
with doubly stochastic gradients***
B. Xie et al.

Use two stochastic approximations simultaneously in kernel PCA: process the data in minibatches (as in stochastic gradient descent) and use random features (different in each batch, as in randomized PCA).

Implied correlation and expected returns
M. Valenzuela

The option-implied correlation

$$\rho = \frac{\sigma^2 - \sum_i w_i^2 \sigma_i^2}{\sum_{i \neq j} w_i w_j \sigma_i \sigma_j}$$

$$\sigma^2 = \frac{2e^{rT}}{F_T} \left(\int_0^{F_T} \text{put}_T(K) dK + \int_{F_T}^{\infty} \text{call}_T(K) dK \right)$$

computed from (30-day) put and call options on the S&P 100 and its constituents, can help predict (3- to 12-month) future returns.

Market timing with a robust moving average
V. Zakamulin (2015)

Among the half-dozen momentum strategies studies, the exponentially-weighted moving average (EWMA) “buy if $\sum_{k \geq 0} \lambda^k \times \text{returns}_{[t-k-1, t-k]} > 0$ ”, with $\lambda = 0.87$, is the most robust to the look-back period.

Market timing with moving averages: anatomy and performance of trading rules
V. Zakamulin

Technical analysis rules can be formulated as “buy if $\sum_{k \geq 0} w_k \text{Price}_{\text{now}-k}$ ” for different weighting schemes (one can also use price changes, with different weights).

Copula-based hierarchical risk aggregation
F. Derendinger (2015)

A *mildly tree-dependent* random vector $(X_i)_{i \in I}$ is

- a rooted tree structure on the index set I ,
- a univariate distribution for each leaf,
- a copula for each node, describing the dependence of its children,

where each node is the sum of its children. This does not uniquely determine the distribution of the random vector, unless one also assumes that, for each node, its descendants are conditionally independent from the other nodes.

Measuring financial asset return and volatility spillovers, with applications to global equity markets
F. Diebold and K. Yilmaz (2009)

To measure spillover in a VAR(p) model $x_t = \Phi x_{t-1} + \varepsilon_t$,

- Write the proces as an MA(∞) process, $x_t = (1 - \Phi L)^{-1} \varepsilon_t$;
- Using the Choleski decomposition $\text{Var } \varepsilon_t = Q_t Q_t^{-1}$, rewrite the process as an MA(∞) process with orthogonal innovations $x_t = (I - \Phi L)^{-1} Q_t^{-1} \cdot Q_t \varepsilon_t = A(L) u_t$;
- The 1-step-ahead error $x_{t+1} - x_{t+1|t} = A_0 u_{t+1}$ has variance $A_0 A_0'$; the K -step-ahead error can be decomposed

$$\sum_{ij} \sum_{1 \leq k \leq K} a_{ij}^{k,2} = \sum_i \left(\sum_k a_{ii}^{k,2} + \sum_{j \neq i} \sum_k a_{ij}^{k,2} \right)$$

where the second term is the spillover of j onto i .

The *spillover index* is

$$S = \frac{\sum_{i \neq j} \sum_k a_{ij}^{k,2}}{\sum_{ij} \sum_k a_{ij}^{k,2}}$$

It depends on the order of the variables, but not too much.

On the computational complexity of high-dimensional Bayesian variable selection
Y. Yang et al. (2015)

The Bayesian hierarchical sparse model

$$\begin{aligned} \gamma &= \{\text{variables entering the model}\} \subset \llbracket 1, n \rrbracket \\ \pi(\gamma) &\propto p^{-\kappa|\gamma|} \mathbf{1}_{|\gamma| \leq s_0} \\ \pi(\phi) &\propto \phi^{-1} \text{ (improper prior)} \\ \beta_\gamma &\sim N(0, g\phi^{-1} I_{|\gamma|}) \\ w &\sim N(0, \phi^{-1} I_n) \\ Y &= X + \gamma\beta_\gamma + w \end{aligned}$$

(the slab-and-spike prior, *i.e.*, a mixture of two Gaussians with different variances, is another popular choice), sampled via Metropolis-Hastings (with the neighbourhood of γ defined by removing or adding a variable; or by removing *and* adding a variable) is an alternative to the lasso for variable selection: it has different, sometimes better, theoretical properties.

Relevance vector machines explained
T. Fletcher

Relevance vector machines (RVM) consider the bayesian model

$$\begin{aligned} w_j &\sim N(0, \alpha_j^{-1}) \\ \varepsilon_i &\sim N(0, \beta^{-1}) \\ t_i &= w' \phi(x_i) + \varepsilon_i \end{aligned}$$

and estimate its posterior

$$\begin{aligned} w \mid t, \alpha, \beta &\sim N(m, \Sigma) \\ m &= \beta \Sigma \Phi' t \\ \Sigma &= (\text{diag } \alpha + \beta^{-1} \Phi' \Phi)^{-1} \end{aligned}$$

iteratively, by computing m and Σ for given values of α and β , then computing the values of the hyperparameters α, β that maximize the evidence $P(t \mid \alpha, \beta)$:

$$\begin{aligned} \alpha_i &\leftarrow \frac{1 - \alpha_i \Sigma_{ii}}{m_i^2} \\ \beta &\leftarrow \frac{N - \sum_i (1 - \alpha_i \Sigma_{ii})}{\|t - \Phi m\|^2}. \end{aligned}$$

Quite often, $\alpha_i \rightarrow \infty$, *i.e.*, $w_i \rightarrow 0$: the corresponding parameters can be pruned. The remaining parameters are the *relevance vectors*.

Shotgun stochastic search for “large p ” regression
C. Hans et al. (2007)

Shotgun stochastic search (SSS) is a variant of Metropolis-Hastings (MH) to look for a sparse model:

- Let Γ be the set of the best k models examined so far and γ_n the current model;
- In parallel (MCMC is usually sequential), examine all the (or a large number of) neighbours of γ_n ; add them to Γ ; discard the worst models if $|\Gamma| > k$;

- Choose γ_{n+1} as with MH (if you allow for three types of neighbours, from deletion moves γ^- , additions γ^+ and replacement γ^0 , they are unbalanced, especially in high dimensions: $|\gamma^0| \gg |\gamma^+| \gg |\gamma^-|$ – you may want to sample from them separately), but with an acceptance probability that depends on the sum of the scores of the neighbours of the current point and the candidate.

***Statistical model criticism
using kernel two sample tests***
J.R. Lloyd and Z. Ghahramani

The notion of p -value can be generalized to a Bayesian setting:

- Choose a statistic T ;
- Estimate $P[T \leq T_{\text{obs}}]$ using the posterior distribution of T .

It measures how surprising the data still is, even after observing it.

***Random bits regression:
a strong general predictor for big data***
Y. Wang et al.

Penalized regression on random binary features performs well on big data (same idea as echo state networks or extreme learning machines, which are just SVMs with a randomized (instead of universal) kernel).

Random feature maps for dot product kernels
P. Kar and H. Karnick (2012)

SVMs with a high-dimensional embedding space tend to have too many support vectors. One can transform the kernel to reduce the dimension, randomly (as in the Johnson-Lindenstrauss lemma). For instance, if the kernel is of the form $k(x, y) = f(\langle x, y \rangle)$, with $f(x) = \sum_{n \geq 0} a_n x^n$, where the a_n are nonnegative, one can use this expression to build an embedding $Z : \mathbf{R}^d \rightarrow \mathbf{R}^D$, with $\langle Zx, Zy \rangle \approx k(x, y)$:

- Select N randomly with $P[N = n] \propto 1/p^{n+1}$;
- Select $\omega_1, \dots, \omega_n \in \{\pm 1\}^d$ randomly;
- Let $Z_1(x) = \sqrt{a_N p^{N+1}} \prod_j \omega_j' x_j$;
- Do the same for the other coordinates Z_2, \dots, Z_D .

An introduction to random indexing
M. Sahlgren

LSA (latent semantic indexing) builds a word-document matrix and computes its (truncated) SVD to produce a lower-dimensional representation of the words. However, the initial word-document matrix can be too large. Instead, one can use a random projection (Johnson-Lindenstrauss): it can be built incrementally, one document at a time.

***A practical guide
to applying echo state networks***
M. Lukoševičius

Implementation advice for *reservoir computing*.

fastFM: a library for factorization machines
I. Bayer

C library, with Python bindings (contrary to libfm). Factorization machines are not limited to recommendation systems, but can add interactions to any model.

***Tensor machines
for learning target-specific polynomial features***
J. Yang and A. Gittens

Tensor machines are a generalization of factorization machines

$$f(x) = w^0 + \langle w^1, x \rangle + \sum_{p=2}^q \left\langle \sum_{i=1}^r w_1^{p_i} \bullet \dots \bullet w_p^{p_i}, x \bullet \dots \bullet x \right\rangle$$

where $\bullet \dots \bullet$ is the outer product and $w_1^{p_i} \bullet \dots \bullet w_p^{p_i}$ is a rank-1 tensor. The model is fitted by minimizing

$$\frac{1}{n} \sum_i \text{loss}(f(x_i), y_i) + \lambda \|w\|_2^2.$$

(Kar-Karnick features are similar, but w is constrained to be in the subspace spanned by a sufficiently large number of random tensors.)

***Score function features for discriminative
learning: matrix and tensor frameworks***
M. Janzamin et al. (2015)

To build features:

- Estimate the probability distribution $p(x)$ of the (unlabelled) data x ;
- Compute the score functions

$$S_m(x) = (-1)^m \frac{\nabla^m p(x)}{p(x)};$$

- Given labeled data (x, y) , we want some information about $G(x) = E[y|x]$; we can estimate the expectation of its derivatives: $E[\nabla^m G(x)] = E[y S_m(x)]$;
- These are (huge) tensors: compute a low rank approximation (SVD, CP), $E[\nabla^m G(x)] \approx \sum_j u_j^{\otimes m}$ (each tensor product only involves a single vector because the tensors are symmetric);
- Use $\sigma(x \cdot u_j)$ as features where σ is a sigmoid function.

***Picture: a probabilistic programming language
for scene perception***
T.D. Kulkarni et al.

A scene description language can be turned into a probabilistic programming language; do not use a fully-rendered (photorealistic) scene to compute the model with the data pixel by pixel: use features instead (from computer vision or deep learning).

Slice sampling for probabilistic programming
R. Ranca (2015)

To sample from a probability distribution only known up to a multiplicative factor, $p(x) \propto p^*(x)$, **slice sampling** proceeds iteratively:

- Pick $u_t \sim U(0, p^*(x_t))$;
- Pick $x_{t+1} \sim U(\{x : p^*(x) \geq u_t\})$.

StocPy is yet another Python-based probabilistic programming language.

Count-min-log sketch: approximately counting with approximate counters
G. Pitel and G. Fouquier (2015)

Count-min-sketch variant with more precision for low counts, with applications to TD-IDF matrices.

Supervised learning from multiple experts: whom to trust when everyone lies a bit
V.C. Raykar et al. (2009)

Binary forecasts y_{ij} , for many tasks i (e.g., medical diagnostic) for several experts j can be combined (use majority voting as a baseline model) with an EM algorithm, alternatively estimating the forecasts and the reliability of each expert; one can add a Bayesian prior if some experts are known to be more or less reliable.

Invariant backpropagation: how to train a transformation-invariant neural network
S. Demyanov et al.

One expects neural networks to be invariants to some transformations (rotations, translations, etc.). The following weight updates achieve that (you do not have to specify the group action):

$$\mathbf{w} \leftarrow \mathbf{w} - \alpha \frac{\partial \text{Loss}}{\partial \mathbf{w}} - \beta \frac{\partial}{\partial \mathbf{w}} \left\| \frac{\partial \text{Loss}}{\partial \text{Input}} \right\|^2.$$

Learning classifiers from synthetic data using a multichannel autoencoder
X. Zhang et al.

Use an autoencoder (trained on real data) on surrogate data to make it more realistic.

Deep transform: cocktail party source separation via probabilistic re-synthesis
A.J.R. Simpson

To separate two speech signals (in a mono-aural signal), learn an auto-encoder

[They used a male and a female speaker: their auto-encoder learned to separate gender, rather than speech.]

Explaining and harnessing adversarial examples
I.J. Goodfellow et al. (2015)

For high-dimensional linear models, you can make infinitesimal changes to the input (e.g., ± 1 to each 8-bit pixel of an image) that add up to a large change in the output. To mitigate the problem:

- Use “deep” neural networks (at least one hidden layer);
- Train on a mixture of adversarial and clean examples.

(RBF networks are immune to those adversarial examples, but do not generalize well.)

Neural Turing machine
A. Graves et al.

A differentiable Turing machine can be trained with gradient descent to learn simple algorithms.

Long short-term memory over tree structures
X. Zhu et al. (2015)

LSTM networks can be generalized from sequences to trees.

LSTM: a search space odyssey
K. Greff et al.

In a recurrent net, there is feedback from the output to the input. In an LSTM net, there is feedback from (some of) the inner nodes to (themselves and) the input: they can be trained like RNN (with the same problems).

jvmr: integration of R, Java and Scala
D.B. Dahl et al.

Embed R in Scala or Java, or the reverse.

Bayesian estimation supersedes the t test
J.K. Kruschke (2013)

For a Bayesian T test, check the BEST R package.

Cubist models for regression
M. Kuhn et al. (2012)

Cubist models generalize decision trees:

- There is a model in each node, and each leaf (or node) is shrunk towards its parent;
- One can add boosting and/or shrink each forecast towards its nearest neighbours (in the training set or the sample to forecast).

1. Several presentations applied social network analysis (SNA) methods to financial networks.

PageRank on a graph weighted by cross-correlations can identify leaders. [Some use the HITS algorithm instead, to identify leaders and followers, extracting information from leaders and investing in followers.]

If the nodes i of a graph represent financial entities, each with a risk C_i , one can compute the following graph metrics:

$$\text{Fragility} = \frac{E[\text{degree}^2]}{E[\text{degree}]}$$

$$\text{Risk score} = \sqrt{C'AC}$$

where A is the incidence matrix The risk score can be decomposed with Euler's formula:

$$\text{Risk score} = \sum \frac{\partial \text{Score}}{\partial C_i} C_i.$$

One can then compute

$$\text{Criticality} = C \odot x$$

where x is the eigenvector centrality (not unlike PageRank) and \odot the elementwise product, and

$$\text{Spillover}_{ij} = \frac{\partial}{\partial C_i} \frac{\partial \text{Score}}{\partial C_j}.$$

A graph (e.g., interbank lending market, in some country) can be decomposed into *core and periphery*, and compute various graph metrics (density, betweenness centrality, closeness centrality, transitivity, average path length, eigenvalues, etc.) over time.

One can apply network analysis (plots, centrality) on raw (SWIFT) financial transactions.

One can compute graph metrics (centrality, etc.) on graphs learnt with **bnlearn**.

2. Higher moments (up to the fifth...) were mentioned a couple of times.

Use differential evolution (**DEoptim**) to optimize the expected utility of a portfolio (using the sample distribution of past returns). The derivatives of the utility function should alternate in sign. They all have names:

$U' > 0$	Non-satiation (high returns)
$U'' < 0$	Risk aversion (low risk)
$U''' > 0$	Prudence (positive skew)
$U'''' < 0$	Temperance (low kurtosis)
$U''''' > 0$	Edginess.

Use, for instance, $U(\text{wealth}) = \text{wealth}/(c + \text{wealth})$.

Investors have a preference for high odd moments and low even moments. The **HighFreq** package estimates them from OHLC data (not unlike all the volatility estimators in **TTR**).

3. A *partially auto-regressive* process is the sum of a stationary AR process and a random walk; it can be estimated with a Kalman filter. Caveats: the tests have low power; the AR component may just capture the market microstructure (e.g., the bid-ask bounce). This is implemented in the **partialAR** package (use the cointegration residuals, from **egcm**).

To identify change points in a time series, find the partition of the indices that maximizes the sample energy distance

$$\mathcal{E}(X, Y) = 2E|X - Y|^\alpha - E|X_1 - X_2|^\alpha - E|Y_1 - Y_2|^\alpha$$

$$\hat{\mathcal{E}}(X, Y) = \frac{2}{\#B} \sum_B |x_i - x_j|^\alpha +$$

$$- \frac{1}{\#W_x} \sum_{W_x} |x_i - x_j|^\alpha - \frac{1}{\#W_y} \sum_{W_y} |y_i - y_j|^\alpha$$

The **e-cp3o** algorithm speeds up the computations by removing points that are unlikely to be change points and reducing the size of B , W_x , W_y . This is implemented in **ecp::ecp3o**.

For large but sparse VARX models (VAR with exogenous variables), add a (nested group) lasso penalty. The Hierarchical VAR (HVAR) model also adds lasso penalties to the lags. This is implemented in the **BigVAR** package.

By combining bits of models that are not often used together, one can build rather complicated models, e.g., a regime switching cointegration model with time-varying transition probabilities

To detect multivariate outliers, use a robust covariance matrix, e.g., the MCD (minimum covariance determinant). Iteratively-reweighted MCD gives the correct false positive rate. This is implemented in the **CeriolliOutlierDetection** package.

4. The **PortfolioAnalytics** package provides many portfolio optimization approaches, including Meucci's fully flexible views or Almgren and Chriss's portfolios from sorts.

Flexible asset allocation with stepwise correlation rank suggests to build a portfolio one asset at a time, adding the asset with the best

$$w_1 \times \text{momentum rank} + w_2 \times \text{volatility rank} +$$

$$w_3 \times \text{correlation rank},$$

where the correlation is the average correlation with the assets already in the portfolio.

It is safer to build a portfolio from a few (smart beta) ETFs than from a large number of stocks: lower estimation error and fewer parameters lead to better out-of-sample performance.

Taxes have an impact on the optimal multi-period 2-asset portfolio (Kelly principle).

5. mVaR and mES (Cornish-Fisher value at risk and expected shortfall) are estimators: we can compute their variance and bias (a computer algebra system

(CAS) is useful – they used the Matlab symbolic toolbox, but you may want to check SAGE, Maxima or Yacas) and compare them with a maximum likelihood estimator (asymptotically no bias and lowest variance). Also check `qrntools::ARA` and the `SharpeR` package. `mVaR` and `mES` are bad for: low α , fat tails, large samples.

One can still decompose the VaR into a sum of contributions (risk factors, managers) in the presence of non-linear assets (e.g., with the delta-gamma approximation).

One can compute an upper bound on the expected Sharpe ratio; it is unclear if/how it depends on the number of assets.

6. The `highfrequency` package provides functions to align non-synchronous time series (wait until there has been a new observation for all time series), compute volatility or jump estimators (realized bipower variation, MedRV, ROWVar), tests for the presence of jumps, etc.

Here is a stylized fact for high frequency data:

Number of transactions \propto USD Volume $^{2/3} \times$ Volatility.

The `creditr` package provides CDS computations, with a Shiny interface, not unlike the Bloomberg or Markit CDS screen/calculator.

7. The `Rborist` package is similar to `RandomForest`, but faster; it can use several cores (or a GPU).

The `irlba` package computes the fast truncated SVD.

8. `data.table` still has an edge on `dplyr`:

- The data is indexed;
- It provides fast aggregation, and ordered joins (aka rolling joins, `lof`);
- `fread` is a fast CSV reader (but `h2o.importFile` is even faster).

The development version of DBI (finally) allows for parametric queries (prepared statements). The `readr` package provides faster functions to read CSV files (but `fread` is even faster). The `httr`, `xml2`, `rvest`, `jsonlite` packages were also mentioned; `dplyr`, `reshape2`, etc. were not.

`Rcpp` provides better integration with RStudio, annotations (e.g. `// [[Rcpp::export]]`), C++11 (closures, type inference), direct access to Boost even on Windows (BH).

`Rblpapi` is a newer interface to Bloomberg, in C++ rather than Java. It does not work well on Windows.

Some suggest to describe the data pipeline in a purely declarative way; to facilitate deployment, this should also include the data cleaning part.

The `simsalapar` package can help you (easily) parallelize computations – when you have to run the same computations/simulations many times, with different parameter values. An example for VaR computations with nested archimedean copulas

(`copula::onacopula`) was given. [I prefer to use `doParallel` (and `foreach`) directly.]

The computation of the expected improvement in dominated hypervolume of Pareto front approximations
M. Emmerich et al. (2008)

For multi-objective Bayesian optimization, replace the expected improvement (EI) with the expected increase in the hypervolume dominated by the Pareto set. While a Monte Carlo approach is possible, it can be computed exactly: decompose the space into boxes, each corresponding to a different shape for the new efficient frontier, and compute the expected improvement conditional on the new point being in a given box.

Faster computation of expected hypervolume improvement
I. Hupkens et al. (2014)

Expensive multiobjective optimization for robotics
M. Tesch et al. (2013)

Bayesian multiobjective optimization to steer snake robots, to optimize both speed and head camera stability: replace the expected improvement (EI) with the expected improvement in (dominated) hypervolume (EIHV). Also gives another test problem, built from the Branin function.

A tutorial on Bayesian optimization of expensive cost functions, with application to active user modeling and hierarchical reinforcement learning
E. Brochu et al. (2010)

Good review article.

ParEGO: a hybrid algorithm with online landscape approximation for expensive multiobjective optimization
J. Knowles (2004)

The following multiobjective optimization algorithm is more economical (in function evaluations) than NSGA-II:

- Initialize the population with a Latin hypercube;
- Take a weight vector $\lambda \in \Delta_n$ at random (a new one for each iteration, possibly with some of the coordinates set to zero);
- Consider the objective function

$$f(x) = \text{Max}_i \lambda_i f_i(x) + \rho \sum_i \lambda_i f_i(x);$$

- Model it using a Gaussian process (if there are more than 80 points in the population, take 80 at random);
- Use some optimization algorithm (say, Nelder-Mead) to maximize the expected improvement;

- Add the new point to the population;
- Iterate.

The paper also provides a few test functions.

***Multiobjective optimization
on a budget of 250 evaluations***
J. Knowles and E.J. Hughes (2005)

ParEGO performs better than a binary-search-based algorithm:

- Pick a point at random in the largest hypercube, and split the hypercube at that point in the direction that yields the most “cube-like” sub-spaces;
- Idem with a point close to a “good point”, for some random aggregation of the scores, e.g. $\sum_i \lambda_i f_i(x)$, $\lambda \sim U(\Delta_n)$;
- Alternate between those steps with a predefined exploration/exploitation ratio.

***Multiobjective optimization
of urban wastewater systems using ParEGO:
a comparison with NSGA-II***
G. Fu et al. (2008)

Another comparison of ParEGO and NSGA-II.

***Efficient global optimization
of expensive black-box functions***
D.R. Jones et al. (1998)

Not very different from DACE: start with a Latin hypercube; check the goodness of fit of the model (and transform the variables if needed); compute the expected improvement in closed form.

***Efficient global optimization (EGO)
for multi-objective problem and data mining***
S. Jeong and S. Obayashi (2005)

Another EGO example.

BOA: the Bayesian optimization algorithm
M. Pelikan et al. (1999)

Variant of CMA-ES with Bayesian networks (suitable for discrete variables) instead of a Gaussian distribution.

***Bayesian optimization algorithms
for multi-objective optimization***
M. Laumanns and J. Ocenasek (2002)

The multiobjective Bayesian optimization algorithm works as follows:

- Keep an archive of best solutions (all those that ε -dominate the solutions seen so far, but allow some dominated solutions to have at least k of them);
- Model the archive, not unlike CMA-ES, but with decision trees (one for each variable – Bayesian networks proved too complex) instead of a Gaussian distribution;
- Sample candidates from this model.

***Multi-objective
Bayesian optimization algorithm***
N. Khan et al. (2002)

BOA can be generalized to multiobjective optimization: use non-dominated sorting and the crowding distance to select the n best solutions.

***Multiobjective evolutionary algorithm
test suites***
D.A. van Veldhuizen and G.B. Lamont (1999)

***Scalable test problems for evolutionary
multi-objective optimization***
K. Deb et al. (2001)

***Combining multiobjective optimization
and Bayesian model averaging to calibrate
forecast ensembles of soil hydraulic models***
T. Wöhling and J.A. Vrugt (2008)

Bayesian optimization with Gaussian processes replaced by a (BMA) ensemble of domain-specific (PDE) models.

***Bayesian optimization
with inequality constraints***
J.R. Gardner et al. (2014)

Constrained Bayesian optimization,

$$\begin{array}{ll} \text{Find} & x \\ \text{To minimize} & f(x) \\ \text{Such that} & g(x) \geq 0, \end{array}$$

where both the objective f and the constraints g are expensive to compute, is a straightforward generalization of Bayesian optimization: replace the expected improvement $E[(f(x^+) - \hat{f}(x))_+]$ with the expected constrained improvement $E[\mathbf{1}_{\hat{g}(x)} \cdot (f(x^+) - \hat{f}(x))_+]$. One often assumes conditional independence: $\hat{g}(x) \perp\!\!\!\perp \hat{f}(x) \mid x$.

***Pareto front modeling for sensitivity analysis
in multi-objective Bayesian optimization***
R. Calandra et al. (2014)

In multiobjective Bayesian optimization (MOBO), do not return a discrete set of solutions but, since a model was used for the optimization, a model of the Pareto front.

Design and analysis of computer experiments
J. Sacks et al. (1989)

One of the first papers on Bayesian optimization.

*A fast and elitist
multiobjective genetic algorithm: NSGA-II*
K. Deb et al. (2002)

The non-dominated sorting genetic algorithm II (NSGA-II) solves multi-objective optimization problems, *i.e.*, estimates their non-dominated front.

1. The candidate solutions are sorted by first finding the non-dominated front, removing it, and iterating. The **non-dominated rank** can be computed efficiently:
 - For each solution, compute the domination count, *i.e.*, the number of solutions that dominate it;
 - For each solution, compute the set of solutions it dominates;
 - The first non-domination front solutions have domination count zero: remove it;
 - Update the domination counts and the domination sets;
 - Iterate.
2. To preserve diversity, look at the **crowding distance** of each solution, defined as the average side length of the cuboid around it with (half) its vertices among the other solutions.
3. Define a partial order on the solutions:
 - Prefer solutions with a lower non-domination rank;
 - If the ranks are equal, prefer solutions with a higher crowding distance.
4. One can add constraints:
 - Prefer feasible solutions;
 - When two solutions are infeasible, prefer that with the smaller constraint violation.

The paper also contains reference problems.

*GPfit: an R package
for Gaussian process model fitting
using a new optimization algorithm*
B. MacDonald et al. (2013)

When fitting a Gaussian process on non-noisy data, with a Gaussian correlation function

$$R_{ij} = \text{Cor}(y_i, y_j) = \prod_k \exp -\theta_k |x_{ik} - x_{jk}|^2,$$

$\theta_k > 0$, the correlation matrix can be ill-conditioned (some of the points are too close), and the likelihood has local extrema very close to zero. One can replace R with $R + \delta I$, with the smallest nugget δ that makes the matrix well-conditioned [this is the idea behind ridge regression; this is also what you naturally do when the eigenvalues are too close to zero], and reparametrize θ as $\theta = \exp \phi$.

Check the R packages **GPfit** (no noise), **tgp** (noise) or **mlegp** (noise, numerically unstable).

Also mentions **lhs::maximinLHS** (random but well-dispersed points).

*News and monetary shocks
at a high frequency: a simple approach*
T. Matheson and E. Stavrev (2014)

Given a bivariate time series X , one can estimate a VAR(1) model $X_t = \alpha + \beta X_{t-1} + \varepsilon_t$ using OLS.

To interpret the residual (*i.e.*, to estimate a structural VAR (SVAR) model), one can try to write it as an MA(1) process, $\varepsilon_t = A\eta_t$ where $\eta \sim N(0, 1)$. The innovations η represent independent (Gaussian, standard) shocks.

There is not enough information to estimate both A and η : if $\Sigma = \text{Var} \varepsilon$ has Choleski decomposition $\Sigma = PP'$, then $A = P$ is a solution, but so is $A = PU$, for $U \in O_2$. One typically adds linear constraints on A to ensure that there is only one solution, *e.g.*, A lower-triangular.

Instead, one can impose constraints on the signs of (some) of the coefficients) of A , *e.g.*,

$$\begin{pmatrix} + & + \\ + & - \end{pmatrix}.$$

This is still insufficient to determine A , but it is sufficient for a Bayesian approach: one can compute the posterior distribution of A (using, *e.g.*, a uniform prior on O_2). The authors use rejection sampling [but since the elements of O_2 admit a simple parametrization, exact computation should be possible – rejection sampling poses even larger problems in higher dimensions]. Since $O_2 \approx \mathbf{S}^1 \amalg \mathbf{S}^1$, it is not straightforward to extract an estimator from the posterior distribution.

*How do fiscal and technology shocks
affect real exchange rates?
New evidence for the United States*
Z. Enders et al. (2008)

More details on SVAR models with sign restrictions: allowance for small deviations to the sign constraints, use of the posterior distribution to test the sign of the non-constrained elements.

*Scaling log-linear analysis
to datasets with thousands of variables*
F. Petitjean and G.I. Webb (2015)

Given M qualitative variables V_1, \dots, V_M , **log-linear analysis** (LLA) greedily builds a model

$$P[V_1 = a_1, \dots, V_M = a_M] = u + \sum_i u_i(a_i) + \sum_{i < j} u_{ij}(a_i, a_j) + \dots$$

only adding a term if it leads to a significant difference.

At each step, it is not necessary to re-examine all the (tuples) of variables: one can identify many of those

that remain insignificant and only re-evaluate the others.

Implementation: Chordalysis (Java, GPL).

A statistically efficient and scalable method for log-linear analysis of high-dimensional data
F. Petitjean et al. (2014)

Use minimum message length (MML) instead of goodness-of-fit χ^2 tests.

Scaling log-linear analysis to high-dimensional data
F. Petitjean et al. (2013)

Considering only decomposable models (if an interaction between k variables is present, then so are all of its subsets, and the corresponding graph is *chordal*) leads to more efficient χ^2 computations.

Unsupervised learning of acoustic features via deep canonical correlation analysis
W. Wang et al.

Canonical correlation analysis (CCA) looks for highly correlated linear combinations between two groups of variables, X and Y :

$$\begin{array}{ll} \text{Find} & u, v \\ \text{To maximize} & \text{Cor}(u'X, v'Y). \end{array}$$

More generally (if X and Y are centered),

$$\begin{array}{ll} \text{Find} & U, V \\ \text{To maximize} & \text{trace } U'XY'V \\ \text{Such that} & U'XX'U = nI \\ & V'YY'V = nI. \end{array}$$

This is equivalent to minimizing

$$\frac{1}{n} \|U'X - V'Y\|_F^2 + \lambda \|U\|_F^2 + \lambda \|V\|_F^2.$$

One can replace X and Y with their embedding in a reproducing kernel Hilbert space (RKHS) or a deep neural net.

Tensor factorization via matrix factorization
V. Kuleshov et al. (2015)

To compute an approximate CP decomposition of a symmetric 3-tensor, evaluate it on a set of random vectors to get symmetric matrices $(M_\ell)_\ell$ and jointly diagonalize them, *i.e.*, find U orthogonal such that $UM_\ell U'$ be almost diagonal (use an L^2 penalty on the off-diagonal elements – it is possible to build U iteratively, as a product of simple (rotation) matrices). This can be generalized to higher-order tensors or to non-symmetric tensors – consider

$$\begin{pmatrix} 0 & M' \\ M & 0 \end{pmatrix}.$$

Fastfood – approximating kernel expansions in loglinear time
Q. Le et al. (2013)

Forecasts from kernel methods require the evaluation of the kernel on a large number of points (e.g., for SVM, one needs

$$f(x) = \sum_{y \text{ support vector}} \alpha_y k(y, x),$$

and the number of support vectors grows linearly with the data).

A kernel can be written

$$k(x, y) = \sum \lambda_i \phi_i(x) \phi_i(y).$$

It can be approximated by drawing i_1, \dots, i_n with $p(i) \propto \lambda_i$ and considering $k(x, y) \approx \sum_{k=1}^n \phi_{i_k}(x) \phi_{i_k}(y)$.

For Gaussian radial basis functions (RBF), one can use $\phi_j(x) = \exp(i(Zx)_j)$ as eigenfunctions, where Z is a Gaussian random matrix.

This matrix is large, but may be replaced with $SHG\Pi HB$ where B has random ± 1 on the diagonal, G has random Gaussian numbers on the diagonal, S is a (diagonal) scaling factor, Π is a random permutation matrix and H is a Walsh-Hadamard matrix:

$$H_2 = \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}, \quad H_{2d} = \begin{pmatrix} H_d & H_d \\ H_d & -H_d \end{pmatrix}.$$

Speeding up convolutional neural network using fine-tuned CP-decomposition
V. Lebedev et al. (2015)

Convolutional neural networks (CNN) can be sped up by replacing the 4D convolution kernel with a low-rank approximation.

An entropy-based early-warning indicator for systemic risk
M. Billio et al. (2015)

Use the entropy

$$-\sum p_i \log p_i \quad (\text{Shannon})$$

$$\frac{1}{\alpha - 1} \left(1 - \sum p_i^\alpha \right) \quad (\text{Tsallis})$$

$$\frac{1}{1 - \alpha} \log \sum p_i^\alpha \quad (\text{Rényi})$$

of

- The marginal expected shortfall

$$\text{MES}_i = E[r_i \mid r_{\text{market}} < \text{VaR}_{\text{market}}^{5\%}];$$

- ΔCoVaR , where

$$\Delta\text{CoVaR}_{m,i}^\alpha = \text{CoVaR}_{m,i}^\alpha - \text{CoVaR}_{m,i}^{1/2}$$

$$\text{CoVaR}_{m,i}^\alpha = \text{VaR}^\alpha[r_{\text{market}} \mid r_i = \text{VaR}_i^\alpha];$$

- The number of edges in the Granger causality graph of asset returns

to predict crises (in the Finance industry).

New ranks for even-order tensors and their application in low-rank tensor optimization
B. Jiang et al. (2015)

For tensors, the notion of rank is complicated.

The Black-Litterman approach: original model and extensions
A. Meucci (2010)

The Black-Litterman model

π	equilibrium market returns
$\mu \sim N(\pi, \tau\Sigma)$	<i>expected</i> market returns
$X \sim N(\mu, \Sigma)$	market returns
$P'\mu \sim N(v, \Omega)$	view on the expected returns

is needlessly complicated and even counter-intuitive (the limiting cases $\Omega \rightarrow 0$ or $\Omega \rightarrow \infty$ are not those the end-user will expect). Instead, one can specify views on the market returns:

$$X \sim N(\mu, \Sigma)$$

$$P'X \sim N(v, \Omega).$$

To compute the posterior distribution, reformulate the model as

$X \sim N(\mu, \Sigma)$	returns
$Z \sim N(0, \Omega)$	error on the views
$v = P'X + Z$	views,

compute the joint distribution of $(X, Z, P'X + Z)$ and then the conditional distribution $X \mid P'X + Z = v$.

A fuzzy R code similarity search detection algorithm
A. Bartoszek and M. Gagilewski

To measure the similarity (plagiarism, copy-paste) between two functions:

- Compare the edit distance μ_1 (`utils::adist`) between the strings (normalized with `deparse(paste(text=f))`);
- Consider the blocks of code as bags of functions (indeed, `<-`, `:`, `+`, `for` are functions) and compute some variant of Jaccard similarity, e.g.,

$$\mu_2(x, y) = \frac{\sum \text{Min}(x_i, y_i)}{\sum x_i + y_i}$$

where \mathbf{x} and \mathbf{y} are the count vectors;

- Compute the abstract syntax tree (AST) (`utils::getParseData`), ignore names and values (`SYMBOL`, `NUM_CONST`) and compute the total length μ_3 of the common substrings above some minimum length;
- Combine those three measures using a training set and logistic regression.

Other plagiarism detection tools include: MOSS, JPlag, GPlag.

Detecting similarity of R functions via a fusion of multiple heuristic methods
A. Bartoszek and M. Gagilewski

To measure code similarity, use asymmetric measures, similar to the previous three ones, but normalized by dividing by the length of the first function, e.g.,

$$\mu_2(x, y) = \frac{\sum \text{Min}(x_i, y_i)}{\sum x_i}.$$

Add another measure,

$$\mu_4 = \frac{\#V(H_{ij})}{\#V(G_i)}$$

where G_i is the *program dependence graph* (PDG: the vertices are the vertices of the AST; there are two types of edges, corresponding to the control flow and to data dependencies) of f_i , and H_{ij} is the largest common (isomorphic) subgraph of G_i and G_j (computed with the McGregor heuristic algorithm, from the Boost C++ library).

An industrial-strength audio search algorithm
A.L.C. Wang

To fingerprint audio files:

- Compute the time×frequency spectrogram;
- Identify peaks; ensure they are approximately uniformly distributed;
- Use rectangular regions of this constellation of peaks as fingerprint.

Search is then an alignment problem.

A comparison of fractal trees to log-structured merge (LSM) trees
B.C. Kuszmaul (2014)

A *fractal tree index* is a B-tree with a buffer at each node: only when the buffer is full is it sent to lower nodes. This requires more memory, but greatly reduces disk writes. [Nothing seems to justify the work “fractal”: “lazy” would have been a better name.]

LSM trees store runs of data, *i.e.*, lists of key-value pairs sorted in key order (some big data databases keep recently-inserted data in memory, sorted, as long as it fits, and then write it to disk, each time in a different file). These runs can be arranged in a tree.

Data structures for text sequences
C. Crowley (1998)

To store and manipulate text, with insert and delete operations (as in a text editor), check the following data structures:

- Array;
- Array with a gap in the middle (corresponding to the current position);
- Doubly-linked list of characters, or lines, or fixed-length (partially-empty) buffers;

- PieceTable: two buffers, one read-only (the original file), one append-only, with an array of pointers indicating which span of which buffer to use in which order.

An efficient natural neighbour interpolation algorithm for geoscientific modelling

H. Ledoux and C. Gold

Move in the space of triangulations using flipping movements $\diamond \mapsto \triangleleft$ until you reach the Delaunay triangulation.

A stable and fast implementation of natural neighbor interpolation

L. Liang and D. Hale (2010)

Java implementation: `edu.mines.booles.jtk.interp.`

Differential privacy and machine learning: a survey and review

Z. Ji et al. (2014)

Differential privacy adds noise to ensure that changes to a single individual have a negligible impact. For instance, one can add Laplace noise to the result $f(D)$, with the amplitude of the noise proportional to

$$\text{Max}_{d(D_1, D_2)=1} \|f(D_1) - f(D_2)\| \text{ or } \text{Max}_{d(D, D')=1} \|f(D) - f(D')\|$$

(in the second case, only D' varies, but you need some smoothing).

Similarly, to compute $\text{Argmax}_a f(D, a)$ (e.g., to maximize a likelihood), one can sample from a Laplace distribution

$$p(a) \propto \exp \frac{\varepsilon f(D, a)}{2 \text{Max}_{\text{dist}=1} \|\Delta f\|}$$

For most machine learning algorithms, adding noise to the data and/or the loss function and/or the result ensures differential privacy.

DREAM_(D): an adaptive Markov chain Monte Carlo simulation algorithm to solve discrete, non-continuous, and combinatorial posterior parameter estimation problems

J.A. Vrugt and C.J.F. Ter Braak (2011)

Differential evolution can be used as a proposal distribution in an adaptive Metropolis simulation with several MCMC chains (DREAM).

For discrete states, one could try to round the results, but this only works with ordered discrete variables. Instead, one can take two chains at random, two coordinates, and swap them.

Discrete MCMC can also be used for optimization or satisfiability problems (e.g., Sudoku). [How different is it from simulated annealing and genetic algorithms?]

A directional multivariate value at risk

R. Torres et al.

The value-at-risk (VaR) can be generalized to a multivariate setup by considering the set $Q_\alpha = \{\mathbf{x} : P[X \leq x] = \alpha\}$ or, if we prefer a single vector, the intersection $Q_\alpha \cap E[X] + \text{Span } \mathbf{u}$, where $\mathbf{u} = (1, \dots, 1)'$ is the vector in the middle of the positive quadrant. This can be generalized to an arbitrary quadrant. [The authors mistakenly claim that the quadrant is entirely determined by \mathbf{u} .]

Shortfall deviation risk: an alternative for risk measurement

M.B. Righi and P.S. Ceretta

There are many, many variants of value at risk (VaR) and expected shortfall (ES). Here is yet another one:

$$\text{ES} = E[\text{loss} \mid \text{loss} \geq \text{VaR}]$$

$$\text{SDR} = \text{ES} + \sigma[\text{loss} \mid \text{loss} \geq \text{ES}]$$

A robust statistics approach to minimum variance portfolio optimization

L. Yang et al.

Estimate the variance matrix as the fixed point $V(\rho)$ of

$$V(\rho) = (1 - \rho) \frac{1}{n} \sum_i \frac{x_i x_i'}{\frac{1}{n} x_i' V(\rho)^{-1} x_i} + \rho I_N$$

and choose ρ to minimize the (ex post) variance portfolio (Tyler's robust M estimator).

Tornadoes and related damage costs statistical modeling with a semi-Markov approach

C. Corini et al. (2015)

Tornadoes can be modeled using a *Markov renewal process* (J, T)

J_n = (discrete) intensity of the n th tornado
(Fujita scale)

T_n = (discrete) time of the n th tornado.

One can also consider

Z_t = intensity of the last tornado

B_t = time since the last tornado.

Both (J, T) and (Z, B) are Markov; Z is a *semi-Markov* process.

Hawkes processes in finance

E. Bacry et al.

Survey: definitions, properties, applications, estimation, simulation (either one event at a time, as for inhomogeneous Poisson processes, or by tracking the parenthood tree: first, generate events coming from the background rate, then their children, then their grand-children, etc.).

Dirac processes and default risk
C. Kenyon and A. Green (2015)

Since the short rate r is always used in an integral, $\int_{t_1}^{t_2} r(s)ds$, it does not have to be a stochastic process: it can be a generalized process. A *Dirac process* is a process of the form $\sum_i \delta_{T_i}$, where the T_i are the arrival times of a Poisson process and δ_a is the Dirac mass in a . They can be used in option pricing.

The Horseshoe+ estimator of ultra-sparse signals
A. Bhadra et al.

Sparse signals can be recovered by thresholding, using the hierarchical model

$$\begin{aligned}\theta_i &\sim (1 - \mu)\delta_0 + \mu N(0, \psi^2) \\ X_i &\sim N(\theta_i, 1).\end{aligned}$$

The Horseshoe prior is another hierarchical model:

$$\begin{aligned}\lambda_i &\sim \text{Half-Cauchy}(\tau) \\ \theta_i &\sim N(0, \lambda_i^2) \\ X_i &\sim N(\theta_i, 1).\end{aligned}$$

The Horseshoe+ prior is yet another one:

$$\begin{aligned}\eta_i &\sim \text{Half-Cauchy}(1) \\ \lambda_i &\sim \text{Half-Cauchy}(\eta_i \tau) \\ \theta_i &\sim N(0, \lambda_i^2) \\ X_i &\sim N(\theta_i, 1).\end{aligned}$$

Hierarchical Bayesian survival analysis and projective covariate selection in cardiovascular event risk prediction
T. Peltola et al.

Prefer the Horseshoe prior to the Laplace one (lasso): it does not shrink large coefficients too much. The resulting (Bayesian, posterior) model is not sparse, but one can find a sparse model with similar forecasts.

Moments determine the tail of the distribution (but not much else)
B.G. Lindsay and P. Basak (2000)

$$\sup_{\substack{F \text{ and } G \text{ have} \\ \text{the same first} \\ p \text{ moments}}} |F(x) - G(x)| \leq w_p(x)$$

$$w_p(x) = (1 \quad x \quad \cdots \quad x^p) \begin{pmatrix} 1 & m_1 & \cdots & m_p \\ m_1 & & & \vdots \\ \vdots & & & \vdots \\ m_p & \cdots & \cdots & m_{2p} \end{pmatrix} \begin{pmatrix} 1 \\ x \\ \vdots \\ x^p \end{pmatrix}$$

Distinguishing cause from effect using observational data: methods and benchmarks
J.M. Mooij et al.

Comparison of bivariate causal discovery algorithms, additive noise models (compare the complexity of the linear models $y \sim x$ and $x \sim y$) and information-theoretic causal inference (compare the flatness or entropy of the margins – for non-linear relations, the flatter is the cause) on a benchmark dataset.

A fast unified algorithm for solving group-lasso penalized learning problems
Y. Yang and H. Zou (2014)

A faster algorithm for the *group lasso*

$$\hat{\beta} = \underset{\beta}{\text{Argmin}} \text{Loss}(\beta) + \sum_{g \in \text{Groups}} \|\beta_g\|_2$$

(this is $\|\cdot\|_2$, not $\|\cdot\|_2^2$), when the loss function has a bounded second derivative (or, more generally, a Lipschitz first derivative: least squares, squared hinge loss, huberized hinge loss).

Implemented in R in `gglasso`. Also check `grplasso`.

Archimedian-based Marshall-Olkin distributions and related copula functions
S. Mulinacci

The generalized Marshall-Olkin copula is the copula of $(\text{Min}(X_1, X_3), \text{Min}(X_2, X_3))$, where (X_1, X_2, X_3) has an archimedian copula and (for instance) exponential margins. The random variables X_1 and X_2 are the failure times of two machines, X_3 is a systemic failure time (it entails the failure of both machines), the archimedian copula represents a common factor that influences all three types of failures in the same way (e.g., the maintenance of the power plant).

Fully automated variational inference of differentiable probability models
A. Kucukelbir et al.

Variational Bayes in Stan: let X denote the observed variable, Z the hidden variable; $p(X, Z)$ is known, but $p(Z|X)$ is too complicated. One can look for $q(Z)$, Gaussian, close to $p(Z|X)$ for the Kullback-Leibler distance, estimated by gradient descent.

blowtorch: an R package for on-line constrained optimization
L. Petito and S. Pollack

The `blowtorch` package solves the equality-constrained optimization problem

$$\begin{aligned}\text{Find} & \quad x \\ \text{To maximize} & \quad f(x) \\ \text{Such that} & \quad G(x) = 0\end{aligned}$$

using Lagrange multipliers

$$\Lambda(x, \lambda) = f(x) - \lambda \cdot G(x)$$

and stochastic gradient descent (SGD) to minimize $\|\nabla\Lambda\|_2^2$. The user must provide f', f'', G, G', G'' ; it can be used as a pre-processing step before CG (conjugate gradient) or BFGS.

***Stochastic dual coordinate ascent methods
for regularized loss minimization***
S. Shalev-Shwartz and T. Zhang

One can replace gradient descent

$$\begin{array}{ll} \text{Find} & w \\ \text{To minimize} & \frac{1}{n} \sum_i \phi_i(w'x_i) + \frac{\lambda}{2} \|w\|^2 \end{array}$$

with dual coordinate ascent

$$\begin{array}{ll} \text{Find} & x \\ \text{To maximize} & \frac{1}{n} \sum -\phi_i^*(-\alpha_i) - \frac{\lambda}{2} \left\| \frac{1}{\lambda n} \sum \alpha_i x_i \right\|^2 \end{array}$$

For faster convergence, start with SGD, then use stochastic DCA.

***The role of Occam's razor
in knowledge discovery***
P. Domingos

There are two versions of Occam's razor:

1. If the generalization error is the same, prefer simpler models: they are easier to understand and explain;
2. If the training error is the same, prefer the simpler model: the generalization error will be lower.

The second is wrong:

- In a regression, one should not round the coefficients, even though “ $x + 2$ ” is simpler than “ $1.17x + 1.98$ ”;
- The VC dimension is a better indicator of the generalization error than the number of parameters;
- The number of models among which the final model is chosen is more important than its complexity (multiple testing);
- Insanely complex models work well: penalized regression, the kernel trick which inflates the dimension of the feature space, ensemble models, deep learning.

***Estimating the algorithmic complexity
of stock markets***
O. Brandouy et al. (2015)

The Kolmogorov complexity $K(s)$ of a binary string s is the minimum length of a program (in some fixed language) that outputs s . An (infinite) string s is *random* (this is *not* a probabilistic notion) if

$$\exists c \quad \forall n \quad K(s_{1:n}) \geq n - c.$$

One can estimate the randomness of a (long) string by looking at its compressibility, with algorithms such as Huffman, RLE or Paq808. To apply this idea to time series, iteratively remove the visible structure, try to compress, and iterate as long as the signal remains compressible:

- Remove the visible structure from the prices: compute the log-returns;
- Remove the visible structure (the distribution of returns): uniformize the returns;
- Remove the visible structure (volatility clustering): uniformize the returns on a moving window;
- Discretize, compress.

What remains is not clear: it could be market microstructure (e.g., tick size) or the artefacts of the structure-removing procedures.

Liquidity crises on different time scales
F. Corradi et al. (2015)

The notion of liquidity depends on the time scale: the depth and breadth of the limit order book around 30 seconds; the speed at which the order imbalance disappears, around 15 minutes.

***Iterated prisoner's dilemma contains strategies
that dominate any evolutionary opponent***
W.H. Press and F.J. Dyson (2012)

In the iterated prisoner's dilemma (IPD), a longer (but still finite) memory does not give any advantage (over a 1-period memory). Strategies can be modeled by a Markov chain. A player can decide on his/her opponent's rewards (but not on his/her own).

***Optimal thresholding of classifiers
to maximize F1 measure***
Z.C. Lipton et al.

Extreme learning machines
E. Cambria and G.B. Huang (2013)

ELMs (or echo networks) are neural nets whose hidden layers are initialized at random; they can be seen as random kernel embeddings.

Text understanding from scratch
X. Zhang and Y. LeCun

Convolutional neural networks can be used on streams of characters (not words) for text classification (6 convolutional layers, 3 fully connected ones, 2 dropout units); the characters are encoded as m -dimensional boolean vectors.

The training data can be augmented with synonyms (mytheas, from LibreOffice, itself from Wordnet). The approach also works with non-alphabetic languages using romanization (for Chinese: pinyin and jieba)

It works better than a bag-of-words (logistic regression on the 5000 most frequent words) or a bag of centroids (idem, after applying k -means, $k = 5000$, to word2vec).

***Delving deep into rectifiers:
surpassing human-level performance
on ImageNet classification***
K. He et al.

Rectified linear units (ReLU) $f(y) = y_+$ can be generalized to parametric rectified linear units $f(y) = y_+ - ay_-$, where a is learned (and not penalized – like biases). The weights can be initialized randomly.

Online passive-aggressive algorithms
K. Crammer et al. (2006)

SVMs or regressions can be estimated online: if the new observation is correctly classified (with high enough a margin), do not update the model (passive step), otherwise, update it a little (aggressive step).

The relaxed online maximum margin algorithm
Y. Li and P.M. Long (2001)

SVMs can be fit online (*i.e.*, one observations at a time).

***Why does deep learning work?
A perspective from group theory***
A. Paul and S. Venkatasubramanian (2015)

In autoencoders formed a group

$$\begin{aligned} G &= \{\text{autoencoder}\} \\ X &= \{\text{possible inputs}\} \\ Y &= \{\text{training data}\} \subset X, \end{aligned}$$

with G acting on X , learning would be a random walk looking for $g \in \text{Stab } Y$. This can be made rigorous.

***Evolutionary artificial neural network
based on chemical reaction optimization***
J.J.Q. Yu et al.

Chemical reaction optimization (CRO) is a population-based simulated annealing optimization algorithm:

- Molecular structure: solution;
- Potential energy: value of the objective function (to minimize);
- Kinetic energy: tolerance to an increase in energy;
- Decomposition (of a molecule): randomization of 50% of the coordinates;
- Synthesis (collision between molecules): cross-over;
- Motion: random neighbour, mutation.

***Reinforcement learning
neural Turing machines***
W. Zaremba and I. Sutskever

A Neural Turing machine is a Turing machine in which everything (input, output, memory access, etc.) has been replaced by a distribution (over inputs, outputs, possible memory locations, etc.). Reinforcement learning can help train it more efficiently, by avoiding accessing all the memory at each iteration.

Markov logic networks
M. Richardson and P. Domingos

A **Markov logic network** (MLN) is a set of *first order logic* formulas (FOL adds functions and quantifiers to *propositional logic*), with weights.

MLNs extend both FOL and Markov networks. A MLN defines a Markov network: write all the formulas in clausal form (the initial universal quantifiers can be omitted; the existential quantifiers can be replaced by functions; only use disjunctions), e.g.,

Formula	Clausal form
$\forall x F(x)$	$F(x)$
$\forall x \exists y F(x, y)$	$F(x, g(y))$
$\forall x F(x) \Rightarrow G(x)$	$G(x) \vee \neg G(x);$

add a node for each possible grounding of each predicate. The network is large (even if we ensure it is finite by demanding that the values of the functions be among the constants), but inference does not always require grounding the whole network,

DL-Learner manual
J. Lehmann (2014)

Perhaps the only open-source ILP learner.

***Efficient program synthesis using constraint
satisfaction in inductive logic programming***
J. Ahlgren and S.Y. Yuen (2013)

ILP systems often arrange the set of candidate clauses into a lattice, and explore it from the bottom (using A* for Prolog and simulated annealing for Aleph), but many candidates are invalid. Atom is similar, but uses a SAT solver (the DPLL algorithm) to generate valid candidates.

Integer sequence discovery from small graphs
T. Hoppe and A. Petrone (2014)

Encyclopedia of finite graphs: all simple connected graphs with up to 10 vertices and many of their invariants, with the corresponding OEIS sequence.

Tools used: **nauty** (**gen -c** to enumerate the graphs), NetworkX, Graph-tool (C++, with Python bindings, GPL), PuPL, SQLite.

***DeepWalk: online learning
of social representations***
B. Perozzi et al. (2014)

A set of (fixed-length) random walks on a graph can be seen as a corpus: NLP techniques apply (language models, LDA, word2vec, etc.).

***Partial correlation analysis:
applications for financial markets***
D.Y. Kenett et al. (2014)

The influence of a random variable Z on the correlation between two random variables X and Y is

$$d(X, Y : Z) = \rho(X, Y) - \rho(X, Y | Z)$$

where

$$\rho(X, Y | Z) = \frac{\rho(X, Y) - \rho(X, Z)\rho(Y, Z)}{\sqrt{(1 - \rho^2(X, Z))(1 - \rho^2(Y, Z))}}.$$

The average influence $d(X : Z) = \langle d(X, Y : Z) \rangle_{Y \neq X}$ or $d(X) = \langle d(X : Z) \rangle_Z$ is asymptotically Gaussian and can be used in statistical tests.

For two dates, one can compute the rank correlation $\text{Cor}(d_{t_1}(X), d_{t_2}(X))$: the corresponding date×date matrix shows the market stability.

By looking at the influence of stocks Y in a given sector S_i on a stock X , $d(X : S) = \langle d(X : Y) \rangle_{Y \in S}$, one can derive a finer sector decomposition, adapted to companies spanning several sectors.

***A multiple network approach
to corporate governance***
F. Bonacina et al. (2014)

Eigenvalue centrality $x_i = \sum_j A_{ij}x_j$ can be generalized to directed graphs (HITS algorithm, identifying hubs and authorities)

$$a_j = \sum_i A_{ij}h_i$$

$$h_i = \sum_j A_{ij}a_j$$

and directed graphs with coloured topics

$$a_j = \sum_{ik} A_{ijk}h_i t_k$$

$$h_i = \sum_{jj} A_{ijk}a_j t_k$$

$$t_k = \sum_{ij} A_{ijk}a_j h_i.$$

The HITS authority \mathbf{a} and hub \mathbf{h} vectors are the first left and right singular vectors of A , obtained from a low rank decomposition $A \approx \sum_r \sigma_r u^{(r)} \circ v^{(r)}$ or the SVD decomposition $A = UDV'$ – the next singular vectors can often be interpreted as well.

These decompositions can be generalized to tensors: parallel factor analysis $A \approx \sum_r \sigma_r u^{(r)} \circ v^{(r)} \circ w^{(r)}$ or Tucker decomposition $A \approx G \times_1 U \times_2 V \times_3 W$.

In a financial context, one could look at the three following networks:

$$A_{ij1} = \text{percentage of company } i \text{ owned by company } j$$

$$A_{ij2} = \text{number of directors sitting on both boards}$$

$$A_{ij3} = \mathbf{1}_{\text{Cor}(X_i, X_j) > 0.65}.$$

The various singular vectors correspond to various influence networks.

***Inside the network: trading of inside and
outside stocks by corporate insiders***
H. Berkman et al. (2014)

Insiders central in the corporate network earn higher returns when they buy or sell their stock, or nearby stocks.

A network approach to portfolio selection
G. Peralta and A. Zareei (2014)

Stocks with high centrality are more stable; stocks with low centrality bring higher diversification benefits. Avoid stocks with extreme centrality: they are either too volatile or fail to bring any diversification benefit.

***Using friends as sensors
to detect global-scale contagious outbreaks***
M. Garcia-Herranz et al. (2014)

Since the S-shaped cumulative epidemic curve is shifted left for more central nodes, one can build an early-warning system (here, for viral spread of hashtags on Twitter) using a random sample of central nodes. For instance, one could take n nodes at random (control group) and then a random neighbour (followee) of each of them (sensor group – they have higher centrality).

***Common pitfalls
using the normalized compression distance:
what to watch out for in a compressor***
M. Cebrián et al. (2005)

The (incomputable) normalized information distance (NID) is

$$\text{NID}(x, y) = \frac{\text{Max}\{K(x|y) - K(x), K(y|x) - K(y)\}}{\text{Max}\{K(x), K(y)\}}$$

where the conditional Kolmogorov complexity $K(x|y)$ is the length of the shortest program that outputs x when fed y , and $k(x) = k(x|\emptyset)$.

The normalized compression distance is

$$\text{NCD}(x, y) = \frac{\text{Max}\{C(xy) - C(x), C(yx) - C(y)\}}{\text{Max}\{C(x), C(y)\}}$$

where $C(x)$ is the length of x after compression with your favourite algorithm (bzip2 (Burrow-Wheeler transform), gzip (LZ77), PMZZ (Markov model)). To really have a distance, one needs $C(xx) = C(x)$ or, at least, $C(xx) = C(x) + O(\log|x|)$ – but if xx exceeds the block size, this is not guaranteed.

Clustering by compression
R. Cilibrasi and P.M.B. Vitányi (2005)

Initial article on NCD, with applications to clustering.
Implementation: `complearn-gui`.

The Google similarity distance
R. Cilibrasi and P.M.B. Vitányi (2007)

Let $N_{\{x,y\}}$ be the number of web pages containing both x and y , according to Google. Define a probability distribution on all singletons and doubletons of search terms by $g(\{x,y\}) \propto N_{\{x,y\}}$ (allowing $x = y$). The Google code is then $G(x,y) = -\log g(\{x,y\}) = -\log N_{\{x,y\}} + \log N$ and $G(x) = G(x,x)$. The normalized Google distance is another approximation of the NID:

$$\begin{aligned} NGD(x,y) &= \frac{G(x,y) - \text{Min}\{G(x), G(y)\}}{\text{Max}\{G(x), G(y)\}} \\ &= \frac{\log \text{Max}\{N_x, N_y\} - \log N_{xy}}{\log N - \log \text{Min}\{N_x, N_y\}} \end{aligned}$$

We do not know N , but the results do not seem very sensitive to it:

$$\#pages \leq N \leq \#words \text{ per page} \times \#pages.$$

Cross-firm information flows
and the predictability of stock returns
A. Scherbina and B. Schlusche (2013)

Test for Granger causality

$$\begin{aligned} x &\sim \text{lag}(x) + \text{lag}(y) + \text{lag}(\text{market}) \\ y &\sim \text{lag}(x) + \text{lag}(y) + \text{lag}(\text{market}) \end{aligned}$$

for all pairs of stocks on a moving window (12 or 36 months, or 52 weeks) to identify leaders ($p < 5\%$ – you may want to control for multiple testing).

For each stock with leaders, forecast the returns from the past returns of the leaders (using the previous regression – there is one forecast per leader) and invest if most leaders agree.

Beware of non-synchronous trading.

Other signs of leadership include: analyst coverage, institutional ownership, trading volume, increased news coverage (but when the coverage is too high, the company ceases to be a leader: information spreads almost instantly).

Exploring multi-layer flow network
of international trade based on flow distances
B. Shen et al. (2015)

After adding source and sink nodes to the world trade flow network (for some commodity) to ensure that the net flow through each node is zero, one can compute distances:

- Expected first passage time;
- Expected (not only first) passage time (only well-defined for open flow networks, *i.e.*, with source and sink);
- The symmetrization of those, *e.g.*, using a minimum or a harmonic mean:

$$\text{Min}(d_{ij}, d_{ji}), \quad \frac{2d_{ij}^\alpha d_{ji}^\alpha}{d_{ij}^\alpha + d_{ji}^\alpha}.$$

The *trophic level* of a node is the (first passage) distance from the source.

The tone of financial news
and the perceptions of stock and CDS traders
M. Liebmann et al. (2014)

One can estimate the relation between news (they are often already tagged, *e.g.*, “results” or “debt/credit”) and returns (for different assets, *e.g.*, stocks and CDS) using a Naive Bayes classifier, *i.e.*, by looking at the words one by one and keeping the most relevant, *e.g.*,

$$\text{Tone}(w) = \frac{P(+|w)}{P(+)} - \frac{P(-|w)}{P(-)}.$$

One could also use association rule mining [mentioned, not tried – should not work well] or logistic regression [not mentioned – should work with a penalty and word pairs].

Commonly-used lexicons do not work well in a financial context (*e.g.*, “cancer” is usually negative, but neutral in a financial context): one needs a bespoke or dynamic lexicon.

Generalized low-rank models
M. Udell et al. (2014)

This is one of the first papers introducing a statistical algorithm with an implementation, not in R, Python, Matlab or C, but in (both) Julia and Spark.

Principal component analysis (PCA) of $A \in \mathcal{M}_{mn}$,

$$\begin{aligned} (X, Y) &= \underset{\substack{X \in \mathcal{M}_{mk} \\ Y \in \mathcal{M}_{nk}}}{\text{Argmin}} \|A - XY'\|_F^2 \\ &= \underset{X, Y}{\text{Argmin}} \sum_{ij} (A_{ij} - x_i y_j')^2 \end{aligned}$$

can be generalized to

$$\underset{X, Y}{\text{Argmin}} \sum_{(i,j) \in \Omega} \text{Loss}(x_i y_j', A_{ij}) + \sum_i r(x_i) + \sum_j s(y_j).$$

Here are a few examples, for the penalty terms:

- Low-rank matrix completion: $\Omega \subsetneq [1, m] \times [1, n]$;
- Quadratically-penalized PCA: $r = s = \|\cdot\|_2^2$;
- Non-negative matrix factorization: $r(x) = I_{\forall j x_j \leq 0}$ where

$$I_{\text{condition}} = \begin{cases} 0 & \text{if condition is true} \\ \infty & \text{otherwise;} \end{cases}$$

- Sparse PCA: $r(x) = I_{\#\{j: x_j \neq 0\} \leq s}$ or its L^1 relaxation $r = \|\cdot\|_1$;
- Quadratic clustering (k -means): $r(x) = I_{\exists \ell: x = e_\ell}$, where the e_ℓ are the basis vectors;
- Quadratic mixtures: $r(x) = I_{x \in \Delta}$, where Δ is the standard simplex;
- Subspace clustering (approximation of the data as a union of low-dimensional subspaces): partition the columns of x into blocks and set $r(x) = I_{\text{at most one block has nonzero entries}}$;

- Feature selection: $r(x) = \|\cdot\|_2^2$, $s(y) = \|\cdot\|_2$ (not $\|\cdot\|_2^2$), to make y column-sparse (most columns are zero);
- Supervised learning;
- Dictionary learning: $r = \|\cdot\|_1$ to enforce sparsity and $s = \|\cdot\|_2^2$ (to ensure the problem is well-posed when $k \gg m, n$).

Here are a few examples for the loss function:

- Robust PCA:

$$\text{Argmin} \|A - XY'\|_1 + \gamma \|X\|_F^2 + \gamma \|Y\|_F^2;$$

- Weighted PCA: $L_{ij}(u, a) = w_{ij}(u - a)^2$;
- Huber PCA: $L(u, a) = \text{huber}(u - a)$, where

$$\text{huber}(x) = \begin{cases} \frac{1}{2}x^2 & \text{if } |x| \leq 1 \\ |x| - \frac{1}{2} & \text{if } |x| \geq 1 \end{cases}$$

- Quantile PCA (if the cost of under- and over-estimating A is different: $L_{ij}(u, a) = \lambda(u - 1)_+ + (1 - \lambda)(u - a)_-$;
- Divergences:

$$L_{\text{KL}}(u, a) = a \log \frac{a}{u} - a + u$$

$$L_{\text{IS}}(u, a) = a \log \frac{a}{u} - 1 + \frac{a}{u}$$

$$L_{\beta}(u, a) = \frac{a^{\beta}}{\beta(\beta - 1)} + \frac{u^{\beta}}{\beta} - \frac{au^{\beta-1}}{\beta - 1};$$

- Boolean PCA: $L(u, a) = (1 - ua)_+$ with $a \in \{0, 1\}$ (hinge loss);
- Logistic PCA $L(u, a) = \text{softplus}(-au) = \log(1 + e^{-au})$, with $a \in \{0, 1\}$;
- Poisson PCA $L(u, a) = e^u - au + a \log a - a = L_{\text{KL}}(e^u, a)$, with $a \in \mathbf{N}$ (count data);
- Ordinal PCA

$$L(u, a) = \sum_{b < a} (1 - u + b)_+ + \sum_{b > a} (1 + u - b)_+;$$

- Interval PCA $L(u, [a, b]) = \text{Max}\{(a - u)_+, (b - u)_+\}$;
- Categorical PCA

$$L(u, a) = (1 - u_a)_+ + \sum_{b \neq a} (1 + u_b)_+,$$

where $a \in \llbracket 1, k \rrbracket$ and $u \in \mathbf{R}^k$, i.e., we consider a block of k columns of Y at a time;

- Ordinal PCA $L(u, a) = \sum_b (1 - I_{a > b} u_b)_+$;
- Permutation PCA $L(u, a) = \sum_i (1 - u_{a_i} + u_{a_{i+1}})_+$;
- Ranking PCA $L(u, a) = \sum_{i < j} (1 - u_{a_i} + u_{a_j})_+$.

The problem is not convex, but often *biconvex* (convex in one variable when the other is fixed) and can be solved by *alternating minimization* (alternatively minimize wrt one variable with the other fixed). Each step is easy to parallelize: treat the rows of X separately. We do not need the exact minimum at each iteration: a single step in the right direction is often enough.

To deal with non-finite regularization terms, one can use the *proximal gradient* method:

$$g_1 = \sum_{j: (i, j) \in \Omega} \nabla \text{Loss}(x_i y_j, A_{ij}) y_j$$

$$x_i \leftarrow \text{prox}_{\alpha r}(x_i - \alpha g_i)$$

where $\text{prox}_f(z) = \text{Argmin}_x f(x) + \frac{1}{2}x - z^2$ and $\alpha = 1/k$ (for the k th iteration) or $\alpha = 1/\|g_i\|_2$.

Stochastic gradient can help.

Careful initialization (e.g., SVD, k-means++) is important.

Adaptive subgradient methods for online learning and stochastic optimization **J. Duchi et al. (2010)**

Gradient descent is the iterative algorithm

$$x_{n+1} \leftarrow x_n - \eta g_n,$$

where η is the learning rate and g_n the gradient (or a subgradient) of the loss function.

Projected gradient descent adds a constraint $x \in \mathcal{X}$:

$$x_{n+1} \leftarrow \text{Argmin}_{x \in \mathcal{X}} \|x - (x_n - \eta g_n)\|_2^2.$$

One can give more importance to the directions in which the gradient is larger:

$$x_{n+1} \leftarrow \text{Argmin}_{x \in \mathcal{X}} \|x - (x_n - \eta G_n^{1/2} g_n)\|_{G_n}^2$$

where $G_n = \sum_{1 \leq k \leq n} g_k g_k'$ or $G_n = \sum \text{diag } g_k g_k'$ and $\|x\|_G^2 = \langle x, x \rangle_G = \langle x, Gx \rangle$ defines the Mahalanobis norm.

The proximal gradient is

$$x_{n+1} \leftarrow \text{Argmin}_{x \in \mathcal{X}} \eta \langle g_n, x \rangle + \eta \phi(x) + B_{\psi_n}(x, x_n)$$

where $\psi_n = \psi$ or $\psi_n = n\phi$ or $\psi_n = \sqrt{n}\psi$ or $\psi_n(x) = \|x\|_{\delta I + G_n^{1/2}}$ or $\psi_n(x) = \|x\|_{\delta I + \text{diag } G_n^{1/2}}$ and

$$B_{\psi}(x, y) = \psi x - \psi y - \langle \nabla \psi y, x - y \rangle$$

is the Bregman divergence. The first term pulls x in the direction $-g_n$, as much as allowed by the other terms; the second is a regularization; the third forces x to be close to x_n .

Identifying and attacking the saddle point problem in high-dimensional non-convex optimization **Y.N. Dauphin et al.**

In high dimension, the local minima (of a draw of a Gaussian process) are very close to the global minimum, but there are many critical points far away from the minima (to see it: plot the value of the objective function at critical points versus the proportion of negative eigenvalues). They are surrounded by plateaus, on which gradient methods get stuck. Newton methods are even worse: the saddle points are attractive (Newton methods assume there are no negative eigenvalues and end up going in the wrong direction).

Trust region methods (minimize a first or second order approximation of the objective, with a constraint on the distance from the previous point) fare better. One can “fix” the Newton method for saddle points by replacing the eigenvalues of the Hessian by their absolute values (saddle-free Newton method). This is actually a trust region method, using $|H|$ as a distance, and a first-order approximation. In high dimension, one can stay on a Krylov subspace (a subspace of the form $\text{Span}\{x, Hx, \dots, H^k x\}$, for some x – this approximates the subspace spanned by the most important eigenvectors).

Fast large-scale optimization by unifying stochastic gradient and quasi-Newton methods
J. Sohl-Dickstein et al. (2014)

Combine the mini-batches of stochastic gradient descent with the approximate Hessian (and absence of hyper-parameters) of quasi-Newton methods by keeping track of the (compressed) approximate Hessian of each mini-batch separately

Deep learning with elastic averaging SGD
S. Zhang et al. (2015)

To parallelize stochastic gradient descent (SGD), add an L^2 penalty for the distance to some central, reference value, updated only once in a while – only send updates to the parameter server for parameters that have drifted enough from their initial values.

More precisely, replace the problem

$$\begin{array}{ll} \text{Find} & x \\ \text{To minimize} & f(x) \end{array}$$

with

$$\begin{array}{ll} \text{Find} & x, x_1, \dots, x_n \\ \text{To minimize} & \sum f(x_i) + \rho \sum \|x - x_i\|^2 \\ \text{Such that} & \forall i \ x_i = x. \end{array}$$

For the implementation, ignore the constraint; worker i knows x_i and x , and can compute the contribution of x_i to the gradient; to update x , the workers need to combine their knowledge (this can be done asynchronously).

Bayesian optimization in a billion dimensions via random embeddings
Z. Wang et al.

Bayesian optimization works best in low dimensions: in high dimensions, project on a random subspace – if the intrinsic dimension of the problem is low, this is good enough.

Practical Bayesian optimization of machine learning algorithms
J. Snoek et al.

Bayesian optimization is a class of optimization algorithms that looks for the minimum of an expensive

function; contrary to other optimization algorithms, it keeps (and uses) all the previous function evaluations.

For instance, one can model the function as a *Gaussian process* (GP), often with a *Matern 5/2 kernel* (this makes the function a.s. \mathcal{C}^2 , but not more) and choose the next point to evaluate by maximizing

- The probability of improvement,

$$\text{PI}(x) = P[y(x) \geq \text{best}];$$

- The expected improvement,

$$\text{EI}(x) = E[(y(x) - \text{best})_+];$$

- The upper confidence bound, $\text{LCB}(x) = \mu_x - \kappa\sigma_x$, where $y(x) \sim N(\mu_x, \sigma_x)$.

(Prefer the expected improvement.)

Possible improvements include:

- Modeling the (log-)duration function as well, and minimizing the expected improvement per second;
- Running several function evaluations in parallel and maximizing the expected improvement over all possible outcomes of the pending evaluations.

Hyperopt: a Python library for optimizing the hyperparameters of machine learning algorithms
J. Bergstra et al. (2013)

If you need to minimize an expensive function, some of whose arguments may be discrete (you need to provide a prior on the parameters, not just bounds). Also check `spearmint`.

Continuous global optimization in R
K.M. Mullen (2014)

Big list of *global* optimization algorithms available in R, *i.e.*, algorithms robust to local minima (simulated annealing, genetic algorithms, particle swarm optimization, branch-and-bound, DIRECT, etc.), with tests on 50 different problems (in the `globalOptTests` package): prefer `nloptr::stogo` (very slow, unless you provide an analytic gradient), `rgenoud::genoud`, `GenSA`.

On best practice optimization methods in R
J.C. Nash (2014)

The `optreplace` package replaces the default optimization algorithms in `optim`:

- `dfoptim::nmkb` instead of Nelder-Mead;
- `Rcgmin` instead of CG;
- `Rvmmmin` instead of BFGS or L-BFGS-B (but it uses a full Hessian, not a low-memory approximation);

`nls` is not replaced, but `nmlrt` is a robust alternative.

Diagnostics are often lacking (there are some in `optimx`).

Stochastic optimization (SANN, DEoptim), constrained optimization (`constrOptim`), fuzzy optimization deserve attention.

Representative/benchmark problems are needed (those in NISTnls/NISTopt are “extreme”).

Convex optimization in R
R. Koenker and I. Mizera (2014)

Long list of applications of convex programming in statistics:

- Median regression;
- Quantile regression;
- Hinge regression (or other piecewise linear convex loss functions);
- Huber M -estimators (the loss function is quadratic when the residuals are small, linear when they are large);
- Penalized quantile regression;
- Support vector machines (hinge loss and L^2 penalty) (**kernlab**);
- Random linear constraints, $P[a'_i x \leq b_i] \geq \eta$, where $a_i \sim N(\alpha_i, \Omega_i)$ are random variables;
- Square root lasso, group lasso;
- Convex regression.

Matrix completion and robust PCA can be expressed with matrix norms such as the spectral norm (largest eigenvalue) or the nuclear norm (sum of the singular values).

Interior point methods usually replace linear inequality constraints with *log-barriers*. For proper cones, one can use a *generalized log* $\lambda : K \rightarrow \mathbf{R}, \mathcal{C}^2$, with $\nabla^2 \lambda \prec_{\text{psd}} 0$ (i.e., concave), such that

$$\exists \theta \quad \forall x \succ_K 0 \quad \forall y \succ_{\mathbf{R}_+} 0 \quad \lambda(yx) = \lambda(x) + \theta \log y.$$

For instance,

$$\begin{aligned} \lambda(x) &= \sum_i \log x_i && \text{for } K = \mathbf{R}_+^n \\ \lambda(x) &= \log(x_0^2 - \|x_{1:n}\|^2) && \text{for } K = \{x \in \mathbf{R}^{n+1} : \|x_{1:n}\| \leq x_0\} \\ \lambda(A) &= \log |A| && \text{for } K = \mathcal{S}_n^+ \end{aligned}$$

Interior point methods work best when the Hessian (of the objective function plus the barrier) is sparse, e.g., when the problem is *additively separable*.

After discretization, infinite mixture models (Kiefer-Wolfowitz)

$$\begin{array}{ll} \text{Find} & f \\ \text{To minimize} & \sum_i \log g_i \\ \text{Such that} & g = Af, \quad f \geq 0, \quad f' \mathbf{1} = 1 \end{array}$$

(where $A_{ij} = \phi(x_i, \theta_j)$, the θ_j are on a fine grid, the x_i are the observations and $\phi(\cdot, \theta_j)$ the probability distribution functions being mixed) or penalized/constrained density estimation problems are convex and additively separable (the penalty could be $\int (\sqrt{f})'$, $\int (\log f)''^2$, $\int |(\log f)''|$; the constraint could be “ f log-concave”). Many of these are implemented in **REBayes**, but it unfortunately relies on Mosek.

trustOptim: an R package for trust region optimization with sparse Hessians
M. Braun (2014)

Trust region optimization minimizes a second order approximation of the objective function in a small region around the current point (it is similar to sequential quadratic optimization, but with constraints, to avoid moving too fast – and it does not misbehave in presence of indefinite Hessians); if the approximation is not good at the new point, or if it does not bring any improvement, shrink the region; if the new point is on the boundary, expand the region.

This is implemented in the **trust** package, but the algorithm does not scale well if the Hessians are dense: **trustOptim** uses the same idea with sparse Hessians (either provide the sparsity structure and use numeric differentiation, or provide an analytic Hessian, e.g., from **CppAD** or **R2admb**).

Square root lasso: pivotal recovery of sparse signals via conic programming
A. Belloni et al.

The square root lasso is

$$\underset{\beta}{\text{Argmin}} \|y - x'\beta\|_2 + \lambda \|\beta\|_1;$$

while the lasso is

$$\underset{\beta}{\text{Argmin}} \|y - x'\beta\|_2^2 + \lambda \|\beta\|_1.$$

Spectral projected gradient methods: review and perspectives
E.G. Birgin (2014)

The spectral projected gradient (SPG, implemented in **BB;** **BBoptim**), combines (projected) gradient descent and secant methods. *Secant methods* approximate the gradient ∇f with an affine function $x \mapsto \phi(x) = a + Bx$, using the last two points,

$$\begin{aligned} \phi(x_{n-1}) &= a + Bx_{n-1} = \nabla f x_{n-1} \\ \phi(x_n) &= a + Bx_n = \nabla f x_n \end{aligned}$$

i.e.,

$$\begin{aligned} B(x_n - x_{n-1}) &= \nabla f x_n - \nabla f x_{n-1} \\ a &= \nabla f x_n - Bx_n \end{aligned}$$

(there are many such functions). The BB method tries to use $B = \sigma I$; this is usually not possible, but the least squares approximation is good enough:

$$\sigma = \frac{\langle \text{previous step, change in gradient} \rangle}{\text{previous step size}}$$

$$\sigma_{n+1} = \frac{s'_n y_n}{s'_n s_n}$$

$$s_n = x_n - x_{n-1}$$

$$y_n = \nabla f x_n - \nabla f x_{n-1}.$$

Spectral methods use this step, multiplied by some coefficient, adjusted to ensure that the objective function improves every M steps (not at every step – it is a non-monotonic method).

What is... a spectrahedron?
C. Vintant

The positive semidefinite cone.

AD model builder: using automatic differentiation for statistical inference of highly parameterized complex nonlinear models
D.A. Fournier et al. (2011)

Automatic differentiation (AD) differentiates a function written in C++ as follows:

- Evaluate the function and keep track of all the floating point operations performed; if there are loops or conditionals, expand them – the sequence of operations need not always be the same;
- Iteratively compute either $\partial t_j / \partial x_i$ (forward mode) or $\partial f / \partial t_i$ (reverse mode, aka, back-propagation), where the t_i are the intermediate results; reverse mode is more efficient.

ADMB provides a C++-like DSL to specify a function and uses a quasi-Newton algorithm with the gradient from AD to minimize it. It also provides diagnostics useful in statistics: inverse of the information matrix (*i.e.*, variance of the estimated parameters), profile likelihood, MCMC samples from the posterior distribution of the parameters (for the Hessian, they use finite differences: the code generated by AD is often “ludicrously obfuscated” and AD tools “frequently cannot differentiate the code they produce, so you are usually limited to derivatives of order 1”).

Using AD model builder and R together: getting started with the R2admb package
B. Bolker (2013)

If you write down the likelihood of your model yourself, want to use gradient-based optimization methods, but your model is too complex to have its gradient computed by hand or for numeric differentiation to be useful, R2admb can compute the (analytic) gradient for you and optimize the log-likelihood. It generates the usual diagnostics (AIC, vcov, profile likelihood) and (MCMC-based) posterior parameter distributions. It needs ADMB (free, but has to be installed separately) and a C++ compiler, and forces you to write the log-likelihood in C++. There does not seem to be a way of accessing the (compiled, analytic) gradient directly.

Also check glmmADMB – PBSadmb and ADMB2R are older.

In Python, check PyAutoDiff (it uses Theano, and can therefore leverage GPUs).

Getting things in order: an introduction to the R package seriation
M. Hahsler et al.

To reorder the rows and columns of a matrix, e.g. a dissimilarity matrix (in R: `seriation`):

- Try to minimize the number of inversions in each row and column;
- Find a Hamiltonian path on the distance matrix (TSP);
- Minimize the moment of inertia around the diagonal $\sum_{ij} d_{ij} |i - j|$;
- Make the dissimilarities close to the distance to the diagonal, *i.e.*, $d_{ij} \approx |i - j|$ (find $\sigma \in \mathfrak{S}_n$ to minimize the sum of squares $\sum_{ij} (d_{ij} - |i - j|)^2$);
- Ensure similar values are close together by minimizing $\sum_p \sum_{q \in \text{Neigh}(p)} (x_p - x_q)^2$, using 4- or 8-element neighbourhoods;
- Use the first principal component;
- Compute a hierarchical clustering and apply some heuristic to select an ordering compatible with it (in R: `gclus`).

Few of those methods can be generalized to rectangular matrices and, in this case, rows and columns are often treated independently.

Generalized association plots: information visualization via iteratively generated correlation matrices
C.H. Chen

Take the correlation matrix of the columns of a correlation matrix, and iterate.

On the first two principal components, the points form an ellipse; the linear order on this ellipse can be used to solve seriation problems (“rank-2 ellipse seriation”).

After a few more iterations, the matrix often only has ± 1 entries and only two different columns; the observations can be split into two groups; recursively iterating gives a hierarchical clustering. [This assumes the matrix has no symmetries, *i.e.*, its stabilizer for the action $\sigma \cdot A = (A_{\sigma i, \sigma j})_{ij}$ is trivial.]

Package hdlm: regression tables for high-dimensional linear model estimation
T.B. Arnold

It is often claimed that penalized regression does not provide p -values or confidence intervals – but one can use a 2-step approach:

- Fit a *sparse* model (least squares with lasso, quantile regression with lasso, Dantzig selector, etc.) on part of the data (be conservative: we want to keep all the variables in the true model with high probability);
- Fit this smaller model on another (independent) part of the data, and compute p -values and confidence intervals.

The hdlm package also bootstraps the p -values and corrects them (by taking the median).

***Exact and approximate area-proportional
circular Venn and Euler diagrams***
L. Wilkinson (2012)

To plot an Euler diagram, representing the intersections of n sets, with circles:

- Encode all possible intersections as n -bit binary numbers (e.g., $Y_{1101} = X_1 \cap X_3 \cap X_4$); use the same numbering for the disjoint sets, $Z_k = Y_k \setminus \bigcup_{\ell: Y_\ell \subsetneq Y_k} Y_\ell$;
- Define the loss as $\sum (\text{area} - \text{desired area})^2$, where the sum is over the disjoint sets;
- Estimate those areas using either exact computations (compute pairwise intersections, compute the area of the polygon and the lunes), polygon approximations of the circles or a bitmap approach (discretize the circles into pixels);
- For the initial guess, use the desired disk areas and place them using multidimensional scaling (MDS) on the Jaccard distance matrix $d_{ij} = |X_i \cap X_j| / |X_i \cup X_j|$;
- In the optimization, only move the circle centers, first using an (analytical) approximate gradient with a small learning rate, then a numeric gradient.

In R, this is implemented in the `venneuler` package.

Visualizations with Venn and Euler diagrams
L. Micallef

A polygonal Euler diagram can be drawn with a force-directed layout, with attractive and repulsive forces, not only between vertices, but also between edges and polygons.

***Statistical computing in functional data
analysis: the R package fda.usc***

M. Febrero-Bande and M. Oviedo de la Fuente

The `fda.usc` package builds on the other functional data analysis (FDA) packages (`fda`, `ftsa`, `rainbow`, `fpca`, `MFDF`, `fdaMixed`) and provides an abstraction for functional objects (an `fdata` type) aimed at making functional data manipulations as easy as categorical variable manipulations (with the `factor` abstraction). It provides:

- Conversion methods from `fdata`: basis expansion, non-parametric kernel smoothing (`min.basis`, `fdata2fd`, `min.np`);
- L^p distances, semi-metrics (L^p distance between the k th derivatives);
- Depth computations (the average distance between a given observation and all the (other) observations – it is minimum for the median) and the corresponding measures of location and dispersion; they can also be used for outlier detection;
- Smoothed bootstrap;
- Regression with scalar response and functional covariates, with cross-validation and influence measures (Cook’s distance).

***Online prediction under model uncertainty
via dynamic model averaging:
application to a cold rolling mill***
A.E Raftery et al. (2010)

Dynamic model averaging (DMA) generalizes Bayesian model averaging (BMA) to time-varying models. Given n time-varying models (e.g., a time-varying regression, which can be fitted with a Kalman filter), assume that the data may come from a different model at each point in time, and that the correct model changes according to a Markov chain; model the correct model as the hidden state in a hidden Markov model (HMM); use the state probabilities as weights when averaging the n models.

***White noise and simulation
of ordinary Gaussian processes***
B. Puig and F. Poirion

White noise can be defined as a *generalized process* (the stochastic analogue of a tempered distribution), *i.e.*, a continuous linear form on the Schwartz space S (the space of rapidly-decreasing functions ϕ : $\forall \alpha, \beta \sup_x |x^\alpha D^\beta \phi| < \infty$); it is entirely defined by its characteristic function

$$C(\phi) = \int_{\Omega} e^{iX_\phi} dP = \int_{S'} e^{i\langle \omega, \phi \rangle} d\mu(\omega) = \exp -\frac{1}{2} \|\phi\|_H^2.$$

With a stochastic process, we can consider X_t (a random variable) or $X_t(\omega)$ (a number). With a generalized process, we can only look at X_ϕ , where ϕ is a test function, *i.e.*, the weighted average of “ X_t ”, using $(\phi(t))_t$ as weights.

ABC model choice via random forests
P. Pudlo et al. (2014)

ABC posterior probabilities for model selection are not trustworthy. Instead, simulate data from several models, compute a summary statistic, and ask some machine learning algorithms (say, random forests) to predict the model (and its aparmeters) from the summary statistic.

***A survey of metric learning for feature vectors
and structured data***
A. Bellet et al. (2014)

Some machine learning algorithms (k -means, k nearest neighbours) rely on a distance, but choosing it beforehand need not be optimal: *metric learning* uses the data to select the best distance for the problem at hand.

Mahalanobis distance learning looks for a distance of the form

$$d_M(x, y) = \sqrt{(x - y)' M (x - y)}$$

with M positive semidefinite, that optimizes some cri-

terion, e.g. (large merging nearest neighbours, LMNN)

$$\begin{aligned} \text{Find} \quad & M \in \mathcal{S}_+ \\ \text{To minimize} \quad & (1 - \mu) \sum_{(i,j) \in S} d_M^2(x_i, y_i) + \mu \sum_{(i,j,k) \in R} \xi_{ijk} \\ \text{Such that} \quad & \forall (i, j, k) \in R \\ & d_M^2(x_i, x_k) - d_M^2(x_i, x_j) \geq 1 - \xi_{ijk} \end{aligned}$$

where

$$\begin{aligned} S &= \{(i, j) : y_i = y_j \text{ and } x_i \in \text{Neigh}(x_j)\} \\ R &= \{(i, j, k) : (i, j) \in S \text{ and } y_i \neq y_k\} \end{aligned}$$

Regularizations include:

- The mixed $L^{2,1}$ norm, $\|M\|_{2,1} = \sum_i \|M_{i,\cdot}\|_2$, which tends to zero out entire rows of M ;
- Log-det divergence,

$$D(M, M_0) = \text{tr}(MM_0^{-1}) - \log \det(MM_0^{-1}) - d,$$

with $M_0 = I$.

Non-Mahalanobis similarities include:

- $k(x, y) = x'My$, with M not necessarily positive, or even symmetric;
- $k(x, y) = \frac{x'My}{\sqrt{x'Mx}\sqrt{y'My}}$ (generalized cosine similarity);
- Kernalization, kernal PCA (kPCA);
- A neural network (deep belief net, convolutional net) to learn a non-linear projection g so that $\|g(x) - g(y)\|_1$ be small for positive pairs and large for negative pairs.

Local metric learning:

- Cluster the data and learn a different Mahalanobis metric in each cluster; one can also consider the barycenter of Mahalanobis distances;
- The symmetrized Bregman divergence is a smoothly-varying Mahalanobis distance:

$$\begin{aligned} d_\phi(x, y) &= \phi x \phi y - (x - y)' \nabla \phi y \\ d_\phi^{\text{sym}}(x, y) &= d_\phi(x, y) + d_\phi(y, x) \\ &= (x - y)' \nabla^2 \phi(z) (x - y) \text{ for some } z \in [x, y] \end{aligned}$$

One can devise distances for specific types of data:

- Histogram data (points in the standard simplex Δ) and the χ^2 distance

$$\begin{aligned} \chi^2(x, y) &= \frac{1}{2} \sum_i \frac{(x_i - y_i)^2}{x_i + y_i} \\ \chi_L^2(x, y) &= \chi^2(Lx, Ly) \quad (\text{with } L\Delta \subset \Delta) \end{aligned}$$

or the earth mover's distance;

- Strings, trees, graphs with the edit distance.

Handling sparsity via the horseshoe V.M. Carvalho et al. (2009)

To estimate a sparse model, besides the Laplace prior (lasso) and the Student prior (relevance vector machine), consider the *horseshoe prior*

$$\begin{aligned} \beta &\sim N(0, \lambda^2 \tau^2) \\ \lambda &\sim \text{Half-Cauchy} \end{aligned}$$

where λ is the local shrinkage and τ the global shrinkage. The model expects two types of observations: strong signal (no shrinkage) or noise (total shrinkage) – the lasso is more moderate and always has some shrinkage.

Missing value estimation for DNA microarray gene expression data: local least squares imputation H. Kim et al.

To impute missing values in a gene \times experiment matrix (many genes, few experiments):

- Assume we want to impute a value in the first gene (row) g_1 ;
- Find the k closest genes (highest correlation) g_{i_1}, \dots, g_{i_k} ;
- Regress $g_1 \sim g_{i_1} + \dots + g_{i_k}$ and fill in g_1 .

This is a refinement of nearest neighbour imputation, which uses an equal- (or empirically) weighted average of g_{i_1}, \dots, g_{i_k} .

SVD imputation works well for low-noise time series:

- Fill in the missing values with row averages;
- Compute the eigenvectors;
- Regress g_1 against the (first) eigenvectors;
- Predict the missing values;
- Iterate until convergence.

Choquistic regression: generalizing logistic regression using the Choquet integral A. F. Tehrani

A *non-additive* discrete measure (sometimes called a capacity or a fuzzy measure) is a function $\mu : \mathcal{P}(C) \rightarrow [0, 1]$ such that

$$\begin{aligned} \mu(\emptyset) &= 0 \\ \mu(C) &= 1 \\ A \subset B &\implies \mu(A) \leq \mu(B). \end{aligned}$$

It is determined by its *Möbius transform* m :

$$\begin{aligned} \mu(B) &= \sum_{A \subset B} m(A) \\ m(A) &= \sum_{B \subset A} (-1)^{|A|-|B|} \mu(B). \end{aligned}$$

A non-additive measure is k -additive if $|A| > k \implies m(A) = 0$; 0-additive measures are (additive) measures.

The **Choquet integral** generalizes the weighted average (a way of aggregating several criteria)

$$\sum_{c \in C} \mu(\{c\}) f(c)$$

from (additive) measures to non-additive measures. Intuitively, it allows for interactions between the criteria being averaged.

$$\begin{aligned} f : C &\rightarrow \mathbf{R}_+ \\ 0 &\leq f(c_{(1)}) \leq \dots \leq f(c_{(m)}) \\ C_\mu(f) &= \sum_{i=1}^m [f(c_{(i)}) - f(c_{(i-1)})] \mu(\{c_{(1)}, \dots, c_{(m)}\}) \\ &= \sum_{T \subset C} m(T) \times \min_{c \in T} f(c). \end{aligned}$$

In logistic regression, we can replace $w'x$ with $\gamma(C_\mu(x) - \beta)$, where x is seen as a function $i \mapsto x_i$ and μ is k -additive, with k small. The log-likelihood is concave.

Mendelian randomization and causal inference in observational epidemiology N.A. Sheehan et al. (2008)

Mendelian randomization is another name for instrumental variables (IV): find a variable IV so that

- IV $\perp\!\!\!\perp$ confounding factors
- IV \rightarrow possible cause
- IV $\perp\!\!\!\perp$ consequence | possible cause

The IV is often a gene. Gene interactions complicate the picture.

Simulation of fractional Brownian motion T. Dieker (2004)

A stationary stochastic process X is *self-similar* if $X^{(m)} = \frac{1}{m}(X_1 + \dots + X_m)$ and X_1 have the same distribution. It has *long-range dependence* if $\sum \gamma_k$ diverges, where $\gamma_k = \text{Cov}(X_0, X_k)$. A standard *fractional Brownian motion* is characterized by

- $B(t)$ has stationary increments
- $B(0) = 0$, $EB(t) = 0$
- $EB(t)^2 = t^{2H}$
- $B(t)$ is Gaussian.

Its increments $X_k = B(k+1) - B(k)$ are *fractional Gaussian noise*. These are Gaussian processes with covariance functions

$$\begin{aligned} E[B(s)B(t)] &= \frac{1}{2}[t^{2H} + s^{2H} + |t-s|^{2H}] \\ \gamma_k &= E[X_n X_{n+1}] = \frac{1}{2}[|k-1|^{2H} - 2|k|^{2H} + |k+1|^{2H}]. \end{aligned}$$

There is no closed form for the spectral density of fractional Gaussian noise

$$\begin{aligned} f(\lambda) &= \sum_{k \in \mathbf{Z}} e^{ik\lambda} = \\ &2 \sin(\pi H) \Gamma(2H+1) (1 - \cos \lambda) \left(|\lambda|^{-2H-1} + \sum \dots \right) \end{aligned}$$

but approximations are available.

ARFIMA processes, $(1-L)^d X_k \sim \text{ARMA}(p, q)$ also have long memory; the fractional integration is defined by

$$\begin{aligned} (1-L)^d &= \sum_{n \geq 0} \binom{d}{n} (-L)^n \\ \binom{d}{n} &= \frac{\Gamma(d+1)}{\Gamma(d-n+1)\Gamma(n+1)} \end{aligned}$$

The *Hosking method* simulates a general stationary Gaussian process iteratively, in $O(n^2)$: since

$$V_{1:n+1} = \text{Var } X_{1:n+1} = \begin{pmatrix} \gamma_0 & \gamma_1 & \dots & \gamma_{n-1} \\ \gamma_1 & \gamma_0 & \dots & \gamma_{n-2} \\ \vdots & \vdots & \ddots & \vdots \\ \gamma_{n-1} & \gamma_{n-2} & \dots & \gamma_0 \end{pmatrix}$$

and $E[X_{1:n+1}] = 0$, we know that $X_{n+1}|X_{1:n} = x_{1:n} \sim N(\mu, v)$, where μ and v are easy to compute (because of the shape of $V_{1:n}$).

The *Choleski method* can simulate arbitrary Gaussian processes; the Choleski matrix can actually be computed explicitly, and this gives an $O(n^3)$ incremental algorithm.

The *Davies and Harte method* embeds the covariance matrix into a circulant matrix

$$\begin{pmatrix} \gamma_0 & \gamma_1 & \dots & \gamma_{n-1} & 0 & \gamma_{n-1} & \dots & \gamma_1 \\ \gamma_1 & \gamma_0 & \dots & \gamma_{n-2} & \gamma_{n-1} & \gamma_0 & \dots & \gamma_{n-1} \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots \\ \gamma_{n-1} & \gamma_{n-2} & \dots & \gamma_1 & \gamma_1 & \gamma_0 & \dots & \gamma_{n-1} \\ 0 & \gamma_{n-1} & \dots & \gamma_1 & \gamma_0 & \gamma_1 & \dots & \gamma_{n-1} \\ \gamma_{n-1} & \gamma_{n-2} & \dots & \gamma_{n-1} & \gamma_1 & \gamma_0 & \dots & \gamma_1 \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots \\ \gamma_1 & \gamma_0 & \dots & \gamma_{n-1} & \gamma_{n-1} & \gamma_1 & \dots & \gamma_0 \end{pmatrix}$$

which can be efficiently inverted (FFT), to find a square root in $O(n \log n)$.

There are approximate simulation methods (*i.e.*, they sample from a distribution which is not exactly a fractional Brownian motion), using:

- The expression of a fractional Brownian motion as a stochastic integral;
- Queueing theory;
- Random midpoint displacement, *i.e.*, replacing $X_{n+1}|X_{1:n}$ with $X_n|X_{i_1, \dots, i_k}$ in the Hosking or Choleski method;
- Spectral analysis: a stationary Gaussian process can be expressed as a stochastic integral involving its spectral density f ,

$$\begin{aligned} X_n &= \int_0^\pi \sqrt{\frac{f(\lambda)}{\pi}} \cos(n\lambda) dB_1(\lambda) - \\ &\int_0^\pi \sqrt{\frac{f(\lambda)}{\pi}} \sin(n\lambda) dB_2(\lambda); \end{aligned}$$

- Wavelets: the wavelet coefficients of a fractional Brownian motion are almost independent and almost Gaussian, with zero mean and known variance;
- Fractional integration of white noise (white noise is the “derivative” of Brownian motion, seen as a generalized process, aka tempered distribution);
- Series expansions.

The Hurst exponent can be estimated in many ways:

- Aggregated variance $\text{Var } X^{(m)} = m^{2H-2} \text{Var } X$ or absolute moments $E |X^{(m)} - \bar{X}^{(m)}|^k \sim m^{k(H-1)} E |X - EX|^k$ but, in presence of autocorrelation, the finite-sample estimators are biased;
- Higuchi estimator: absolute moment estimator, with $k = 1$ and overlapping windows;
- The slope of the periodogram;
- The variance of the regression residuals, on a moving window (*i.e.*, the aggregated variance, after detrending);
- R/S analysis;
- Likelihood estimator: $(X_1, \dots, X_N) \sim N(0, \Gamma_H)$, where Γ_H is known (as a function of H) – unfortunately, $\det \Gamma_H$ and Γ_H^{-1} are expensive to compute;
- Whittle estimator: compare the periodogram $I(\lambda)$ with the spectral density $f_H(\lambda)$,

$$\hat{H} = \underset{H}{\text{Argmin}} \sum_k \frac{I(\lambda_k)}{f_H(\lambda_k)};$$

- Local Whittle estimator: replace $f_H(\lambda)$ with $C |\lambda|^{1-2H}$;
- Variance of the wavelet coefficients (no detrending is needed if the wavelet has enough vanishing moments).

Speeding up convolutional neural networks using fine-tuned CP-decomposition
V. Lebedev et al. (2015)

In image processing, convolutional neural networks (CNN) perform the convolution of an image with a 4-dimensional tensor:

$$\begin{aligned} x_{ijk} &= \text{pixel at coordinates } (i, j), \text{ in RGB plane } k, \\ &\text{for one of the patches} \\ y_\ell &= b_\ell + \sum_{ijk} a_{ijk\ell} x_{ijk} \\ &= \ell\text{th coordinate of the output, for this patch} \end{aligned}$$

The tensor can be replaced by a low-rank approximation, *e.g.*, the CP-decomposition (a higher-order analogue of PCA).

FitNets: hints for thin deep nets
A. Romero et al. (2015)

To have a small network (*e.g.*, a thin but deep) mimic a large one (wide and deep) do not only learn the outputs, also use the intermediate representations.

Effective use of word order for text categorization with convolutional neural networks
R. Johnson and T. Zhang

Convolutional neural networks (CNN), often used to process images, apply convolutional and pooling layers (one or several pairs) to the data before passing it to a linear classifier.

- A *convolutional layer* takes $k \times k$ (overlapping) regions of the image and gives each of them to m neurons; the weights are shared accross regions; each region, a $3k^2$ -dimensional vector, becomes an m -dimensional vector;
- A *pooling layer* takes the output of a convolutional layer, cuts it into non-overlapping regions, and aggregates them (max-pooling or average pooling), so that each region becomes an m -dimensional vector.

This can also be applied to text:

- Encode length- k regions as bags of vords (*i.e.*, $|V|$ -dimensional vectors) or using indicator variables (*i.e.*, $k|V|$ -dimensional vectors);
- To deal with variable sentence or text length, fix the number of pooling units and dynamically select the pooling region size;
- Use linear rectifiers.

Link analysis, eigenvectors and stability
A.Y. Ng et al.

HITS and PageRank are eigenvalue problems: if the eigengap (the difference between the two largest eigenvalues) is small, the first eigenvector is not stable. HITS is unstable if the maximum degree is large; PageRank is not robust to perturbations to pages with a high score. *Latent semantic indexing* (LSI) (compute the left and right singular vectors of the binary term-document matrix) is a special case of HITS and has the same problem.

Stable algorithms for link analysis
A.Y. Ng et al. (2001)

The *randomized HITS* algorithm is the HITS algorithm, expressed as a random walk with teleportation, à la PageRank (teleportation increases stability).

The *subspace HITS* algorithm uses the first k eigenvectors and defines the scores as

$$a_j = \sum_{i=1}^k f(\lambda_i) \langle e_j, x_i \rangle^2$$

where e_j are the basis vectors (zeroes except in position j), $f(\lambda) = \lambda^2$ (but other weight functions are possible), x_i are the eigenvectors and λ_i the eigenvalues.

Intriguing properties of neural networks
C. Szegedy et al. (2014)

Deep neural networks are discontinuous: it is possible to manufacture an imperceptible alteration of an image to misclassify it.

While it is possible to interpret individual hidden neurons, it is equally easy to interpret random linear combinations of neurons.

***On the effective measure of dimension
in the analysis cospase model***
R. Giryes et al. (2014)

Compressed sensing tries to reconstruct a vector x so that $y = Ax + \text{noise}$, assuming x is sparse.

The cospase model tries to reconstruct a vector x so that $y = Ax + \text{noise}$ assuming Bx is sparse – for instance, x could be an image and Bx its gradient.

***Adaptive compressed sensing for estimation
of structured sparse sets***
R.M. Castro and E. Tanczos (2014)

Compressed sensing, *i.e.*, the reconstruction of a signal from noisy and partial observations, under the assumption that it is sparse, can be generalized to more general supports, e.g., subsets of length s of $\llbracket 1, n \rrbracket$, subintervals of length s of $\llbracket 1, n \rrbracket$, disjoint unions of k such intervals, s -element stars in a graph, etc.

***An exact mapping between the variational
renormalization group and deep learning***
P. Mehta and D.J. Schwab (2014)

The renormalization group is the hierarchical description of a physical phenomenon by progressively integrating out (marginalizing over) small features (“iterative coarse-graining scheme”). It is not unlike deep networks, which integrate small features into larger ones, from layer to layer.

***Taming the monster: a fast and simple
algorithm for contextual bandits***
A. Agarwal et al. (2014)

The ϵ -greedy or epoch-greedy algorithm have a suboptimal regret. Randomized UCB has an optimal regret, but it is complex and slow: it can be simplified and sped up.

***Learning to discover social circles
in ego networks***
J. McAuley and J. Leskovec

A generalization of BigCLAM that allows overlapping or nested communities (not unlike topics) and uses both graph structure and node features.

***Fast, simple and accurate handwritten digit
classification using extreme learning machines
with shaped input-weights***
M.D. McDonnell et al. (2014)

Extreme learning machines (ELM, echo nets – neural nets whose hidden layer is random and not learned) perform as well as deep nets in the digit classification task:

- Augment the training set by distorting it;
- Each hidden unit only operates on a randomly sized and positioned patch of the image.

***Selfieboost: a boosting algorithm
for deep learning***
S. Shalev-Shwartz

Adaboost sequentially fits a model, assigning more weight to currently misclassified observations, and returns a linear combination of the models. Selfieboost only returns the last one; to avoid losing the performance of the earlier models, it adds a penalty to keep the new model forecasts close to the previous ones.

***Move evaluation in Go
using deep convolutional networks***
C. Maddison et al. (2015)

The positions on a Go board are not unlike the pixels of an image: use convolutional neural networks to evaluate a position or a move, using training data from the KGS server

***Teaching deep convolutional neural networks
to play Go***
C. Clark and A. Storkey

More details.

***Efficient gradient-based inference through
transformations between Bayes nets and
Neural nets***
D.P. Kingma and M. Welling (2014)

Bayesian networks and neural networks are the same thing: each can (often) be transformed into the other.

***Hogwild!: a lock-free approach to parallelizing
stochastic gradient descent***
F. Niu et al.

Stochastic gradient descent (SGD) is often easy to parallelize: reformulate the objective function to make it almost separable (a large sum of functions of a small number of variables – that is usually possible if the input is sparse) and forget about concurrency problems (let the processors overwrite each other’s work – it happens too rarely to have a noticeable effect).

***Crypto-nets:
neural networks over encrypted data***
P. Xie et al. (2015)

Homomorphic encryption can be used with neural networks – but since it only provides $+$ and \times , you need to approximate the transfer function with a polynomial (the input space should be compact).

***libDAI: a free and open source C++ library
for discrete approximate inference
in graphical models***
J.M. Mooij (2010)

To estimate Bayesian networks or Markov random fields (MRF). Also check OpenGM2.

***LSH forest: self-tuning indexes
for similarity search***
M. Bawa et al.

Given a locality-sensitive hash (LSH) family $\mathcal{H} = (h_i)_{i \geq 1}$, one usually assigns a fixed-length label $g(p) = (h_1(p), \dots, h_n(p))$ to each point p . Instead, one can use variable-length labels, arranged in a prefix tree, sufficiently long so that all the points have a different label. An LSH forest is a set of such LSH trees.

***A performance evaluation
of open source graph databases***
R. McColl et al. (2014)

Stinger, MTGL, Boost, Giraph and NetworkX perform well.

***Trend filtering methods
for momentum strategies***
B. Bruder et al. (2011)

Here are a few algorithms to identify trends in a time series:

- Moving average, exponential moving average;
- Local regression, which can be seen (for a rectangular kernel) as the discretization of the *Lanczos derivative* (a noise-robust slope)

$$f'(x) = \lim_{\varepsilon \rightarrow 0} \frac{3}{2\varepsilon^2} \int_{-\varepsilon}^{\varepsilon} tf(x+t)dt;$$

- Local polynomial regression, loess smoothing;
- Hodrick-Prescott filter,

$$\hat{y} = \underset{y}{\operatorname{Argmin}} \|y - x\|_2^2 + \lambda \|D^2 y\|_2^2;$$

- Structural model (Kalman filter);
- Low-pass filter, from a Fourier or Wavelet transform;
- Singular spectrum analysis (SSA): let

$$H = \begin{pmatrix} y_1 & \cdots & y_m \\ \vdots & & \vdots \\ y_n & \cdots & y_t \end{pmatrix}$$

and perform a dimension reduction on H ;

- Support vector machines, $Y \sim$ time, with radial basis functions (RBF), and their standard deviation as smoothing parameter;
- Empirical mode decomposition (EMD), Hilbert filter;
- Gaussian processes (not mentioned).

Multivariate filtering methods were listed but not detailed: Kalman filter (with a small number of stochastic components), error correction models, permanent-transitory decomposition.

Chaos in economics and finance
D. Guégan (2009)

Let X_0 be a random variable and $X_n = f(X_{n-1})$ a deterministic dynamic system. To study time series using this model:

- Estimate the embedding dimension;
- Estimate f and f' (using k -NN, radial basis functions, neural nets, etc.);
- Estimate the Lyapunov exponent

$$\lambda = \lim_{n \rightarrow \infty} \frac{1}{n} \sum_{1 \leq t \leq n} \ln |f'(X_t)|,$$

i.e., the speed at which trajectories diverge:
 $\|x_n - y_n\| \approx e^{\lambda n} \|x_0 - y_0\|;$

- Test if it is positive.

***Computing present values:
capital budgeting done correctly***
R. Jarrow (2014)

The value V_t of an asset is related to its expected returns as follows.

$$\begin{aligned} 1 + \mu_{T-1} &:= E_{T-1} \left[\frac{V_T}{V_{T-1}} \right] \\ V_{T-1} &= E_{T-1} \left[\frac{V_T}{1 + \mu_{T-1}} \right] \\ V_{T-2} &= E_{T-2} \left[\frac{V_{T-1}}{1 + \mu_{T-2}} \right] \\ &= E_{T-2} \left[\frac{1}{1 + \mu_{T-2}} E_{T-1} \left[\frac{V_T}{1 + \mu_{T-1}} \right] \right] \\ &= E_{T-2} \left[\frac{V_T}{(1 + \mu_{T-2})(1 + \mu_{T-1})} \right] \\ V_t &= E_t \left[\frac{V_T}{(1 + \mu_t) \cdots (1 + \mu_{T-1})} \right] \end{aligned}$$

(This is the real-world measure, P).

Some textbooks incorrectly price stochastic cash flows as

$$V_0^{\text{wrong}} = \frac{E[V_T]}{(1 + E\mu_0) \cdots (1 + E\mu_{T-1})}.$$

***Correlation in the magnitude
of financial returns***
J. Hämäläinen (2014)

Look at $\operatorname{Cor}(|r_i|, |r_j|)$.

***Understanding the relationship
of momentum with beta***
T. Cenesizoglu et al. (2014)

Beta explains momentum performance.

The stability and accuracy of credit ratings

P. Viegas de Carvalho et al. (2014)

Reratings are not related to changes in the probability of default, but rather to changes in the relative probability of default. Ratings depend on the business or economic cycle.

Data science at the command line

J. Janssens (2014)

Traditional Unix tools (`grep`, `sort`, `uniq`, `head`, `seq`, `paste`, `shuf`, `parallel`, etc.) can be complemented with more recent or specialized tools to process data (download, clean, explore, model) such as `csvkit` (in particular `csvlook` and `csvsql`), `jq` (to transform JSON data, à la XPath), `json2csv`, `scrape` (to transform XML/HTML data, using XPath or CSS selectors), `Rio` (to use R as a filter, to convert a CSV file into another one, or into a plot).

Some of those tools are not standard and were developed by the author for the book. All are available in a (Vagrant) virtual machine.

The book suggests Drake to manage data science workflows and gives a few examples of actual computations, with Tapkee (a C++ library, part of Shogun, for dimension reduction: PCA, MDS, t-SNE, LLE, isomap), Weka, R (via `Rio`), SKLL, BigML – but no mention of Vowpal Wabbit, libsvm, liblinear or libfm. Some traditional and useful Unix commands were also missing: `xargs` (mostly replaced by `parallel`), `dc` (but many prefer `bc`), `file`, `screen`, `tmux`, `csplit` (though `split` was mentioned).

Big data analytics summer school

(Caltech, JPL, Coursera, 2014)

The k -nearest neighbours (kNN) algorithm can be implemented as follows:

- In dimension 1, with binary search;
- In dimensions 2 to 8, with a kd-tree;
- In dimensions greater than 8, with locality-sensitive hashing (LSH) – this only provides approximate neighbours.

In much higher dimensions, kNN no longer works: all the distances are approximately equal (curse of dimensionality).

The Euclidian distance is not a good choice for distance-based algorithms in presence of correlations or differences of scale. One could use the Mahalanobis distance but, for supervised learning, this is suboptimal. For instance, for a classification problem, multi-class discriminant analysis (a form of **metric learning**) looks for the distance that best separates the classes, *i.e.*, maximizes

$$\gamma(V) = \frac{|V'\Sigma_b V|}{|V'\Sigma_w V|}$$

where

V = linear projection of the data

Σ_b = between scatter matrix

Σ_w = within scatter matrix.

The course also covered the following topics:

- Dimension reduction: kNN, feature selection, PCA, metric learning, kernel PCS (kPCA);
- Bootstrap (classical, N out of M , subsampling);
- Visualization;
- Random forests (the sample proximity is the number of trees in which samples i and j end up in the same leaf).

Mining massive datasets

J. Leskovec, A. Rajaraman, J. Ullman
(Stanford, Coursera, 2014)

The complexity of a *map-reduce* algorithm should be measured by the communication cost – that is the main bottleneck, and it is reasonable to assume that all the data has to be moved around. For instance, matrix multiplication is more efficient with a 2-step algorithm: first divide the matrix into blocks (*tiles*) and compute the partial sums, then aggregate them.

Page-rank can be personalized by teleporting to a random page in a set of reference pages (e.g., the DMOZ pages for the topic of interest) instead of a random page; it can be made more robust to spam farms by teleporting to a random page in a set of trusted pages (e.g., edu domains).

Min-hashing is an approximate test for set equality – a **locality-sensitive hashing** (LSH) function for sets. Let $\Omega = \{1, \dots, n\}$ be a set (in practice, it will be a set of words or n -grams); a random permutation $\sigma \in \mathfrak{S}(\Omega)$ defines a (random) hash function

$$h_\sigma(C) = \inf\{i : \sigma(i) \in C\}, \quad C \subset \Omega.$$

The probability that two subsets C_1 and C_2 agree on this hash function is their Jaccard similarity,

$$P[h_\sigma(C_1) = h_\sigma(C_2)] = J(C_1, C_2) = \frac{|C_1 \cap C_2|}{|C_1 \cup C_2|}.$$

A family H of hash functions $h : S \rightarrow X$, where (S, d) is a metric space and P a probability on H , is said to be (d_1, d_2, p_1, p_2) -sensitive if

$$\forall x, y \in S \quad d(x, y) \leq d_1 \implies P[h(x) = h(y)] \geq p_1$$

$$\forall x, y \in S \quad d(x, y) \geq d_2 \implies P[h(x) = h(y)] \leq p_2.$$

It can be “amplified” by the AND or OR construction, or an AND-OR or OR-AND combination (the distances d_1, d_2 remain the same, probabilities are transformed by $p \mapsto p^r$ or $p \mapsto 1 - (1 - p)^r$).

$$\text{AND} : \forall i, j \in [1, r] \quad h_i(x) = h_j(x)$$

$$\text{OR} : \exists i, j \in [1, r] \quad h_i(x) = h_j(x)$$

Here are some examples of LSH families:

- For the cosine distance, project on a random hyperplane

$$h_v(x) = \text{sign}(v \cdot x), \quad P[h(x) = h(y)] = 1 - \frac{\theta}{\pi};$$

- For the Euclidian distance, project the points on a random line, and put them in buckets of length a .

For approximate text similarity (Jaccard similarity of the bag of words, or the bag of n -grams), one can also look at the following:

- The number of distinct words;
- The N least common words – that gives a lower bound on the distance;
- An index (word, position, number of remaining words), where “position” is the position in the bag of words, sorted with the rarest words first.

The apriori algorithm, for *frequent itemset mining*, proceeds in two steps (for item pairs – n steps for n -item sets): first count the number of occurrences of each item, and pick those that appear at least s times; then, count the pairs of items (but only for those found in the first step), and keep those that appear at least s times. The memory consumption can be reduced:

- PCY: in the first pass, also count pairs, but after hashing them;
- Multihash: idem, with several hash functions;
- Multistage: in pass 1.5, count the hashed pairs, but only for the items from pass 1;
- Toivonen: run the algorithm on a random subset of the data that fits in memory; enlarge the set of candidate itemsets by adding the immediate subsets of those selected by the algorithm; count them (on the whole dataset); enlarge the set of candidate itemsets if necessary; iterate until convergence.

One can model communities using a bipartite graph, with nodes and communities as vertices, and a link probability p_c for each community c ; a link emerges between nodes u and v with probability

$$P(u, v) = 1 - \prod_{c: u, v \in c} (1 - p_c)$$

(or $\text{Max}\{\varepsilon, P(u, v)\}$). The **BigCLAM** model replaces the binary community membership structure with a community strength matrix, $F_{uc} \in [0, 1]$, and a link emerges between u and v with probability

$$P(u, v) = 1 - \prod_c (1 - P_c(u, v)),$$

$$\text{where } P_c(u, v) = 1 - \exp(-F_{uc} \cdot F_{vc}),$$

$$\text{i.e., } P(u, v) = 1 - \exp(-F_u \cdot F'_v).$$

The strength matrix can be estimated as

$$F = \underset{F}{\text{Argmax}} \prod_{(u,v) \in E} P(u, v) \prod_{(u,v) \notin E} (1 - P(u, v))$$

$$= \underset{F}{\text{Argmax}} \sum_{(u,v) \in E} \log \left(1 - e^{-F_u \cdot F'_v} \right) \sum_{(u,v) \notin E} F_u \cdot F'_v.$$

If all the nodes of a graph have the same degree d , $\mathbf{1}$ is an eigenvector of its adjacency matrix with eigenvalue d ; if the graph is not connected, $(1 \cdots 10 \cdots 0)$ and $(0 \cdots 01 \cdots 1)$ are eigenvectors for eigenvalue d ; if there are few edges between the clusters, those vectors are approximate eigenvectors for an eigenvalue close to d . In the general case (**spectral graph partitioning**), consider the Laplacian $L = (\deg G)\text{Id} - A$; the vector $\mathbf{1}$ is an eigenvector with eigenvalue 0; the second smallest eigenvalue is

$$\lambda_2 = \min_x \frac{x' L x}{x' x} = \min_{x' x = 1} \sum_{(i,j) \in E} (x_i - x_j)^2.$$

The coordinates of that vector give the clustering: if there are two clusters, of the same size, they are $\{i : x_i > 0\}$ and $\{i : x_i < 0\}$; in general, look for a jump in $\text{sort}(\mathbf{x})$ and/or look at the third eigenvector.

Trawling finds small communities by looking for complete bipartite subgraphs $K_{s,t}$ – it is a frequent itemset problem.

One can approximately count the number of 1s in a stream of bits, on a moving window of size $k \gg 1$, by keeping track of the counts for blocks of sizes $2^0, 2^1, 2^2, \dots$ and merging them when needed, but the result can be imprecise if the smaller blocks are empty; instead, one can define “size” as being the number of 1s instead of the number of positions.

To estimate the number of different elements in a stream, look at the maximum number R of leading zeroes in a binary hash of those elements (and repeat for many hash functions): 2^R is an estimator of the number of distinct elements but, unfortunately, $E[2^R] = \infty$. This problem can be fixed (*HyperLogLog*).

The singular value decomposition (SVD) gives the best rank- k approximation of a matrix, but it does not preserve sparsity. The **CUR decomposition** addresses this problem:

- C is obtained by taking (say) $4k$ columns of A , at random, sampled with probability $P(j) \propto \|A_{\cdot j}\|_{L^2}^2$ (with replacement): $C = A_{\cdot J}$;
- Similarity, R is obtained from rows of A : $R = A_{I \cdot}$;
- $U = A_{IJ}^\dagger$ (the pseudo-inverse is also computed from the SVD: if $W = XSY'$ is the SVD of W , then $W^\dagger = YS^\dagger X'$, where $S = \text{diag}(s_i)$, $S^\dagger = \text{diag}(s_i^{-1})$ and $s_i^{-1} = 0$ if $s_i = 0$).

Content-based recommendation systems look at the features (e.g., TDIDF, for text) of items highly rated by the user. User-user *collaborative filtering* finds users similar to the target (cosine similarity, or centered cosine similarity aka correlation); item-item collaborative filtering is similar. *Latent factor recommendation systems* decompose the user \times item rating matrix (e.g., SVD with missing values).

There are big-data (1-pass) approximations of the k -means clustering algorithm:

- Read the data in batches; build the clusters progressively; for each cluster, only keep the mean, standard

deviation and count;

- CURE: Run k -means on a random sample of the data; pick 4 points per cluster; move them towards the center; read all the data and assign each observation to the nearest point.

Support vector machines (SVM) are looking for the separating hyperplane with the largest margin

$$\begin{array}{ll} \text{Find} & w, b \\ \text{To maximize} & \min_i (w \cdot x_i + b)y_i \\ \text{Such that} & \|w\| = 1 \end{array}$$

where $y_i \in \{\pm 1\}$. This can be written

$$\begin{array}{ll} \text{Find} & w, b, \gamma \\ \text{To maximize} & \gamma \\ \text{Such that} & \forall i (w \cdot x_i + b)y_i \geq \gamma \\ & \|w\| = 1. \end{array}$$

The *support vectors* are the observations x_i such that the margin $(w \cdot x_i + b)y_i$ is γ . If we remove the constraint $\|w\| = 1$ and impose $(w \cdot x_i + b)y_i = 1$, the margin becomes $\|w\|^{-1}$ (to prove it, consider a support vector x_+ , its symmetrix x_- wrt the hyperplane, and add their margins), and the problem

$$\begin{array}{ll} \text{Find} & w, b \\ \text{To minimize} & \|w\|^2 \\ \text{Such that} & \forall i (w \cdot x_i + b)y_i \geq 1. \end{array}$$

If the data is not separable, add a penalty $c\xi_i$ for each misclassified point

$$\begin{array}{ll} \text{Find} & w, b, \xi \\ \text{To minimize} & \|w\|^2 + c \sum_i \xi_i \\ \text{Such that} & \forall i (w \cdot x_i + b)y_i \geq 1 - \xi_i \\ & \forall i \xi_i \geq 0. \end{array}$$

This can be written with a *hinge loss*

$$\begin{array}{ll} \text{Find} & w, b \\ \text{To minimize} & \|w\|^2 + c \sum_i \text{Max}\{0, 1 - y_i(w \cdot x_i + b)\}. \end{array}$$

The constraints have disappeared: we can use (stochastic) gradient descent.

Process mining

W. van der Aalst (Coursera, 2014)

Process mining is the study and modeling of logs (a *log* is a set of traces, a *trace* is a sequence of actions or tasks or activities, with timestamps, and often ancillary data – usually as CSV files, but there is an XML standard: XES). The model is often represented using the business process modeling notation (**BPMN**), with activities \square and decision nodes (XOR split \diamond , XOR join, AND join, \oplus , AND split)

To more easily keep track of the “current state” (the process can be in several branches at the same time), one can use a **Petri net** instead: it is made of transitions \square and places \circ , and the current state is tracked with one or several tokens \bullet : a transition is enabled when there is a token in each of its input places; when it fires, it consumes a token in each of its input places and produces one in each output place (the number of tokens is not constant).

A Petri net is k -bounded if there are at most k tokens in any given place; it is *safe* if it is 1-bounded; a *dead-lock* is a reachable dead marking, *i.e.*, a state in which no transition is enabled; a *live transition* is a transition that can be enabled from any reachable marking; a *workflow net* is a Petri net, with one source place, one sink place, in which all nodes are on a path from source to sink; a workflow net is *sound* if it is safe, has no dead parts, has proper completion (if there is a token in the sink, there are no tokens anywhere else), and has the option to complete.

If x and y are events appearing in the log, $x < y$ means that x is sometimes immediately followed by y . The **causal footprint** of a log is the set (matrix) of relations between events, where the possible relations are:

- $x \rightarrow y$ if $x < y$ and not $y < x$;
- $x \parallel y$ if $x < y$ and $y < x$;
- $x \# y$ if neither $x < y$ nor $y < x$.

The **alpha algorithm** tries to build a Petri net from the causal footprint of a log. Intuitively, it tries to recognize patterns for XOR/AND split/join (e.g., $a \rightarrow b$, $a \rightarrow c$, $b \# c$ corresponds to a XOR split). More formally:

- L = the set of traces (the log); a trace is a sequence of tasks;
- T = the set of tasks;
- T_i = the set of initial tasks;
- T_o = the set of final (output) tasks;
- X is the set of candidate places, where a candidate place is a pair (A, B) , $A, B \subset T$, such that

$$\begin{array}{lll} \forall a \in A & \forall b \in B & a \rightarrow b \\ \forall a_1, a_2 \in A & & a_1 \# a_2 \\ \forall b_1, b_2 \in B & & b_1 \# b_2 \end{array}$$

- $Y \subset X$ only contains the maximal elements of X ;
- For the set of places $P = Y \cup \{i, o\}$, just add an initial and a final place;
- The set of arcs, F , contains an arc from i to each element of T_i ; an arc from each element of T_o to o ; for places (A, B) , an arc from each element a of A to (A, B) , and an arc from (A, B) to each element b of B .

The algorithm is related to frequent itemset mining. The model learned by the alpha algorithm is not minimal (one can sometimes remove places with no visible effect), and cannot capture loops or non-local dependencies; it is not robust to noise: you can end up with a flower model, which allows any behaviour.

Region-based process discovery tries to address some of those problems. First, define states from the log; for instance, a state could be the trace before a given point, or the trace after a given point, or the whole trace, or the last (or next) k actions (as a sequence, or as a set, or as a multiset); one could also use the other attributes (*resources*) of the events. The states form a transition system. A *region* is a subset of states such that, for each activity a , either a always enters the region, or a always exits the region, or a never enters nor leaves the region. The places are the non-trivial minimal regions.

Language-based regions reduce the problem of finding the places to a linear algebra problem: a place is a solution $(x, y, c) \in \mathbf{N}^3$ of $c\mathbf{1} + Bx - Ay \geq 0$, where A and B are binary matrices, with one column per activity and one row for each prefix of a trace, an element of A is 1 if the activity is in the prefix an element of B is 1 if the activity is in the prefix without its last element; c is the number of tokens, the nonnegativity condition ensures that the number of tokens in a place is never negative, x and y describe the arcs, x is the number of transitions to the place (x, y, c) , y is the number of transitions from the place (x, y, c) .

Inductive process mining decomposes the event log using SEQ, XOR and AND operations. Genetic algorithms are also used in process mining.

To measure the *conformance* of a log and a model:

- Compute the causal footprint of the log and the model, and count the discrepancies;
- Replay the log, add tokens to enable transitions when needed, and count the number of tokens added and the number of tokens remaining at the end (but once the net is flooded with tokens, anything is possible);
- Align the log and the model [no details].

Process models can be *enhanced*:

- At decision points, use statistical models to guess which branch will be taken (data-aware Petri nets);
- Identify bottlenecks and their causes;
- Social networks (for instance, it is easy to identify the structure of an organization);
- Operational support: detect problems, predict the remaining time, predict and recommend the next activity or resource.

MEG decoding using Riemannian geometry and unsupervised classification

A. Barachant

To forecast a binary class $k \in \{0, 1\}$ from multidimensional signals $x_i : [1, N] \rightarrow \mathbf{R}^c$:

- Compute the average for each class, $p_k : [1, N] \rightarrow \mathbf{R}^c$;
- For each class $k \in \{0, 1\}$, combine the signals

$$w_1 p_{k1} + \dots + w_c p_{kc}$$

$$w_1 x_1 + \dots + w_c x_c$$

to maximize the signal-to-noise ratio

$$w^{(k)} = \underset{w}{\operatorname{Argmax}} \frac{\|w' p_k\|_2}{\|w' x\|_2} = \underset{w}{\operatorname{Argmax}} \frac{w' p_k p_k' w}{w' x x' w};$$

- It is an eigenvalue problem: keep the first four eigenvectors w^{k1}, \dots, w^{k4} ;
- As features, use the covariance matrix $\Sigma_i = \frac{1}{N} Z_i Z_i'$ of

$$Z_i = \begin{pmatrix} w^{01'} p_0 \\ \vdots \\ w^{04'} p_0 \\ w^{11'} p_1 \\ \vdots \\ w^{14'} p_1 \\ w^{01'} x_i \\ \vdots \\ w^{14'} x_i \end{pmatrix}$$

- Do not use the variance matrices themselves, but project them on the tangent space (at I , using the logarithm) of the space S_+ of positive definite matrices.

The actual Kaggle task was a form of *transfer learning* (the test samples were not from the same distribution as the training samples – MEGs from a different patient): one can use the forecasts from the trained model as a starting point for the k -means algorithm. But this requires barycenters: in S_+ , the average of a set of points is the point that maximizes the sum of the squared distances, and the distance is

$$d(\Sigma_1, \Sigma_2) = \left\| \log \Sigma_1^{-1/2} \Sigma_2 \Sigma_1^{-1/2} \right\|_F$$

$$= \sqrt{\sum_c \log^2 \lambda_c}$$

where the λ_c are the eigenvalues of $\Sigma_1^{-1/2} \Sigma_2 \Sigma_1^{-1/2}$.

A Riemannian geometry with complete geodesics for the set of positive semidefinite matrices of fixed rank

B. Vandereyken et al. (2013)

It is easy to describe the geodesics of $S_+(n, n)$, the manifold of positive definite matrices of size n , and use them in optimization problems (e.g., line search along a geodesic), but the algorithms do not scale (they are $O(n^3)$). Low-rank approximations are attractive, but the space of positive semidefinite matrices of size n

and rank p , $S_+(n, p)$, has no canonical metric. It can be described as the orbit of

$$\begin{pmatrix} \mathbf{1}_p & \mathbf{0}_{p, n-p} \\ \mathbf{0}_{n-p, p} & \mathbf{0}_{n-p} \end{pmatrix}$$

under the action of GL_n^+ defined by $A \cdot X = AXA^{-1}$. The natural right-invariant metric on GL_n , $g_A(\eta_A, \nu_A) = \text{tr}(A^{-1} \eta'_A \nu_A A^{-1})$, defines a metric on $S_+(p, n)$.

***A differential geometric approach
to the geometric mean
of symmetric positive-definite matrices***
M. Moakher

The matrix exponential $\exp : S(n) \rightarrow S_+(n)$ establishes a bijection between symmetric matrices $S(n)$ and symmetric positive definite matrices $S_+(n) \simeq \text{GL}_n/O_n$.

The geodesic on $S_+(n)$ from I in the direction S is $t \mapsto e^{tS}$.

The geodesic on $S_+(n)$ from P in the direction $S \in S(n) \simeq T_P S_+(n)$ is $t \mapsto P^{1/2} e^{tP^{1/2} S P^{-1/2}} P^{1/2}$.

The distance on $S_+(n)$ is

$$d(P, Q) = \|\text{Log}(P^{-1}Q)\|_F = \left(\sum_{\lambda \in \text{Spec } P^{-1}Q} \ln^2 \lambda \right)^{1/2}$$

(note that $P^{-1}Q$ is not symmetric, but $\text{Spec } P^{-1}Q = \text{Spec } Q^{1/2} P^{-1} Q^{1/2} \subset \mathbf{R}_+^\times$).

The Riemannian mean of positive definite matrices P_1, \dots, P_n , defined as $P = \text{Argmin}_P \sum_k d(P, P_k)^2$, satisfies $\sum_k \text{Log}(P_k^{-1}P) = 0$; it is a generalization of the geometric mean.

***Multiclass brain computer interface
classification by Riemannian geometry***
A. Barachant et al. (2012)

If your data consists of positive definite matrices, rather than arbitrary vectors, algorithms that only use the notions of distance and mean (e.g., kNN, k-means, etc.) are directly applicable using the Riemannian structure of $S_+(n)$. For other algorithms, project the data on the tangent space (at the identity, or any other point, if one makes better sense), using the logarithm.

***Classification of covariance matrices using a
Riemannian-based kernel for BCI applications***
A. Barachant et al. (2013)

More details; algorithm to compute the mean; application to support vector machines.

MEG decoding accross subjects
E. Olivetti et al. (2014)

Transductive transfer learning (TTL):

$$\hat{\theta} = \text{Argmin}_{\theta} \frac{1}{n} \sum_i \frac{P_{\text{target}}(x_i)}{P_{\text{source}}(x_i)} \text{loss}(\theta, x_i, y_i).$$

Factorization machines
S. Rendle

A **factorization machine** is a linear model with interactions,

$$y = \alpha + \sum_i \beta_i x_i + \sum_{ij} \gamma_{ij} x_i x_j$$

where the interaction terms have low rank $\gamma_{ij} = \langle v_i, v_j \rangle$, $v_i \in \mathbf{R}^k$, k small (you can add higher order interactions). It is an alternative to the “hash trick” Vowpal Wabbit uses. It works better than support vector machines for sparse data. (Without α and β , it would just be a matrix factorization.)

For an implementation, check `libfm`.

***Learning recommender systems
with adaptive regularization***
S. Rendle (2012)

Simultaneously learn the model and the regularization parameter:

$$\begin{aligned} \beta_{n+1} &= \underset{\beta}{\text{Argmin}} \text{Loss}(\text{training set}, \beta, \lambda_n) \\ \lambda_{n+1} &= \underset{\lambda}{\text{Argmin}} \text{Loss}(\text{test set}, \beta_{n+1}, \lambda). \end{aligned}$$

(Here, Argmin does not have to be the minimizer: taking a few steps towards the minimum is sufficient.)

***Scaling factorization machines
to relational data***
S. Rendle (2013)

When fitting a model on relational data (often, a star schema, e.g., movie ratings, with movie characteristics (genre, year) and user characteristics (age, gender, friends)), one typically joins (denormalizes) the data. this needlessly inflates the volume of data to process and the running time. Learning on data in normal form is possible (process the fact table; update the weights of the rows on the dimension tables; process the dimension tables).

Tensor decompositions and applications
T.G. Kolda and B.W. Bader (2009)

There are two generalizations of PCA to tensors (using Einstein’s summation convention):

$$\begin{aligned} \text{CP:} \quad & x_{ijk} = g^r a_{ir} b_{jr} c_{kr} \\ \text{Tucker:} \quad & x_{ijk} = g^{pqr} a_{ip} b_{jq} c_{kr} \end{aligned}$$

The CP (canonical decomposition/parallel factors) expresses the tensor x as a sum of rank-1 tensors. The *rank* of x is the minimal number of terms in such a sum. Contrary to the notion of rank for matrices:

– The ranks over \mathbf{R} and \mathbf{C} may be different;

- Among tensors of a given shape, the typical rank (any rank that occurs on a set of non-zero measure) and the maximum rank can differ;
- “The” typical rank is not unique;
- The best rank-1 approximation need not be part of a best rank-2 approximation;
- The best rank- k approximation need not exist: the set of rank- k tensors is not closed, *i.e.*, some tensors can be approximated arbitrarily closely by a tensor of smaller rank – the *border rank* of x is the minimum number of rank-1 tensors needed to approximate x with an arbitrarily small error.

The CP decomposition can be estimated using alternating least squares (ALS).

Probabilistic principal component analysis
M.E. Tipping and C.M Bishop (1999)

PCA is a limiting case of (isotropic) factor analysis, $X \sim N(\mu, WW' + \sigma^2 I)$, when $\sigma^2 \rightarrow 0$ (σ^2 is the average variance due to discarded components). PPCA allows for missing values.

In R, check the `pcaMethods` package (for probabilistic and bayesian PCA).

NICE: non-linear independent component estimation
L. Dinh et al. (2014)

Given a random variable $X : \Omega \rightarrow \mathbf{R}^n$, a non-linear independent component decomposition is a transformation $f : \mathbf{R}^n \rightarrow \mathbf{R}^n$ such that the density of $H = f(X)$ factorizes: $p_H(h) = \prod_d p_{H_d}(h_d)$.

It can be estimated by maximum likelihood, $p_X(x) = p_H(f(x)) |\det f'|$, *i.e.*,

$$\text{Argmax}_{f, p_{H_1}, \dots, p_{H_n}} \sum_x \sum_d \log p_{H_d} f_d x + \log |\det f'|.$$

We look for a transformation (built from three layers of building blocks) of the form

$$\begin{aligned} y_1 &= x_1 \\ y_2 &= x_2 + m(x_1) \end{aligned}$$

which ensures that $|\det f'|$ and f^{-1} are easy to compute.

Sparse matrix factorization
B. Neyshabur and R. Panigrahy (2014)

The sparse matrix factorization problem aims to write a matrix Y as a product of sparse matrices $Y = X_1 X_2 \dots X_n$ – PCA can be seen as a special case, where X_1 has few columns and X_2 few rows.

Assuming the matrices are square, random, centralized, normalized, and the coefficients of Y are 0, 1 or -1 , $X_1 X_1' = \text{round}(Y Y')$ with high probability; X_1 can be recovered from $X_1 X_1'$, and one can then iterate.

Blind denoising with random greedy pursuits
M. Moussallam et al. (2014)

To find a sparse reconstruction of a time series y , choose “atoms” (elementary time series $\Phi = (\phi_1 | \dots | \phi_n)$) and fit $y = \Phi \alpha + w$, where α is sparse:

$$\begin{aligned} &\text{Find} && \alpha \\ &\text{To minimize} && \|\alpha\|_0 \\ &\text{Such that} && \|y - \Phi \alpha\| \leq \varepsilon. \end{aligned}$$

One can use a greedy algorithm (matching pursuit, MP) to find an approximate solution – for the stopping criterion, look at

$$\text{Max}_{\phi} \frac{|\langle y, \phi \rangle|}{\|y\|_2 \|\phi\|_2}.$$

Instead of a single sparse representation, one can compute several (as with random forests: at each step, choose a new atom in a random subset of Φ) and average them.

Dimensionality reduction for k -means clustering and low rank approximation
M. Cohen et al. (2014)

To speed up approximate k -means or PCA, use a sketch of the data (row and column sampling, approximate SVD (CUR), Johnson-Lindenstrauss projection).

Alternating least squares for personalized ranking
G. Takács and D. Tikk (2012)

Alternating least squares (ALS) are often used to find $\hat{R} = P'Q$, with P and Q rectangular with a small number of columns, to minimize

$$\sum_{u \in \text{Users}} \sum_{i \in \text{Items}} c_{ui} (\hat{r}_{ui} - r_{ui})^2.$$

It can also be used with a ranking objective

$$\sum_{uij} c_{ui} s_j ((\hat{r}_{ui} - \hat{r}_{uj}) - (r_{ui} - r_{uj}))^2.$$

HyperLogLog in practice: algorithmic engineering of a state of the art cardinality estimation algorithm
S. Heule et al. (2013)

HyperLogLog is biased for small counts: one can (empirically) estimate the bias and correct it. (HyperLogLog++ introduces a few more changes, mostly to reduce memory usage.)

***In-code computation
of geometric centralities with HyperBall:
hundred billion nodes and beyond***
P. Boldi and S. Vigna

To count the number $|B(x, r)|$ of nodes in the ball of center x and radius r in a graph, use a HyperLogLog counter c_v for each node and estimate $B(x, r+1)$ from $B(x, r)$.

This can be used to compute the *harmonic centrality*

$$\text{centrality}(x) = \sum_y \frac{1}{d(x, y)} = \sum_{r \geq 1} \frac{|B(x, r)|}{r}.$$

The power of comparative reasoning
J. Yagnik et al.

The winner-takes-all (WTA) locality-sensitive hash (LSH) is

$$\begin{cases} \mathbf{R}^n & \longrightarrow \{1, \dots, k\} \\ \mathbf{x} & \longmapsto \underset{1 \leq j \leq k}{\text{Argmax}} x_{\sigma(j)} \end{cases}$$

for a random permutation $\sigma \in \mathfrak{S}_n$.

By using several permutations σ and choosing $k = 2$, we get a binary hash.

One can apply a kernel before computing the hash.

***OpenGM: a C++ library
for discrete graphical models***
B. Andres et al. (2012)

C++ template library implementing algorithms for discrete graphical models (loopy belief propagation, sequential tree reweighted belief propagation, graph cut, etc.), *i.e.*, given a factor graph and a semiring $(\Omega, \otimes, 1, \oplus, 0)$, computing $\bigoplus_x \bigodot_F \phi_F(x_{\text{neigh}(x)})$; examples include

Optimization	$(\mathbf{R}, +, 0, \min, \infty)$
Marginalization	$(\mathbf{R}^+, \cdot, 1, +, 0)$
Constraint satisfaction	$(\{0, 1\}, \wedge, 1, \vee, 0)$

***MPPack:
a scalable C++ machine learning library***
R.R Curtin et al. (2012)

An LGPL C++ template machine learning library (also check Weka, Shogun, mlpy, sklearn, MLLib).

Practically accurate floating point math
N. Toronto and J. McCarthy (2014)

Measure the floating point error when approximating a real number r with a floating point number x as

$$\text{error}(x, r) = \frac{x - r}{\text{ulp}(\text{fl}(r))}$$

where

$\text{ulp}(y)$ = distance from y to the next float

$\text{fl}(r)$ = float closest to r

$\text{ord}(x)$ = (signed) number of floats between 0 and x

$\text{ord}^{-1}(n)$ (needed to compute ulp).

It is the number of floats between x and r .

When implementing a numeric function, check where it is ill-conditioned (“the badlands”), e.g., for functions $f : \mathbf{R} \rightarrow \mathbf{R}$, check where the condition number $|xf'(x)/f(x)|$ exceeds 4.

The examples use typed/racket (for the plots as well) and MPFR.

***Fast approximate nearest neighbors
with automatic algorithm configuration***
M. Muja and D.G. Lowe

Comparison of randomized kd-trees and hierarchical k -means for fast approximate nearest neighbours (FANN).

***CRDTs: consistency
without concurrency control***
M. Leřia et al. (2009)

CRDTs are data structures whose operations commute: they can be used in a distributed environment. For instance:

- A set with a single add-element operation;
- A set with add and delete operations, if no element is ever added twice: keep two lists, one for added elements, one for deleted elements, and clean them from time to time;
- An ordered set, with insert-at and delete operations: use a dense index space (not \mathbf{R} , but paths in a binary tree).

***A comprehensive study of convergent
and commutative replicated data types***
M. Shapiro et al. (2011)

Eventual consistency, in a distributed/asynchronous environment, can be guaranteed by the data structures themselves, without synchronization. For instance:

- Add-only set;
- Distributed maximum (when the maximum changes, broadcast it to the other replicas);
- Counter: broadcast +1 or −1 – the reception order is irrelevant;
- Register: store value-timestamp pairs and only keep the value with the latest timestamp;
- Set with add and remove operations, if removed elements cannot be added back: use two add-only sets, for elements added and elements removed, and occasionally garbage-collect them;
- Set with add and remove operations, in which add has priority over remove in case of a conflict (e.g.,

shopping cart): when adding an element, also store a unique identifier (a new one, if the element was already there); remove removes the elements with the identifiers known to the replica that received the order;

- Graphs: like sets;
- Directed acyclic graphs: that is a global property; it cannot be ensured in general without synchronization.
- Partial order: like sets;
- Total order (e.g., collaborative editing): either add an `addRight(position,content)` operation, which stores the content-timestamp pair in a linked list or an `addBetween` operation, for which the total order is defined by a dense set of identifiers (trees: Logoot or Treedoc – but they have to be rebalanced (garbaged-collected) from time to time).

Generation and analysis of constrained random sampling patterns
J. Pierzchlewski and T. Arildsen

Random sampling of analog (1-dimensional) signals is preferable to regular sampling. Simple sampling patterns include: a regular grid with noise, or adding noise to the previous point.

The algorithmic foundations of differential privacy
C. Dwork and A. Roth (2014)

To ensure plausible deniability, use randomized algorithms (e.g., answer truthfully with probability $\frac{1}{2}$, answer randomly otherwise – for real-valued functions, perturb the result with the Laplace distribution). A randomized algorithm \mathcal{M} is differentially private if

$$\|x - y\| \leq 1 \implies P[\mathcal{M}(x) \in S] \leq e^\epsilon P[\mathcal{M}(y) \in S] + \delta.$$

The privacy loss is $\ln \frac{P[\mathcal{M}(x) = \xi]}{P[\mathcal{M}(y) = \xi]}.$

When answering several queries, the system should refuse to answer similar ones (e.g., the number of people with disease D, and the number of people not named X with disease D).

Computing arbitrary functions of encrypted data
C. Gentry (2008)

The following encryption scheme, which adds noise to the cleartext, is somewhat homomorphic – the noise progressively increases and eventually becomes too large.

cleartext: $m \in \{0, 1\}$
 key: $p \in \{0, 1\}^P, p \equiv 1 \pmod{2}$
 ciphertext: $c = m' + pq$
 where $m' \in \{0, 1\}^N, m' \equiv m \pmod{2}$
 $q \in \{0, 1\}^Q$
 somewhat preserved: $+, -, \times$

To make it homomorphic, try to find functions $f_{i \rightarrow i+1}$ that transform $\text{Encrypt}(p_i, m)$ to $\text{Encrypt}(p_{i+1}, m)$ (i.e., that change the key and reset the noise), using the somewhat preserved operations (this is possible after a small change in the encryption scheme). This is slow, there is no division, and no inequalities.

A comparative study of discretization methods for naive Bayes classifiers
Y. Yang and G.I. Webb (2002)

When discretizing data, use \sqrt{n} quantile bins, but make sure each bin has at least 30 observations.

The Winograd schema challenge
H.J. Levesque et al. (2012)

A replacement for captchas (or the Turing test): resolve referential ambiguity (e.g., “the trophy does not fit in the suitcase because it is too big”, what is too big: the trophy or the suitcase?).

Sloane’s gap: do mathematical and social factors explain the distribution of numbers in the OEIS?
N. Gauvrit et al. (2011)

Plotting the number of occurrences of an integer in the OEIS shows two clouds, with a similar exponential decay, and a gap inbetween. Computational complexity explains the decay, but not the gap – it could be due to social factors.

Profiling R on a contemporary processor
S. Sridharan and J.M. Patel (2014)

R is slow because of cache misses, caused by:

- Pointer-chasing the the garbage collector (GC);
- Linear algebra operations: R should provide both row- and column-major storage and/or use blocking;
- Custom C code in packages (e.g., `rpart`): it should be cache-conscious.

The GC problems are made worse by:

- Unnecessary attributes (e.g., row names, which are automatically added);
- Unnecessary copies; intermediate object creation (arithmetic operations on vectors or matrices);
- Inefficient implementations (e.g., subsetting with a boolean vector recomputes the row indices for each column).

Convex optimization in Julia
M. Udell et al. (2014)

The `Convex.jl` package brings disciplined convex programming (DCP) to Julia.

Besides the positive orthant, the second order cone, and the semi-definite cone, note the *exponential cone*,

$$\{(x, y, z) \in \mathbf{R}^3 : y \geq 0, ye^{x/y} \leq z\},$$

used for the convex functions $\exp(x)$, $-\log(x)$, $\log \sum_i \exp x_i$.

Computing in operations research using Julia
M. Lubin and I. Dunning (2013)

JuMP.jl relies on macros rather than operator overloading (as in CVX, Convex.jl, PuPL, Pyomo, etc.) and can therefore efficiently build larger problems.

A review of goal programming for portfolio selection
R. Azmi and M. Tamiz (2010)

“Goal programming” is a vague notion that refers to the various ways of selecting a single solution of a multi-objective optimization problem, “find x to minimize $g_1(x), \dots, g_n(x)$ ” somewhere on the efficient frontier. For instance:

- Minimize $\sum_i \lambda_i g_i(x)$;
- Minimize $\text{Max}_i g_i(x)$;
- Minimize $g_1(x)$; among the solutions, minimize g_2 ; continue until there is only one solution left;
- etc.

Portfolio selection with higher moments: a polynomial goal programming approach to ISE30 index
G. Kemalbay et al. (2011)

Indicator-based selection in multiobjective search
E. Zitzler and S. Künzli (2004)

Multiobjective search tries to find a good approximation of the Pareto set – a good solution is close to the Pareto set and diversified. These notions are rarely clearly defined, but could be formalized, e.g., one could try to maximize the volume dominated by the solution. Here is one algorithm:

- Start with a large candidate set;
- Compute the “fitness” of each point in it (relative to the others);
- Remove the worst point; update the fitness of the others;
- Iterate (until some termination criterion is met, e.g., the population size).

The *indicator-based evolutionary algorithm* (IBEA) defines the fitness of a point $a \in A$ as

$$F(a) = \sum_{b \in A \setminus \{a\}} -\exp -I(\{a\}, \{b\})/\kappa$$

where κ is a parameter (the temperature) and I is a *binary quality indicator*, e.g.,

$$I(A, B) = \text{Min}\{\varepsilon : \forall b \in B \quad \exists a \in A \quad \exists i \in \llbracket 1, n \rrbracket \\ f_i(a) - \varepsilon \leq f_i(b)\}$$

or

$$I(A, B) = \begin{cases} I(B) - I(A) & \text{if } \forall b \in B \exists a \in A \ a \succ b \\ I(A \cup B) - I(A) & \text{otherwise} \end{cases}$$

where $I(A)$ is the volume dominated by A .

Sparse and stable Markowitz portfolios
J. Brodie et al. (2008)

For sparse portfolios, add an L^1 penalty to the portfolio optimization problem.

Sparse portfolio selection via quasi-norm regularization
C. Chen et al. (2013)

For sparse portfolios, add an L^p penalty ($0 < p < 1$) to the portfolio optimization problem; it is no longer convex, but can still be solved in polynomial time via interior point methods.

Optimal risk budgeting under a finite investment horizon
M. López de prado, R. Vince and Q. Zhu (2013)

To decide which proportion x_i of one’s wealth to invest in asset i , one can use $\hat{x} = \text{Argmax}_x f_{Q,U}(x)$, where $f_{Q,U}(x)$ is the expected utility for utility function U after Q periods. The Kelly principle is $\hat{x} = \text{Argmax}_x f_{\infty, \text{linear}}(x)$. The *leverage space* seems to be the graph of $x \mapsto f_{Q, \text{linear}}(x)$.

A factor model for non-linear dependences in stock returns
R. Chicheportiche and J.P. Bouchaud (2013)

The *non-linear correlation* between two random variables X and Y generalizes $\text{Cor}(|X|, |Y|)$ and $\text{Cor}(X^2, Y^2)$:

$$C_p(X, Y) = \frac{1}{p^2} \log \frac{E[|XY|^p]}{E[|X|^p]E[|Y|^p]}.$$

In the standard factor model $x_i = \sum_k \beta_{ki} f_k + e_i$, the non-linear correlations $C_p(f_k, f_\ell)$, $C_p(f_k, e_i)$, $C_p(e_i, e_j)$ are non-zero. The nested factor model, for the volatilities of the factors f and the residuals e , with two factors, Ω_0 and Ω_1 , can account for them:

$$f_k = \varepsilon_k \exp[A_{k0}\Omega_0 + A_{k1}\Omega_1 + \omega_k] \\ e_j = \eta_j \exp[B_{j0}\Omega_0 + B_{j1}\Omega_1 + \varpi_k].$$

Commodity futures and market efficiency
L. Kristoufek and M. Vosvrda (2013)

To measure the efficiency of a given market (or asset), average the following measures:

- Hurst exponent (long-term efficiency): local Whittle estimator, GPH estimator;
- Fractal dimension (short-term): Hall-Wood estimator, Genton estimator;
- Entropy: Pincus approximate entropy.

The article also gives a concise review of those estimators.

Implied Hurst exponent and fractional implied volatility: a variance term structure model
K.Q. Li and R. Chen (2014)

One can compute the Hurst exponent from option prices:

- Using the fractional Black-Scholes formula; a single option does not give (σ, H) , but just $V = \sigma^2 T^{2H}$; use several maturities and regress $\log V \sim \log T$;
- Using a model-free approach, very similar to the VIX computations, to compute V .

Forecasting the NOK/USD exchange rate with machine learning techniques
T. Papadimitriou et al.

One can forecast the exchange rate

$$FX_{t+1} \sim FX_t + (M_2 - M_2^{\text{US}}) + (\text{GDP} - \text{GDP}^{\text{US}}) + (\text{IR} - \text{IR}^{\text{US}}) + (\text{Inflation} - \text{Inflation}^{\text{US}}) + \text{Oil} + t,$$

where the inflation is a forecast from an ARMA model or from the forward rate, using support vector regression

$$\hat{\beta} = \underset{\beta}{\text{Argmin}} \frac{1}{2} \|\beta\|^2 + C \sum_i \phi(y_i - \beta' x_i)$$

$$\phi = \begin{array}{c} \diagup \quad \diagdown \\ | \end{array}$$

(with the kernel trick). The resulting model can be made more interpretable using a “dynamic evolution neuro-fuzzy inference system” (DENFIS), *i.e.*, a set of fuzzy rules of the form “Rule m : if x_1 is R_{m1} and ... and x_n is R_{mn} then $y = \sum_i \beta_{mi} x_i$ ”, where R_{m1} is a Gaussian membership function

$$R_{m1} \propto \exp - \frac{(x - c)^2}{2\sigma^2}.$$

Rationality of survival, market segmentation and the equity premium puzzle
Y. Gabovich (2014)

A supply-and-demand model, with young people investing in equities and retirees in bonds, can explain the equity premium puzzle (the difference in returns between bonds and equities is too large to be explained by risk aversion alone).

Do patented innovations affect cost of equity capital?
S.P. Hegde and D.R. Mishra (2014)

Cost of equity increases with R&D expenses but decreases with patents: they reduce the uncertainty about the marketability of the research.

Say it again Sam: the idiosyncratic information content of corporate conference calls
J. Cicon (2014)

To measure the information content of corporate conference calls, compare the two parts of the call (management presentation and Q&A session), *e.g.*, with cosine similarity, to estimate how much unscripted information is provided.

Management forecasts and the cost of equity capital: international evidence
Y. Cao et al. (2014)

The presence of management forecasts lowers the cost of equity.

Do social firms catch the drift? Social media and earnings news
V. Bhagwat and T.R. Burch (2013)

Twitter firms (more than 0.1 tweet per day, on average, since the creation of the twitter account – the mapping from firm to twitter account was done manually) have stronger post-earnings announcement drift (PEAD).

A general option valuation approach to discount for lack of marketability
R. Brooks (2014)

To price a non-marketable asset, one can model the price of the corresponding marketable asset as the sum of the unmarketable price and an option, *e.g.*, an option to sell the asset at the current market price, or at the best price in the period (if the investor has market timing abilities) or at the average price in the period (European put, lookback put, average-strike put).

Stock market ambiguity and the equity premium
P.C. Andreou et al. (2014)

Ambiguity (uncertainty about the probability distribution of future assets) can be measured as the dispersion (standard deviation or mean absolute deviation) of the volume-weighted strike prices of S&P 500 index options. It is a better predictor of future returns than other ambiguity proxies (analysts' forecasts, stock turnover, press) or other option-implied measures (slope of the volatility smirk, risk-neutral variance, skewness or kurtosis, hedging pressure, *i.e.*, OTM puts / ATM calls), and almost as good as the variance risk premium, $(VRP = \text{Var}^Q X_t - \text{Var}^P X_t)$, where $\text{Var}^Q X_t$ is computed from option prices and $\text{Var}^P X_t = \text{Var}^{\text{realized}} X_{t-1}$.

Credit risk models II: structural models
A. Elizalde (2005)

Structural default models model the value of the assets of a company as a geometric Brownian motion; a default occurs when the value of the assets is below some threshold

- at the end of the period;
- at any point during the period;
- or on some sufficiently long subinterval of the forecast period.

These correspond to the Merton model (European options), first passage models (FPM, barrier options) and liquidation process models. Those models do not work well.

To account for correlation and contagion, one can model the value of the assets (of several companies) as diffusions with correlated innovations and correlated jumps.

***Asymmetric dependence, tail dependence
and the time interval
over which the variables are measured***
B.U. Kang and G. Kim (2014)

Look at the asymptotic behaviour of the n -period copula:

$$\left| \lambda^{(n)}(q) - \lambda^{(n)}(1-q) \right| \xrightarrow{n \rightarrow \infty} 0$$

$$\lambda_U^{(n)}, \lambda_L^{(n)} \xrightarrow{n \rightarrow \infty} 0$$

where $\lambda^{(n)}(q)$ is the n -period quantile and $\lambda_U^{(n)}, \lambda_L^{(n)}$ the upper and lower tail dependence indices.

Stock and index derivatives and markets
J. Spina (2014)

The main option strategies are:

- Dividend spread: profit from investors that fail from exercising their American options in time;
- If you own stocks of your own firm, want to keep the dividends and voting rights, but want some protection: buy OTM puts (you may also want to sell OTM calls to finance the puts);
- Variable prepaid forward (sell the stock you own in the future, but get the money now);
- If you want to bet on the performance of a stock (e.g., your firm), use an option collar, sell ATM puts, buy ATM calls.

Relative alpha
J.C. Jackwerth and A. Slavutskaya

The relative alpha of a hedge fund is the excess performance wrt its peers, where the peers are funds for which the return difference has a small variance. More formally,

$$\alpha_i = \sum_{j \neq i} w_{ij} E[r_i - r_j]$$

$$w_{ij} \propto k(h^{-1} \text{Var}[r_i - r_j])$$

k : kernel

h : bandwidth (Silverman's rule of thumb).

Factor high-frequency based volatility models
K. Sheppard and W. Xu (2014)

Factor model to estimate large realized covariance matrices.

***A multivariate model
of strategic asset allocation with longevity risk***
E. Bisetti et al. (2014)

If you use reinsurance as a cheap source of leverage (like Berkshire), do not forget to account for longevity risk – it is negligible for short-term investors, but significant for long-term ones.

***Consumption-based asset pricing
with rare disaster risk***
J. Grammig and J. Sönksen (2014)

High equity risk premium may be due to fears of rare disasters.

***Optimal hedging
with the vector autoregressive model***
L.T. Gatarek and S. Johansen (2014)

With several assets (3+) and cointegration relations (2+), use portfolio construction tools (e.g., minimum variance) on the set of stationary portfolios.

***Classifying as defensive or cyclical
a bivariate wavelet analysis perspective***
J. Bruzda

Given two signals x and y , compute the non-decimated Hilbert coefficients u and v and define

$$\text{Cov}_j(x_t, y_{t+\tau}) = u_{jt} \bar{v}_{j,t+\tau}$$

$$\text{Var}_j x_t = \text{Cov}_j(x_t, x_t)$$

$\text{Re Cov}_j(x_t, y_t)$: wavelet cospectrum

$\text{Im Cov}_j(x_t, y_t)$: wavelet quadrature spectrum

$$\text{Cor}_j(x_t, y_t) = \frac{\text{Cov}_j(x_t, y_t)}{\sqrt{\text{Var}_j x_t \text{Var}_j y_t}}$$

$|\text{Cor}_j(x_t, y_t)|^2$: wavelet coherence

$|\text{Cor}_j(x_t, y_t)|$: wavelet coherency

$\theta_j(x_t, y_t) = \arg \text{Cov}_j(x_t, y_t)$ phase spectrum

$$\tau_j(x_t, y_t) = -\theta_j(x_t, y_t) \cdot \frac{2^{j+2}}{6\pi} \quad \text{time delay}$$

$$\beta_j(x_t, y_t) = \frac{\text{Cov}_j(x_t, y_t)}{\text{Var}_j x_t}$$

$|\beta_j(x_t, y_t)|$: wavelet gain.

In R, check `waveslim::modwt.hilbert(x, "k313", 4)`.

Optimality of momentum and reversal
X.Z. He et al. (2014)

One can add momentum and reversal to a geometric

Brownian motion

$$\frac{dS}{S} = [\phi m_t + (1 - \phi) \mu_t] dt + \sigma_S dZ_S$$

$$d\mu_t = \alpha(\bar{\mu} - \mu_t)dt + \sigma_\mu dZ_\mu \quad \text{Ornstein-Uhlenbeck}$$

$$m_t = \frac{1}{\tau} \int_{t-\tau}^t \frac{dS_u}{S_u} \quad \text{Momentum}$$

and compute the optimal strategy, for a 2-asset universe (stock and bond) and an investor maximizing the expected utility of final wealth. The model can be fitted to historical data (S&P 500, monthly, 1 century).

Discounting the distant future
J.D. Farmer et al. (2014)

If the interest rate (is non-constant and) follows an Ornstein-Uhlenbeck process $dr = -\alpha(r - m)dt + k dW$, the discount factor $D(t) = E[\exp - \int_0^t r(s)ds]$ satisfies $\log D(t) \sim_{t \rightarrow \infty} (m - k^2/2\alpha^2)t$, in particular, the long-term interest rate $r_\infty = m - k^2/2\alpha^2$ is not the long-term average of the interest rate. The interest rate distribution, $r \sim N(m, k^2/2\alpha)$, does not determine r_∞ .

Independence of stock markets before and after the global financial crisis of 2007
B.M. Ibrahim and J. Brzezczński (2014)

To measure the impact of a variable z on a regression $y \sim x$, where x, y, z are time series, assume that the coefficients of the regression are AR(1) processes whose coefficients depend on Z ,

$$\begin{aligned} y_t &= (\alpha + \varepsilon_t) + (\beta + \eta_t)x_t + u_t \\ \varepsilon_{t+1} &= (a + bz_t)\varepsilon_t + v_{t+1} \\ \eta_{t+1} &= (c + dz_t)\eta_t + w_{t+1} \end{aligned}$$

For instance, x and y could be the returns in two markets and z the difference in turnover of volatility between those two markets.

An empirical investigation of methods to reduce transaction costs
T. Moorman (2014)

To reduce transaction costs, define a no-trade zone around the optimal portfolio, using some measure of distance (Euclidian, cosine, etc.) and an “optimal” threshold.

Causal dependency in extreme returns
K. Echaust

There is more long memory in return tails: look at the cross-correlation of block maxima and minima.

Option pricing with the logistic return distribution
M. Levy and H. Levy

Black Scholes option pricing formulas can be generalized to the logistic distribution (the distribution whose

cdf is the logistic function). A possible justification is that while aggregated log-returns are asymptotically Gaussian, normal market conditions are still far away from this limit.

Forecasting crashes: correlated fund flows and the skewness in stock returns
X. Gong et al. (2014)

Correlated demand for liquidity (from mutual funds) explains the negative skewness of stock returns:

- Use mutual fund holdings to estimate how much of the trading of a fund is due to liquidity shocks (inflows and outflows);
- Assume that the stock returns are linearly related to those liquidity shocks;
- Estimate the variance and skewness of the returns, conditional on the liquidity shocks;
- Decompose it into contributions of the variance, covariance, skewness, coskewness of the liquidity shocks.

Non-linear forecasting of energy futures: oil, coal and natural gas
G.G. Creamer (2014)

Use Brownian distance correlation

$$\begin{aligned} \nu(X, Y) &= \|f_X f_Y - f_{XY}\| \\ c(X, Y) &= \frac{\nu(X, Y)}{\sqrt{\nu(X)\nu(Y)}} \end{aligned}$$

as an alternative to Granger causality, and for feature selection (to build leading indicators).

Agent-based models of financial markets
E. Samanidou et al. (2007)

Clear review of a few agent-based models of financial markets:

- Rebalancers (targeting $w_{\text{cash}} = w_{\text{stock}} = \frac{1}{2}$) and CPPI investors, reviewing their portfolios (and trading) at random times, each agent estimating the “fair price” from the order book to make her decision, with random deposits and withdrawals;
- Traders with a noisy log-utility (so that the optimal weight of stock and bond is independent of wealth, up to noise), assuming the forward returns will be one of the past k returns (the look-back k is investor-dependent);
- Gamblers, $\text{wealth}_{i,t+1} = \lambda \times \text{wealth}_{i,t}$, with λ random around 1, and a welfare state ensuring $\text{wealth}_{i,t} \geq q \times \text{average wealth}$;
- *Percolation*: traders are the occupied sites on a lattice of dimension 2 to 7, clusters are groups of traders making the same decision (herding), $P[\text{buy}] = P[\text{sell}] = a$, $P[\text{sleep}] = 1 - 2a$, $\Delta \log \text{price} \propto \text{supply} - \text{demand}$; this gives the correct stylized facts, including log-periodic oscillations (if you add some rationality and hysteria);

- The supply and demand balance between noise traders and fundamentalists drives price changes, and each trader reviews her beliefs based on those price changes.

Only the last two models give credible prices.

Electricity price forecasting: a review of the state-of-the-art with a look into the future

R. Weron (2014)

Review of many methods to forecast electricity prices:

- Agent models (Nash equilibrium, multi-agent simulations);
- Jump diffusion model, Markov-switching model;
- Exponential smoothing, regression, AR, SARMA, ARX, TAR, GARCH, etc.;
- Neural nets (MLP, recurrent, fuzzy), SVM.

Financial sector tail risk and real economic activity: evidence from the option market

M. Neumann

An option-implied measure of tail risk can be computed from the price of deep OTM put options on a financial index (cheaper than it should be because of (implicit) government guarantee) and the constituents of this index.

Q-learning-based financial trading systems with applications

M. Corazza and F. Bertoluzzo (2014)

Use reinforcement learning (e.g., Q-learning) to design your automated trading systems.

TrueSkillTM: a Bayesian skill rating system

R. Herbrich et al.

Generalization of the (already Bayesian) Elo system.

Intrinsic ratings compendium

K.W. Regan (2012)

To estimate Elo ratings from moves rather than game outcomes (there are more of them):

- Compute the value of the position before and after each move (with a chess program);
- Assume $P[\text{move}] \propto p_0^{\alpha(\text{value}, \Delta\text{value})}$, where α is a function to estimate;
- Discard openings (first 8 moves), repeated positions, clearly advantageous positions;
- Estimate the Elo rating from α .

A different angle on fitting ROC curves to rating data using the first principal component

J.R. Vokey (2014)

To estimate a ROC curve from a few points, convert the p -values to a Gaussian (qnorm – the points are likely to be aligned) and take the first principal component (rather than a regression line).

From Archimedian to Liouville copulas

A.J. McNeil and J. Nešlehová

Archimedian copulas are copulas of d -dimensional ℓ_1 -norm symmetric distributions, *i.e.*, copulas of random variables $X = RS_d$, where S_d is uniform on the unit simplex $\Delta_d = \{x \in \mathbf{R}_+^d : \sum x_i = 1\}$ and R is an independent nonnegative random variable. Replacing the uniform distribution on Δ_d with a Dirichlet distribution, $P(x_1, \dots, x_n) \propto \prod x_i^{\alpha_i - 1}$ gives the (non-exchangeable) *Liouville copulas*.

An introduction to state space models

M. Wildi (2013)

Detailed presentation of state space models and the Kalman filter in R, with

- Detailed explanations of the formulas (the Kalman filter is a sequence of Bayesian updates – in particular, a prior is needed);
- The various objective functions for model estimation (look at the out-of-sample residuals $y_t = \hat{y}_{t|t-1}$, or the in-sample ones, $y_t = \hat{y}_{t|t}$, and minimize their sum of squares or their likelihood – prefer the out-of-sample maximum likelihood estimator);
- A few examples:
 - Regression, where the coefficients are the hidden state, and the covariates form the (time-changing) observation matrix;
 - Intervention studies;
 - Missing values, dealt with by skipping the observation $\hat{\xi}_{t|t} \leftarrow \hat{\xi}_{t|t-1}$;
 - Time-changing AR(1) process;
 - Decomposition into trend and SARMA components.
- Smoothing was not detailed – there are many applications in signal processing, but few/none in time series analysis.

In R, check the `dlm`, `KFAS`, `dlmodeler` packages.

Parallel Markov chain Monte Carlo

D.N. VanDerwerken and S.C. Schmidler (2013)

Use importance sampling weights to merge parallel MCMC simulations and get a consistent estimator much earlier, even in case of slow mixing (e.g., multimodal or highly correlated distributions).

Testing the equality of two positive definite matrices with applications to information matrix testing

J.S. Cho and H. White (2014)

Build a test for equality of positive definite matrices using

$$A = B \iff (\det D)^{1/k} = \frac{1}{k} \text{tr } D = 1,$$

where $D = BA^{-1}$.

***Birds of a feather flock together
Local learning of mid-level representations
for fine-grained recognition***
A. Freytag et al.

Local learning is similar to local regression, but for arbitrary machine learning algorithms: given a new observation to classify, find the k -nearest ones ($k \gg 1$), train a model on them, and use it.

***Multivariate Weibull distributions
for asset returns I***
Y. Malevergne and D. Sornette (2004)

Asset returns X can be described by a modified Weibull distribution,

$$p(x) \propto |x|^{c/2-1} \exp - \left(\frac{|x|}{\sigma} \right)^c$$

(perhaps with a different exponent c for $x > 0$ and $x < 0$), *i.e.*, some power of the returns, $\text{sign}(X)|X|^\alpha$, is Gaussian. For the correlation structure, use a Gaussian copula.

***Tweedie family densities:
methods of evaluation***
P.K. Dunn and G.K. Smyth

The Tweedie distribution is an exponential dispersion model in which the variance is some power of the expectation

$$f(y) = a(y, \phi) \exp \frac{y\theta - \kappa(\theta)}{\phi}$$

$$\text{Var } y \propto E[Y]^p.$$

Special cases include Gaussian ($p = 0$), Poisson ($p = 1$), Gamma ($p = 2$) and inverse Gaussian ($p = 3$). The pdf can be approximated by inverting the cumulant generating function (it has a simple form) or by an infinite series.

In R, check the `cplm` and `tweedie` packages.

***Series evaluation of Tweedie exponential
dispersion model densities***
P.K. Dunn and G.K. Smyth (2005)

If $Y \sim \text{ED}_p(\mu, \phi)$ follows a Tweedie distribution with $0 < p < 1$, it can be written $Y = X_1 + \dots + X_N$, with $X_i \sim \Gamma$, X_i iid, $N \sim \text{Poisson}$. When p is close to 1, the distribution is multimodal ($p = 1$ gives the Poisson distribution, which is discrete).

***Model identification
using stochastic differential equation
grey-box models in diabetes***
A.K. Duun-Henriksen et al. (2013)

A white-box model is a system of ODEs (here, pharmacokinetics) based on domain knowledge. A grey-box model is a noisy system of SDEs; it mixes

domain knowledge and data. A black-box model is entirely data-driven.

For grey-box models in R, check the `ctsm` package (SDEs with noisy measurements at discrete times, *i.e.*, non-linear Kalman filter).

***Approximate bayesian inference
for latent Gaussian models by using
integrated nested Laplace approximations***
H. Rue et al. (2009)

One can use *nested* Laplace approximations (asymptotic expansion of $\int_a^b e^{Mf(x)} dx$, when $M \rightarrow \infty$, if f has a unique maximum x_0 , using a Taylor expansion of f around x_0) to estimate posterior probabilities in latent Gaussian models.

In R, check the `INLA` package (not on CRAN).

***Non-linear causal inference
using Gaussianity measures***
D. Hernández-Lobato et al. (2014)

If x causes y (through a linear model with non-Gaussian noise), the residuals of $y \sim x$ are less Gaussian than those of $x \sim y$.

***Ranking the economic importance
of countries and industries***
W. Li et al. (2014)

Country- and sector-level imports and exports (world input-output data, www.wiod.org) defines a (weighted, directed) graph, amenable to *cascading failure tolerance analysis*: check what happens when a node fails – other nodes fail if their revenue drops by a fraction greater than $p \in [0, 1]$. The critical value p_c beyond which most nodes fail measures the centrality of the first failing node.

***Interdependencies and causalities
in coupled financial networks***
I. Vodenska et al. (2014)

To identify lead-lag relations from log-return time series, complexify the signals with a Hilbert transform; compute the “complex correlation matrix”; build a directed network using the sign of the phase of the correlation to infer the direction of the edges. One can also look at the principal components (complex PCA) and use random matrix theory (or its resampling-based equivalent, rotational random shuffling, RRS).

***SIMoNe: statistical inference
for modular networks***
J. Chiquet et al. (2008)

If you suspect your network has a modular structure, *i.e.*, the adjacency matrix has a block structure, with dense diagonal blocks and sparse off-diagonal blocks.

***Maps of random walks on complex networks
reveal community structure***

M. Roswall and C.T. Bergstrom (2008)

One can describe paths on a graph by using a Huffman code for the outgoing edges of each node – but there is a different code for each node. Instead, one can use a unique code, and encode the target nodes instead of the outgoing edges (Huffman code for the limiting distribution of a random walk on the graph). To identify clusters, use a 2-level code: each cluster has a unique name, each node has a code unique in its cluster, but reused on other clusters. The path is encoded by using the node codes, as long as it remains in the same cluster and, when it changes cluster, an exit code, the name of the cluster, and the code of the new node. The average description length is

$$P[\text{change cluster}]H[\text{cluster codes}] + \sum_{\text{cluster}} P[\text{same cluster}]H[\text{node codes in that cluster}]$$

where H is the entropy.

To find the optimal partition into clusters, use a greedy agglomerative algorithm, and refine with simulated annealing. Contrary to other clustering algorithms, the edge weights are used. By adding teleportation (à la PageRank), the algorithm can also deal with directed graphs.

***Online community detection
for large complex networks***
G. Pan et al. (2014)

To estimate communities online, do not optimize the modularity, but the expected modularity, for some generative model, e.g.:

- Link a new node to a community C with probability proportional to $\deg C$;
- Link two nodes in communities C and C' with probability proportional to $\deg C \times \deg C'$.

***Nowcasting economic and social data:
when and why search engine data fails,
an illustration using Google flu trends***
P. Ormerod et al. (2014)

Search engine data (e.g., Google flu) is less reliable when social influence is high: the *Bass diffusion model* (fitted between the two low points on both sides of a peak) can help distinguish between independently-motivated and socially-motivated searches.

***Do we need hundreds of classifiers
to solve real-world classification problems?***
M. Fernández-Delgado et al. (2014)

Comparison of 179 classifiers (the output is binary), in R, Weka, C, Matlab (no Python) on 121 datasets: prefer random forests and SVM, but do not reject neural networks, boosting, C5.0, avNNet (caret) or ELM (extreme learning machines).

***Generating abbreviations
using Google Books library***

V.D. Solovyev and V.V. Bochkarev

Abbreviations are prefixes (or substrings) with the same context.

***Improved part-of-speech tagging for online
conversational text with word clusters***
O. Owoputi et al. (2013)

TweetNLP is a POS tagger for twitterese; it uses a hidden Markov model (HMM) with Brown clustering to recognize new words and alternate spellings.

***Selecting influential examples: active learning
with expected model output changes***
A. Freytag et al.

Active learning refers to the algorithms used to decide which unlabeled samples to label next (when labeling is costly and online), *i.e.*, which sample is the most informative. Strategies include:

- Rapid exploration: prefer samples far away from already-labeled ones – but this gives too much emphasis on outliers;
- Maximum uncertainty: label the samples the model is the most uncertain about;
- Maximize the expected model change;
- Reduce the estimated classification error (expected entropy minimization);
- Maximize the expected model output change (EMOC).

Logarithmic-time online multiclass prediction
A. Choromanska and J. Langford (2014)

For multiclass classification problems with a large number of classes, arrange the classes in a logarithmic-depth tree, either:

- Known in advance;
- Constructed using class frequencies (Huffman coding);
- Constructed online, recycling orphan nodes when needed.

Model compression
C. Bucilă et al. (2006)

To compress an ensemble of thousands of models into a simpler, smaller model, fit the smaller model on the forecasts of the complicated model on a large set of unlabeled examples. If there is no such set, use a synthetic one: add noise to each feature of existing observations, where the amplitude of the noise is the distance to the closest observation (for qualitative variables, replace the value with that of the nearest neighbour with probability p).

Do deep nets really need to be deep?

L.J. Ba and R. Caruana (2014)

Shallow neural networks are as expressive as deep ones:

- Learn a deep model;
- Use it to create a huge synthetic training set from unlabeled data;
- Train a shallow model on the synthetic dataset (to speed things up, use a low-rank approximation of the weight matrix).

Towards automated discovery of artistic influence

B. Saleh et al. (2014)

Linguistic models can be used with non-text data: for instance, one can use topic models (latent Dirichlet analysis, LDA) on images, by replacing the words with image features (first identified by the Laplace Harris detector, then reduced to a set of 600 features (“words”) using k -means).

Memory networks

J. Weston et al. (2014)

One can combine neural networks with a memory component:

- Convert the input to features;
- Store them in memory (more generally, update the memory from the input features and the current memory);
- Predict the output features from the memory and the input text;
- Generate the output from the output features.

The various components can use your favourite machine learning algorithm (SVN, decision tree, neural net, etc.). The idea can be used on text data, using a bag-of-words approach, e.g., to answer questions about a story (store the raw input, verbatim, sequentially, time-stamped, in memory; compute the memory m_1 “closest” to the input question; compute the memory m_2 closest to both the input and m_1 and with $m_1 \prec m_2$; output a single word).

Modeling interestingness with deep neural networks

J. Gao et al. (2014)

Use a deep neural net, with a convolutional and a max-pooling layer (often used in image processing) to model text; train it to forecast followed links, *i.e.*, $f(\text{text}_1, \text{text}_2) = 1$ if text_2 was read after text_1 .

Understanding locally competitive networks

R.K. Srivastava et al.

Visualizing the nodes of a neural network with rectified linear units (RLU, ) , maxout (output the maximum of the inputs) or local winner takes all (in a group of nodes, the maximum passes its input unchanged, but the others output 0) (these are often trained with

droupout) suggest that the nodes cluster – only part of the network is activated for any given input pattern.

Political ideology detection using recursive neural networks

M. Iyyer et al.

A **recursive neural net** (RNN) is a model that

- Uses a vector representation of the words in the sentence (initialize it with word2vec);
- Combines them, along the parse tree of the sentence (all nodes share the same parameters);
- And outputs the predicted class (here, liberal vs conservative) using a softmax.

Efficient programmable learning to search

H. Daumé III et al. (2014)

In structured prediction, the search space can be described by an arbitrary imperative program (or a grammar).

Software to model sequence data (segmentation, tagging in NLP): CRF++, crfsgd, VW.

Dropout: a simple way to prevent neural networks from overfitting

N. Srivastava et al. (2014)

When iteratively training a neural net (e.g., with stochastic gradient descent, SGD), forget (drop) a random subset of the nodes at each iteration (and update this smaller set). The resulting neural net can be seen as an ensemble of (all the) 2^n sparser subnets.

This can be interpreted as the addition of noise to the hidden nodes; this noise can be integrated out to compute the gradient (for regression, this is similar to ridge regression).

Monte Carlo non-local means: random sampling for large-scale image filtering

S.H. Chan et al. (2013)

To denoise a pixel i in an image, take the weighted average of the pixels j , $\sum_j w_{ij} x_j$, where w_{ij} measures the similarity of the regions around i and j (non-local means, NLM); the pixels j can be from the same image or from an image database. To speed up the algorithm, consider:

- Only looking at pixels j close to i ;
- Dimension reduction (SVD);
- Effective data structures (kd-trees);
- A low rank approximation of the weight matrix W ;
- Random sampling.

Modeling the shape of the scene: a holistic representation of the spatial envelope

A. Oliva and A. Torralba (2000)

It is possible to recognize scenes by looking at their texture and structure, without any segmentation (GIST descriptors):

- Presence of textured zones;
- Undulating contours;
- Uncluttered horizon line;
- Size of the major components;
- How straight the horizon line is;
- Parallels and perpendiculars;
- Converging lines.

***Evaluation of GIST descriptors
for web-scale image search***
M. Douze et al. (2009)

Useful for duplicated image search.

***Random search
for hyper-parameter optimization***
J. Bergstra and Y. Bengio (2012)

Avoid grid search for hyper-parameter optimization: if some of the directions are irrelevant, random search (or a low discrepancy sequence) performs better.

Freeze-thaw bayesian optimization
K. Swersky et al. (2014)

Bayesian optimization searches the (global) minimum of an expensive, noisy function (over $[0, 1]^D$). The function is often modeled as a Gaussian process (GP). To choose the next point on which to evaluate the function, one can use:

- The point that gives the best expected improvement

$$a_{EI}(x) = (f(x_{\text{best}}) - \mu(x))_+$$

(where the positive part is smoothed – they do not use $u_+ \approx \log(1 + e^u)$, but $u_+ \approx u\Phi(u) + \phi(u)$ – and the smoothing is larger when the variance $V(x)$ is large);

- The point that reduces the expected uncertainty about the location of the minimum the most (entropy search).

It is actually not needed to precisely estimate the function at each point: one can stop early (freeze), estimate the limiting value (by assuming exponential convergence – this is not unlike the classical series acceleration techniques) and, at each iteration, decide to either explore a new point, or continue (thaw) the computations for a frozen point.

For bayesian optimization in Python, check HIPS/spearmint.

***MA-SW-Chains: memetic algorithm
based on local search chains
for large scale continuous global optimization***
D. Molina et al. (2010)

A memetic algorithm is an evolutionary algorithm, hybridized with local search. The chains refer to the fact that the local search is not run until the end, but just a few more steps at each generation.

***Approximate bayesian computation
and particle filters***
D. Prangle (2014)

Maximum likelihood estimation can still be used when the likelihood is not computable:

- Simulate data y_{sim} for many values of the parameter θ ;
- Select the θ for which y_{sim} and y_{obs} are the closest (instead of using all of y , you can use some summary statistic).

In a bayesian framework, this likelihood-free method becomes “approximate bayesian computation” (ABC):

Repeat N times:

- Draw θ from the prior
- Draw $y_{\text{sim}}|\theta$ from the model
- Accept θ if $d(y_{\text{sim}}, y_{\text{obs}}) < \varepsilon$.

To avoid degeneracy (no samples accepted), repeat until there are M samples (alive ABC).

Adding noise makes the estimate consistent (noisy ABC).

For state space models, one can start with a *particle filter*

$t = 1$

Sample $x^{(i)}$ from the prior

$w^{(i)} \propto \text{likelihood}(y_t^{\text{obs}}|x^{(i)})$

Increment t , resample, propagate the particles

and replace the likelihood

$$\begin{aligned} &\text{Simulate } y^{(i)}|x^{(i)}, \theta \\ &w^{(i)} = \mathbf{1}_{d(y_t^{\text{obs}}, y^{(i)}) < \varepsilon} \end{aligned}$$

***Accurate methods
for approximate bayesian computation filtering***
L. Calvet and V. Czellar (2012)

In the ABC particle filter

$$p_t^{(n)} \propto \mathbf{1}_{d(\tilde{y}_t^{(n)}, y_t) < \varepsilon},$$

where y is the data and \tilde{y} is the data sampled from the model (N samples), choosing ε is akin to selecting the bandwidth of a kernel density estimator (this guarantees $\varepsilon \xrightarrow[N \rightarrow \infty]{} 0$).

Relevant statistics for Bayesian model choice
J.M. Marin et al. (2013)

The choice of a (non-sufficient) summary statistic T (i.e., using $\pi(\theta|T(y))$ instead of $\pi(\theta|y)$, where θ =model, y =data, T =summary statistic) in bayesian statistics (in particular ABC) leads to incorrect Bayes factors, and therefore incorrect model selection. Under some conditions on the summary statistics, the Bayes factor is asymptotically correct.

Bayesian computation via empirical likelihood
K.L. Mengersen et al. (2012)

The *empirical likelihood* (in R, `empLik`) is an alternative to approximate bayesian computations (ABC): given a set of equations uniquely determining the parameters of interest θ , $E[h(y, \theta)] = 0$, let

$$L_{\text{el}} = \text{Max} \left\{ \prod_i p_i : p \in [0, 1]^n, \sum p_i = 1, \sum p_i h(y_i, \theta) = 0 \right\}.$$

Multidimensional scaling using majorization: SMACOF in R
J. de Leeuw and P. Mair

To find the minimum of a function f , *majorization* suggests to find a simpler function g such that

$$\begin{aligned} \forall x, y \quad g(x, y) &\geq f(x) \\ \forall y \quad g(y, y) &= f(y) \end{aligned}$$

and iterate $x_{n+1} = \text{Argmin}_x g(x, x_n)$.

Multi-dimensional scaling (MDS) is the problem

$$\text{Argmin}_{x_1, \dots, x_n} \sum_{ij} w_{ij} (\delta_{ij} - \|x_i - x_j\|)^2;$$

the objective function can be written

$$\begin{aligned} \sigma(X) &= 1 + \text{tr } X' V X - 2 \text{tr } X' B(X) X \\ &\geq 1 + \text{tr } X' V X - 2 \text{tr } X' B(X) Y \end{aligned}$$

(the rhs is now a quadratic function).

Variants include:

- Several dissimilarity matrices;
- Linear constraints (they can be formulated as a reparametrization: find C to minimize $\sigma(ZC)$, with Z known);
- Rectangular matrices: given a judge×object rating matrix, find coordinates for both judges and items in the same space – this is a special case of the previous setup, with weights $W = \begin{pmatrix} 0 & * \\ * & 0 \end{pmatrix}$;
- Non-metric MDS:

$$\text{Argmin}_{\substack{X, f \\ f \text{ non-decreasing}}} \sum_{ij} w_{ij} (f(\delta_{ij}) - \|x_i - x_j\|)^2,$$

the estimate of f changes at each step, and is obtained by *monotone regression* (aka *isotonic regression*)

- MDS on quadratic surfaces (mostly spheres).

Hierarchical k-means clustering
A. Böcker et al. (2004)

The hierarchical k -means algorithm is a sequence of k -means invocations:

- Start with the mean;
- Split all the centroids in two, add noise, and start the k -means algorithm with these centroids;
- Iterate until the number of centroids equals the number of points.

Clustering with Bregman divergences
A. Banerjee et al. (2005)

The k -means algorithm (of the k -medoid one – the cluster centers are chosen among the data points) can be generalized to other distances or divergences. The *Bregman divergence* associated to a convex function $\phi : S \rightarrow \mathbf{R}$, with $S \subset \mathbf{R}^n$, is

$$d_\phi(x, y) = \phi(x) - \phi(y) - \langle x - y, \nabla \phi(y) \rangle.$$

Examples include $\phi(x) = \|x\|^2$, for the Euclidian distance; $\phi(x) = \sum x_i \log x_i$, for the Kullback-Leibler divergence on the simplex $S = [\sum x_i = 1, \forall i \ x_i \geq 0]$; $\phi(x) = -\log x$, for the Itakura-Saito distance,

$$D(p, q) = \sum_i \left(\frac{p_i}{q_i} - \log \frac{p_i}{q_i} - 1 \right).$$

Itakura-Saito nonnegative matrix factorization and friends for music signal decomposition
C. Févotte (2012)

The β -divergence,

$$d_\beta(x|y) = \frac{1}{\beta(\beta-1)} (x^\beta + (\beta-1)y^\beta - \beta xy^{\beta-1}),$$

which specialized to the Euclidian distance ($\beta = 2$), the Kullback-Leibler divergence ($\beta = 1$) or the Itakura-Saito divergence ($\beta = 0$, non-convex, but scale-invariant) is a popular cost function in nonnegative matrix factorization (NMF). It is non-convex in general, but can be optimized by majorization-minimization (MM) by majorizing the convex and concave parts separately (using Jensen's inequality and the tangent, respectively). IS divergence NMF is actually a maximum likelihood estimator for a generative model of the short-term Fourier transform (STFT) of the signal.

In music, NMF can recover instruments and notes.

***On the surprising behavior of distance metrics
in high-dimensional space***
C.C. Aggarwal et al. (2009)

The curse of dimensionality states that, in high dimensions, the closest point and the farthest point are approximately at the same distance. A study of the asymptotic behaviour of

$$\frac{\max_{1 \leq i \leq n} \|X_i\|_{L^k}}{\min_{1 \leq i \leq n} \|X_i\|_{L^k}}$$

as the dimension d tends to infinity suggests that the situation is worse if k is large. Prefer the L^1 distance or, even better, the L^k semi-metric for $k \in (0, 1)$. It is not a metric – it does not satisfy the triangle inequality – but, for algorithmic purposes (e.g., to look for the k nearest neighbours), it is usually fine.

***Feature selection strategies for classifying
high-dimensional astronomical data sets***
C. Donalek et al.

Algorithms to select features include:

- Fast relief: compare the distribution of $f(\text{nearest hit}) - f(x_0)$ and $f(\text{nearest miss}) - f(x_0)$;
- Fisher discriminant ratio: $\text{FDR} = \left(\frac{\mu_1 - \mu_2}{\sigma_1/\sigma_2} \right)^2$;
- Correlation-based feature selection: find a subset of the variables with low correlation between themselves and high correlation with the target;
- Least angle regression.

***Distribution's template estimate
with Wasserstein metrics***
E. Boissard et al. (2013)

The notion of mean (and barycenter) can be generalized to arbitrary metric spaces,

$$(x_1, \dots, x_n) = \underset{\mu}{\text{Argmin}} \sum_i d(\mu, x_i)^2,$$

but unicity, or even existence, is not guaranteed in general. Given a metric measurable space (E, d, Ω) , the Wasserstein distance between two probability measures μ and ν on E is

$$d(\mu, \nu)^2 = \inf_{\substack{m \text{ measure on } E \times E \\ \text{pr}_1 m = \mu \\ \text{pr}_2 m = \nu}} \int_{E \times E} d(x, y) m(dx, dy).$$

If $E = \mathbf{R}^n$ and μ is absolutely continuous wrt the Lebesgue measure, there exists $T : \mathbf{R}^n \rightarrow \mathbf{R}^n$ (Brenier map) such that $\nu = T * \mu$ and

$$d(\mu, \nu) = \int |T(x) - x|^2 \mu(dx).$$

It measures the deformation needed to transform μ into ν and can be used to compute barycenters.

***Item response models
to measure corporate social responsibility***
N. marco et al. (2013)

To combine several signals into one (here, various CSR measures, provided by KLD – now MSCI ESG), one can use:

- Equal weights;
- Weights reflecting stakeholders' preferences;
- Data envelopment analysis (DEA – the weights are company-specific and determined by the data);
- The first principal component, from PCA, ICA, NMF, etc. [not mentioned];
- Item response theory (IRT): this automatically identifies the offset for each variable and how discriminative they are.

***Measuring corporate social performance:
an efficiency perspective***
C.M. Chen and M. Delmas (2010)

Data envelopment analysis (DEA) is a way of measuring the distance (of a firm) from the efficient frontier (of its peers). Let i denote companies, k the measures to be maximized (profit, etc.), x_{ki} the value of measure k for firm i , $F = \{i : \forall j \exists k x_{ki} \geq x_{kj}\}$ the efficient frontier. The aggregated score for company i is $\sum_k \lambda_{ki} x_{ki}$, where the optimal weights are

$$\lambda_{\cdot i} = \underset{\substack{\lambda_{\cdot i} \\ \lambda \geq 0 \\ \sum_k \lambda_{ki} = 1}}{\text{Argmin}} \max_{j \in F} \sum_k \lambda_{ki} (x_{kj} - x_{xi}).$$

Traditionnaly, DEA separates the measures into inputs x_{ki} (to be minimized) and outputs x_{kj} (to be maximized):

$$\begin{aligned} \text{Find} & \quad \lambda_{\cdot i}, \mu_{\cdot i} \\ \text{To maximize} & \quad \sum_{\ell} \mu_{\ell i} y_{\ell i} / \sum_k \lambda_{ki} x_{ki} \\ \text{Such that} & \quad \forall j \quad \sum_{\ell} \mu_{\ell i} y_{\ell j} / \sum_k \lambda_{ki} x_{kj} \leq 1 \\ \text{and} & \quad \lambda, \mu \geq 0. \end{aligned}$$

(To make the program linear, rescale it by adding the constraint $\sum_k \lambda_{ki} x_{xi} = 1$.)

The ratio $\sum_{\ell} \mu_{\ell i} y_{\ell i} / \sum_k \lambda_{ki} x_{ki}$ is the efficiency of the firm; it is 1 iff it is on the efficient frontier.

The article uses an extension of DEA to ordinal variables to aggregate corporate social responsibility measures.

[Would the bootstrap help give more stable results?]

***Non-linear shrinkage of the covariance matrix
for portfolio selection:
Markowitz meets Goldilocks***
O. Ledoit and M. Wolf (2014)

Linear shrinkage estimates a covariance matrix as $(1 - \lambda)V + \lambda I$, where V is the sample variance matrix

and λ is chosen to minimize some loss function. The loss function could be the asymptotic Frobenius distance between the estimator and the population variance (the population variance is not known but, to compute the *asymptotic* distribution, we do not need all of it: the eigenvalues actually suffice). In a financial context, one can minimize the variance of the tangential portfolio: the results turn out to be similar.

Instead of letting just one parameter vary, one can let $O(N)$ parameters vary, e.g., the eigenvalues of the sample covariance matrix.

The estimator is defined as follows:

$c = N/T$ concentration
 $V = U\Lambda U'$ sample covariance matrix
 $\lambda_1, \dots, \lambda_n$ eigenvalues of V
 τ_1, \dots, τ_n eigenvalues of the population variance

$s(x) \in \mathbf{R} \cup \mathbf{C}^+$ solution of $s^{-1} = \frac{1}{T} \sum_{i=1}^N \frac{\tau_i}{1 + \tau_i s} - x$

$d_i = \frac{1}{\lambda_i s(\lambda_i)}$ new eigenvalues

$D = \text{diag}(d_1, \dots, d_n)$

$S = UDU'$ desired estimator.

The population eigenvalues can be estimated by discretizing the relation between the asymptotic empirical distribution function H of the population eigenvalues and that, F , of the sample eigenvalues: for all $x \in \mathbf{C}^+$, the Stieltjes transform of F ,

$$s = \int \frac{dF(\lambda)}{\lambda - z}$$

is determined by

$$-\frac{1-c}{z} + cs \in \mathbf{C}^+ \\ s = \int \frac{dH(\tau)}{\tau(1-c-czs) - z}.$$

Linear vs quadratic portfolio selection models in practice F. Cesarone et al.

The standard quadratic programming problem

Find $x \in \mathbf{R}^n$
 To minimize $f(x) = x'Qx$
 Such that $x \geq 0, x'1 = 1$

can be solved efficiently with the *increasing set* algorithm. The minimum is attained in the relative interior of a face where f is strictly convex; furthermore, there is an increasing sequence of faces $F_1 \subset F_2 \subset \dots \subset F_k$, $\dim F_i = i$, on which f is strictly convex, has an interior global minimizer x_i^* and $x^* = x_k^*$. The algorithm looks at all possible faces of dimension 1 satisfying the conditions, and tries to extend them (breadth-first).

For cardinality-constrained problems, that is even easier: stop early.

This can be used to find cardinality-constrained minimum variance portfolios.

Premium indexation: CVaR-lasso optimal index replication Y.J. Jin and X. Zhong (2014)

To replicate an index, use CVaR optimization rather than mean-variance and add an L^1 constraint (the authors suggest a hard constraint, $\sum_i |w_i| \leq 2$) to control the number of stocks in the replicating portfolio.

Portfolio selection under directional predictability of returns J. Hämäläinen (2014)

Forecasting return signs is easier than forecasting returns, and the signs can still be used in a mean-variance optimization: the retrun distributions can be computed using

- Sign forecasts, s_i for sign X_i ;
- The probability that they are correct, $p_i = P[\text{sign } X_i = s_i]$;
- The probability that they are jointly correct or incorrect, $p_{ij} = P[(\text{sign } X_i)(\text{sign } X_j) = s_i s_j]$.

Diversification management of a multi-asset portfolio M. Poonia (2014)

Comparison of various notions of diversification: number of stocks, diversification ratio, risk parity, PCA risk diversification, torsion bets.

Conditional Sharpe ratios K.V. Chow and W.C. Lai

When computing the Sharpe ratio, replace the excess returns by 0 unless the benchmark returns are below their α quantile.

Portfolio choice in the presence of estimation error: a pricing model filter approach M. Lozano (2014)

Use the sample covariance matrix of the CAPM (or some factor model) residuals.

Sparse and robust normal and t-portfolios by penalized Lq likelihood minimization D. Ferrari et al. (2014)

The lasso can be generalized to

$$\hat{\beta} = \underset{\beta, \mu, \sigma}{\text{Argmin}} - \sum_{i=1}^n L_q f \frac{x_i' \beta - \mu}{\sigma} - \sum_{j=1}^p L_p \pi(\beta_j, \lambda)$$

where

x_i = observations

f = Gaussian distribution (for instance)

L_q = generalized logarithm,

$$L_q(z) = \begin{cases} \frac{z^{q-1} - 1}{1 - q} & \text{if } q \neq 1 \\ \log z & \text{if } q = 1 \end{cases}$$

π = prior on the parameters, e.g., Laplace,

$$\pi(\beta, \lambda) = \lambda e^{-\lambda|\beta|/2}.$$

The lasso is obtained for $q = 1$, π = Laplace, f = Gaussian.

***Portfolio spillovers
and a limit to diversification***
B. Argyle (2013)

After a sharp price change to a stock, investors holding the stock will rebalance their portfolio, but not necessarily by buying/selling this stock – it may be easier, faster to buy/sell more liquid assets. In the case of large institutional investors, and/or many investors holding a similar portfolio, there could be a price impact to those other stocks: can we detect it?

***Dynamic portfolio selection
by augmenting the asset space***
M.W. Brandt and P. Santa-Clara (2006)

To compute an (approximately) optimal dynamic asset allocation when all you can do is compute static asset allocations (Markowitz portfolio optimization), just add a few managed portfolios (e.g., weights proportional to some factor) to your universe of assets, and compute the corresponding “static” optimal portfolio. Use a VAR model if you end up with too many assets.

Tilt Nickel to Diamond
G. Xiang and T. Yu (2014)

Take a set of risk factors (Fama-French, Carhart, etc.) and a set of alpha factors. Starting with a capital-weighted portfolio (or some other benchmark), increase the exposure to the alpha factors while keeping the exposure to the risk factors close to zero.

***The deflated Sharpe ratio: correcting
for selection bias and backtest overfitting***
M. López de Prado (2014)

When computing the Sharpe ratio of the best strategy in your backtests, you can account for multiple testing and non-Gaussian returns as follows:

- Estimate the return distribution,
 $X_{it} \sim F(\mu, \sigma, s, \kappa)$ iid;
- Estimate the corresponding distribution of the (sample) Sharpe ratios S_i ;
- Estimate the distribution of the best one, $\max_{1 \leq i \leq n} S_i$;

- Convert the best Sharpe ratio into a p -value, using this distribution;
- Convert the p -value into a z -score – a deflated Sharpe ratio.

The independence assumption is unrealistic, in this context: when backtesting many strategies, they are often just variants of the same idea, so their returns are very similar.

Evaluating trading strategies
C.R. Harvey and Y. Liu (2014)

To compare several strategies, take multiple testing into account:

- FWER (family-wise error rate, e.g., Bonferroni or Holm correction) is often too conservative;
- FDR (false discovery rate, e.g., BHY correction) gives more usable results.

The discussion is needlessly complicated by the use of T values instead of p -values.

In R check `bonferroni`, `holm`, `BY`, in the `mutoss` package.

Optimal asset pricing
R. Turner et al. (2014)

Asset selling (sometimes called “asset pricing”) studies the optimal price of a perishable asset (airline ticket, hotel room, TV advertising slots) for which customers arrive randomly (inhomogeneous Poisson process) with (known) decreasing price elasticity (they are less and less price-sensitive as time passes).

Pricing policy $x_q(t)$ (price of the asset at time t if there are still q in inventory) and expected revenue $v_q(t)$ are related by a system of ODEs. For the optimal policy, just add

$$\frac{\partial R_q(x, t)}{\partial x} = 0,$$

where $R_q(x, t)$ is the expected revenue if a customer arrives at time t and is quoted price x .

Disentangling rebalancing return
W.G. Hallerbach (2014)

The “rebalancing return”, *i.e.*, the difference between a rebalanced portfolio and a buy-and-hold portfolio, can be decomposed into a volatility return (“volatility harvesting”) and a “dispersion discount” (a negative contribution), coming from the dispersion between the growth rate $\mu_i - \frac{1}{2}\sigma_i$ of the assets.

***Signal-wise performance attribution
for constrained portfolio optimization***
B. Durin (2014)

One can decompose the performance of a constrained portfolio built from several signals into the contribution of each signal and that of the constraints (with no residual term).

***Learning bayesian networks in R:
an example in systems biology***
M. Scutari (UseR 2013)

The **bnlearn** package can learn the structure of a Gaussian or discrete bayesian network, using

- Constraint-based algorithms (incremental association), that perform tests of conditional independence (mutual information, χ^2 , partial correlation);
- Score-based algorithms, that maximize (hill-climbing, tabu search) the goodness of fit (likelihood, AIC, BIC, Dirichlet posterior density, etc.) of the network;
- Hybrid algorithms, local search using statistical tests to define the neighbourhoods.

If the data is continuous but non-Gaussian, one can discretize it with *Hartemink's method*: discretize each variable into 60 quantile bins, collapse them while reducing the mutual information as little as possible, stop when each variable has 3 levels (low, average, high).

The **deal**, **catnet**, **pcalg** packages can also learn the graph structure, and some even accept mixed data (but each only provides one algorithm). All those packages can also fit the model parameters. For inference, use **gRain** (fast) or **bnlearn** (flexible).

Bootstrap can improve the stability of the result.

To model *interventions*, either whitelist all the edges from the intervention node, or blacklist all the edges to the intervention node.

```
b <- boot.strength(d, R=200, algorithm="hc")
g <- averaged.network(b, threshold=.85)
plot(cpdag(g)) # Remove ambiguous directions
```

***Learning bayesian networks
with the bnlearn R package***
M. Scutari (JSS, 2010)

More (but terse) details about the underlying algorithms, tests and scores.

***Bayesian networks in R
with applications in systems biology***
R. Nagarajan et al. (2013).

After a chapter on **bnlearn** (see the presentation above for a more thorough exposition), the book reviews, the book quickly presents dynamic networks. VAR models can be represented as dynamic bayesian networks (DBN), and estimated using shrinkage (**GeneNet**), lasso (**var**, **lars**, **glmnet**, **penalized**), low order independencies (**G1DBN**), change point models (**ARTIVA**), modular assumptions (**simone**).

The inference chapter names the main algorithms (variable elimination, junction trees, particle methods), with few details, and gives examples with **gRain** (**setFinding**, **querygrain**) and **bnlearn** (**cpdist**, **cpquery**).

***Inferring dynamic genetic networks
with low order independencies***
S. Lèbre (2009)

The structure of undirected Bayesian networks (random Markov fields) can be estimated from the partial correlation (which can be computed from the inverse of the correlation matrix, or from regressions): add an edge between i and j if $\text{pCor}(X_i, X_j) \neq 0$.

When there are not enough observations ($p \gg n$), one can use a shrinkage estimator (e.g., replace the correlation matrix C with $(1 - \lambda)C + \lambda I$ to make it invertible, or use a Lasso regression), or the first order partial correlation: add an edge between i and j if $\text{Cor}(X_i, X_j) \neq 0$ and $\forall k \neq i, j, \text{Cor}(X_i, X_j | X_k) \neq 0$ (the 0th order partial correlation is the correlation, the $(q+1)$ st order partial independence graph is a subgraph of the q th).

This can be used to infer the structure of *dynamic bayesian networks* (DBN). There is an implementation in the **G1DBN** R package.

***Inferring causal impact
using bayesian structural time-series models***
K.H. Brodersen et al. (2014)

To measure the effect of an intervention on a time series y_t , the difference-in-difference approach just compares

$$y_{\text{after}} - y_{\text{before}} \mid \text{intervention}$$

with

$$y_{\text{after}} - y_{\text{before}} \mid \text{no intervention,}$$

ignoring time series dynamics. Instead, one can model the time series, before the intervention, with a state space model, including a linear trend (whose slope is a random walk or a mean-reverting time series), seasonality, and covariates with dynamic coefficients. A *spike-and-slab* prior  provides automated variable selection. This is implemented in the **CausalImpact** R package, and used for A/B testing.

***Credit risk spillovers among financial
institutions around the global credit crisis:
firm-level evidence***
J. Yang and Y. Zhou (2013)

To study spillover risk, fit a VAR model to the data, and perform a “DAG analysis” on (the correlation matrix of) the residuals, *i.e.*, fit a bayesian network, and check if the direction of the edges is well-defined.

Reducing bias through directed acyclic graphs
I. Shrier and R.W. Platt (2008)

Identifying causal relations in observational data is tricky. Introducing a confounding variable in the regression can reduce or increase the bias, e.g.,

Real world causal networks are more complicated. If the DAG is known, one can find whether the variable will increase or decrease the bias as follows: the co-variables should not be descendants of X ; keep only ancestors of X , Y or Z ; delete arcs leaving X ; moralize, convert to undirected; delete Z ; if X and Y are no longer connected, then Z can be used as a confounder in $Y \sim X$.

There are potential problems: the DAG need not be known (consider all DAG candidates), or may be incomplete; the method does not account for synergistic or antagonistic actions.

***Causal diagrams for epidemiologic research*
S. Greenland et al. (1999)**

Earlier article on the same topic.

***Using directed acyclic graphs to guide analyses of neighbour health effects: an introduction*
N.L. Fleischer and A.V. Diez Roux (2008)**

Algorithms to decide whether a set of confounders is sufficient, necessary, minimally sufficient.

For implementations, check: DAGitty (browser-based), Tetrad (Java) or dagR (undocumented).

***Adjustment criteria in causal diagrams: an algorithmic perspective*
J. Textor and M. Liškiewicz (2011)**

Efficient algorithm.

***A tool for filtering information in complex systems*
M. Tumminello et al. (2005)**

The minimum spanning tree (take the edges one by one, starting with the most important ones, and keep them if they do not introduce a loop) discards too much information: instead of looking for an acyclic graph, one can look for planar graphs (giving the “planar maximally filtered graph”, PMFG) or, more generally, graphs of genus g . Instead of highlighting edges, this highlights 3- and 4-cliques,  and .

***Spread of risk across financial markets: better to invest in the peripheries*
F. Pozzi et al. (2013)**

Stocks in the periphery of the minimum spanning tree (MST) or the planar maximally filtered graph (PMFG) provide more diversification benefit. Those graphs can be used to represent the contents of a portfolio. Try a long-short strategy, periphery vs center, with minimum variance portfolios on each side, using the following measures of centrality: degree, betweenness, eccentricity, closeness, eigenvector centrality.

`import sage.graphs.genus`

To compute the genus of a graph $G = (V, E)$, consider all possible *combinatorial embeddings*, i.e., all possible cyclic orderings at each vertex. Formally, a combinatorial embedding is an action of the free group $\mathbf{Z} * \mathbf{Z} = \langle v, e \rangle$ on the set of half-edges, with the orbits for $\langle v \rangle$ corresponding to the vertices and those for $\langle e \rangle$, to the edges (e is an involution). The genus of the embedding is given by $2 - 2g = V - E + F$, where V , E and F are the number of orbits for v , e and ve .

***Determining the genus of a graph*
A. Perez (2009)**

A graph is planar iff it does not contain (a subdivision of) $K_5 = \star$ or $K_{3,3} = \bowtie$ (Kuratowski theorem).

The *genus* of a graph is the minimum g such that the graph can be embedded in a surface of genus g .

The *maximum genus* of a graph is the maximum g such that the graph can be embedded in a surface of genus g and, cutting the surface along the graph gives 2-cells, i.e., pieces homeomorphic to the open disk.

***The use of correlation networks in parametric portfolio policies*
H. Lohre et al. (2014)**

Nothing new: the authors suggest to look at the minimum spanning tree (MST) built from the correlation matrix of stock or sector returns, and look at graph metrics such as

- The graph diameter (a small stock network diameter, or a *large* sector network diameter, is a sign of market instability);
- The betweenness centrality, which can be used in a parametric portfolio (a parametric portfolio is a portfolio whose weights are a linear combination of some investment signals: since only the coefficients have to be estimated, the quadratic optimization problem is much simpler).

***Finding community structure in very large networks*
A. Clauset et al.**

To find communities in a graph, one can use a greedy agglomerative algorithm: start with each node in its own cluster; merge the two clusters that produce the largest increase in modularity (the *modularity* is the difference between the fraction of edges inside clusters and the expected fraction); iterate. Instead of keeping track of the adjacency matrix A_{ij} as you merge the clusters (it is sparse, but finding the pair that increases the modularity the most creates dense matrices), keep track of ΔQ_{ij} , the increase in modularity if we merge i and j .

***Quadrature rule-based bounds for functions of adjacent matrices*
M. Benzi and P. Boito (2010)**

Many graph metrics can be computed using matrix functions (often, the exponential) and the adjacency matrix A , e.g.:

- Degree;
- Subgraph centrality of a node i : $[e^A]_{ii}$;
- Estrada index, $EE(G) = \sum e^{\lambda_k} = \text{tr } e^A$;
- Communicability between i and j , $[e^A]_{ij}$; average communicability from i ;
- Communicability betweenness of k :

$$\sum_{ijk \text{ different}} \frac{[e^A]_{ij} - [e^{A-E_k}]_{ij}}{[e^A]_{ij}}$$

where E_k is the adjacency matrix of the graph without the edges linked to node k ;

- Resolvent subgraph centrality, etc.: replace e^x with

$$f(x) = \left(1 - \frac{x}{N-1}\right)^{-1}.$$

They can be estimated by Gaussian quadrature (*i.e.*, $\int_{-1}^1 f(x)dx \approx \sum w_i f(x_i)$; choose n and w_i ; compute the optimal x_i).

Ranking hubs and authorities using matrix functions M. Benzi et al.

Graph metrics defined by matrix functions applied to the adjacency matrix A can be generalized to directed graphs by considering the undirected bipartite graph $\begin{pmatrix} 0 & A \\ A' & 0 \end{pmatrix}$. The node metrics then have two variants: the hub and authority ones.

Functions of matrices N.J. Higham (2005)

A complex function f can be evaluated on a matrix A as follows.

- If $f(z) = \sum a_n z^n$ has convergence radius R , and $\text{Spec } A \subset B(0, R)$, then $f(A) = \sum a_n A^n$.
- If f is \mathcal{C}^∞ on a neighbourhood of $\text{Spec } A$, and $Z^{-1}AZ = \text{diag}(J_1, \dots, J_p)$ is the Jordan decomposition of A , then $f(A) = Z \text{diag}(f(J_1), \dots, f(J_p))Z^{-1}$, where

$$J_k = \begin{pmatrix} \lambda & 1 & & 0 \\ & \lambda & \ddots & \\ & & \ddots & 1 \\ 0 & & & \lambda \end{pmatrix}$$

$$f(J_k) = \begin{pmatrix} f(\lambda) & f'(\lambda) & \dots & \frac{f^{m-1}(\lambda)}{(m-1)!} \\ & f(\lambda) & \ddots & \\ & & \ddots & f'(\lambda) \\ 0 & & & f(\lambda) \end{pmatrix}$$

- If $\lambda_1, \dots, \lambda_s$ are the eigenvalues of A , n_1, \dots, n_s the sizes of the largest Jordan blocks for each of them, r the polynomial of degree at most $\sum n_i$ such that

$$\forall i \in [1, s] \quad \forall j \in [0, n_i - 1] \quad r^{(j)}(\lambda_i) = f^{(j)}(\lambda_i),$$

then $f(A) = r(A)$.

- $f(A) = \frac{1}{2\pi i} \oint_{\Gamma} f(z)(zI - A)^{-1} dz$, where f is analytic inside Γ and $\bar{\Gamma}$ encloses $\text{Spec } A$.

Common examples include exponential, logarithm, sine, cosine, square root (not always defined), sign (only defined if $i\mathbf{R} \cap \text{Spec } A = \emptyset$).

Numeric methods include:

- Polynomial or rational approximations (for exp, log, sin, cos: use Padé's approximation and scaling);
- Factorization: write $A = X^{-1}BX$, where $f(B)$ is easier to compute; for instance, if B is upper triangular, the diagonal of $f(B)$ is $f(b_{ii})$, the coefficients immediately above the diagonal can be computed by solving $f(B)B = Bf(B)$, and one can iterate for the rest (Parlett recurrence – if only works if the eigenvalues are different, but there is a block variant if they are not).
- Iterative methods, $X_{n+1} = g(X_n)$, often coming from Newton's method for some equation satisfied by $f(z)$ (but beware of numeric instability). For instance,

$$X_0 = A$$

$$Y_0 = I$$

$$X_{k+1} = \frac{1}{2}(X_k + Y_k^{-1})$$

$$Y_{k+1} = \frac{1}{2}(Y_k + X_k^{-1})$$

for the square root or

$$X_0 = A$$

$$X_{k+1} = \frac{1}{2}(X_k + X_k^{-1})$$

for the sign.

Quantitative easing and volatility spillovers across countries and asset classes Y. Zhou

One can use contemporaneous causal inference to study the relations between various volatility indices.

Dynamical macro-prudential stress testing using network theory S. Levy-Carciente et al. (2014)

There are two main channels of risk contagion:

- Direct interbank liability linkages;
- Changes in bank asset values.

One can account for the latter with a bipartite bank-asset network.

**Global portfolio investment network
and stock market co-movement**
T. Chuluun (2014)

Cross-border capital flows (data from the IMF CPIS (coordinated portfolio investment survey), 2001–present) define a network of countries. Central countries (high degree, indegree (better), outdegree (worse) or eigenvector centrality) are more correlated with global indices. Other flows define other networks: trade flows, foreign direct investment, bank loans, etc.

Stochastic flow diagrams
N.J. Calkin and M. López de Prado (2014)

The authors have re-invented graphical models and/or recurrent neural networks, with a slightly different graphical notation.

The topology of macro financial flows
N.J. Calkin and M. López de Prado (2014)

Instead of building a minimum spanning tree (or more general graph) from a correlation matrix, one can build a graphical model from an SVAR(p) model.

**Structural analysis
with independent innovations**
H. Herwartz (2014)

Often, multi-variate time series models (e.g., SVAR, structural vector autoregressive model) are not identified: independent component analysis (ICA) can help.

**Emergence of statistically validated financial
intraday lead-lag relationships**
C. Curme et al. (2014)

Compute the cross-correlation matrix of stock returns, convert the correlations to p -values, adjust them for multiple testing, truncate them, and build the corresponding graph. As the lag increases (from 5 minutes to 1 hour), the graph becomes sparser.

**Optimizing directed acyclic graph
support vector machines**
F. Takahashi and S. Abe

When using support vector machines (SVM) on multiclass problems with the one-against-all or the pairwise approach, there are unclassified regions. To avoid them, one can use a smaller number of pairwise models, arranged in a tree, either by eliminating one element at each level of the tree

or using a tournament,

But the performance depends on the directed acyclic graph (DAG) chosen. It is better if easy-to-classify class pairs (low support vectors/observations ratio) appear in the top layers of the graph, and the hard-to-classify ones in the leaves.

**A comparison of methods
for multiclass support vector machines**
C.W. Hsu and C.J. Lin (2002)

Among the multiclass SVM algorithms, prefer the pairwise or DAG ones to the (more complicated) “all together” methods.

Algorithms for the multi-armed bandit problem
V. Kuleshov and D. Precup (2000)

Simple multi-arm bandit algorithms (to manage the exploration-exploitation trade-off in *reinforcement learning*) work well:

- ε -greedy: select the arm with the highest empirical mean reward $\hat{\mu}_i$ with probability $1 - \varepsilon$, and a random arm with probability ε ;
- Boltzmann: $p_i \propto \exp(\hat{\mu}_i/T)$, where the temperature T slowly decreases;
- Pursuit:

$$p_i \leftarrow \begin{cases} (1 - \beta)p_i + \beta \cdot 1 & \text{if } i = \text{Argmax}_j \hat{\mu}_j \\ (1 - \beta)p_i + \beta \cdot 0 & \text{otherwise;} \end{cases}$$

- Reinforcement comparison:

$$\begin{aligned} p_i &\propto \exp \pi_i \\ \pi_j &\leftarrow \pi_j + \beta(r - \bar{r}) \\ \bar{r} &\leftarrow (1 - \alpha)\bar{r} + \alpha r \end{aligned}$$

where

$$\begin{aligned} \pi_i &= \text{preference} \\ j &= \text{arm selected} \\ r &= \text{reward} \\ \bar{r} &= \text{average reward;} \end{aligned}$$

- Upper confidence bound

$$j = \text{Argmax}_i \left(\hat{\mu}_i + \sqrt{\frac{2 \ln t}{n_i}} \right)$$

where

$$\begin{aligned} \hat{\mu}_i &= \text{average reward for arm } i \\ n_i &= \text{number of times } i \text{ was chosen} \\ t &= \sum n_i = \text{number of steps.} \end{aligned}$$

Applications include clinical trials and online advertising.

***Hierarchical temporal memory
including HTM cortical learning algorithms***
Numenta (2011)

Recurrent (convolutional?) deep neural network, with connections *within* layers, binary weights, and sparsity constraints.

A survey on transfer learning
S.J. Pan and Q. Yang (2010)

Transfer learning studies what to do when the training and test sets are significantly different. For instance: how to extend a document classification model to a new domain (say, a sentiment model, from camera reviews to hotel reviews)? How to deal with a time-changing domain? Some new learning will be needed, but we want to reuse as much information as possible – we want to automatically identify the bits of the model that can be kept and those that should be discarded. Approaches include:

- Instance transfer: reweight the source data (Ada-boost, importance sampling);
- Feature transfer: reweight/select the features to reduce the distance between the source and the target domains;
- Semisupervised learning;
- Use the source model as a prior for the target one.

Markov logic networks (MLN) and inductive logic programming (ILP) were also mentioned, with no details.

MEG decoding across subjects
E. Olivetti et al. (2014)

Application of transfer learning (instance transfer, *i.e.*, importance sampling): decoding an MEG when training and test data are from different subjects.

***Correlation and large-scale simultaneous
significance testing***
B. Efron

In presence of high correlation, the p -values are still $U(0, 1)$ under H_0 , but not iid: their sample distribution can be: wider (if many correlations are large and negative); narrower and skewed (if many correlations are large and positive).

***High-dimensional variable selection
for survival data***
H. Ishwaran et al. (2010)

To gauge the importance of a variable in a random forest model, look at (the distribution of) its minimum depth.

***A factor model to analyze heterogeneity
in gene expression***
Y. Blum et al. (2010)

Approaches to multiple testing often assume independence – FAMT (factor analysis for multiple testing) relaxes that assumption [no details]. In R, check the FAMT package.

***Measuring and testing dependence
by correlation of distances***
G.J. Székely et al. (2008)

Original article on distance covariance

$$V^2(X, Y) = \int_{\mathbf{R}^{p+q}} \frac{|f_{XY}(t, s) - f_X(t)f_Y(s)|^2}{\|t\|_p^{1+p} \|s\|_q^{1+q}} dt ds.$$

***A non-iterative bayesian approach
to statistical matching***
S. Rässler (2003)

Statistical matching (aka “data fusion”) can be seen as a missing data problem, and tackled by *stochastic regression imputation* (NIBAS): compute the regressions $X \sim Z$, $Y \sim Z$ (where Z are the common variables), Σ_X , Σ_Y , $\text{Cor}(X, Y)$ (use the identity if you have no information), and sample Σ , β_X , β_Y , $X|y, \beta, \Sigma$, $Y|x, \beta, \Sigma$.

***Coherent mortality forecasting:
the product-ratio method
with functional time series***
R.J. Hyndman et al. (2012)

Forecasts (using functional PCA, and time series models for the coefficients of the principal components) of the mortality rates of two subpopulations (say, males and females) often diverge. Instead, forecast the sum and the difference of the (log) rates (if the variances are equal, they are uncorrelated: $\text{Cov}(X + Y, X - Y) = \text{Var } X - \text{Var } Y$). For more than two populations, consider the average (of the log-rates) and the difference with the average.

***Forecasting elections
with non-representative polls***
W. Wand et al. (2014)

Non-representative polls are just stratified surveys: after adjustment, they are perfectly usable.

Super Learner
M.J. van der Laan et al. (2007)

Use *cross-validation* to choose among various models. Besides the usual models (GLM, GLMnet, GAM, etc.), the **SuperLearner** R package also wraps DSA (deletion, substitution, addition), **LogicReg** (logic regression – “logic”, not “logistic”), **polsspline** (adaptive regression splines, aka MARS).

***Subsemble: an ensemble method
for combining subset-specific algorithms fits***
S. Sapp et al. (2013)

Bagging fits models on samples of the data, and averages them. Instead of an unweighted average, one can use cross-validation to find the best weights.

Bayesian estimation supercedes the t-test
M. Meredith and S. Kruschke (2014)

The BEST package replaces the T test with Bayesian statistics (with a Student T distribution to allow for outliers).

```
library(BEST)
r <- BESTmcmc(y1,y2)
r
summary(r)
plot(r)
plotPostPred(r)
s <- r$sigma1^2 / r$sigma2^2
hdi(s)
plotPost(s)
```

***The OpenCPU system: towards a universal
interface for scientific computing through
separation of concerns***
J. Ooms (2014)

OpenCPU is a REST interface (with a well-defined API, inviting other implementations) to R; it is stateless (function results are stored on the server, and a key to access them is returned to the client).

***The stringdist package
for approximate string matching***
M.P.J. van der Loo

The `stringdist` package implements many string distances: Hamming (limited to same-length strings), longest common substring, Levenstein (number of insertions, deletions, substitutions), optimal string alignment (idem, with transpositions of adjacent characters – not a distance), Damerau-Levenstein (idem, but corrected to make it a distance), n -gram distance (L^1 distance between the n -gram count vectors), cosine distance ($1 - \langle u, v \rangle$ is not a distance on the sphere – but $\arccos \langle u, v \rangle$ is), Jaccard distance (number of common n -grams divided by the number of n grams), heuristics (Jaro and Jaro-Winkler distances count “matches” and penalize “non-matches”).

***ScagExplorer: exploring scatterplots
by their scagnostics***
T.N. Dang and L. Wilkinson

To examine a large number of scatterplots, one can summarize them with a small number of metrics (outlying, skewed, clumpy, sparse, striated, convex, skinny, stringy, monotonic), look at the resulting parallel-plot-with-violins and/or cluster them. The authors suggest

the *leader algorithm* (start with an empty leader list and add a new scatter plot if the nearest leader is beyond some Euclidian distance threshold; only display the leaders, or only display the scatterplots attached to a given leader).

***New approaches in visualization
of categorical data: R package extracat***
A. Pilhöfer and A. Unwin (2013)

If you have more than two qualitative variables, check:

```
# Relative multiple barchart
extracat::rmb( ~ V1 + V2 + V2 )
# Categorical parallel coordinate plot
extracat::cpcp(d)
vcd::mosaic(xtabs( freq ~ V1 + V2 + V2 ))
vcd::doubledecker( xtabs(...) )
```

The `extracat::optile` function, used by `cpcp` to re-order the levels of the qualitative variables to reduce overplotting, may also be of interest.

Rainbow color map (still) considered harmful
D. Borland and R.M. Taylor (2007)

It is not perceptually uniform, it is not naturally ordered, its luminance does not vary monotonically.

***RnavGraph: an R package to visualize
high-dimensional data using graphs as
navigational infrastructure***
A. Waddell and W. Oldford (2013)

Not unlike `ggobi`: move from one (2D) scatterplot to another by a rotation (in 3D if they share a variable, in 4D otherwise).

***Dealing with stochastic volatility in time series
using the R package stochvol***
G. Kastner

Bayesian estimation of stochastic volatility models.

***Parallel computing for data science,
with examples in R and beyond***
N. Matloff (2013)

This book reviews, with detailed examples, the main types of parallel systems, mostly in R (clusters, multi-core systems, GPUs):

- `parallel::clusterApply`, `parallel::clusterApplyLB` (with load balancing);
- `parallel::mclapply`;
- `foreach`, `%dopar%`;
- `Rmpi` (low-level programming on clusters, via message passing);
- `Rdsm` (based on `bigmemory`): shared memory (you have to manage the locks yourself);
- `OpenMP`, to automatically parallelize loops in C (yes, it is that easy);
- `TBB` (Threads building blocks): thread-safe C++ containers, with a few parallel algorithms;

- Cilk++: adds `spawn` and `sync` keywords to C (I am not sure how relevant this is, given that C++ now has futures);
- `gputools`
- Thrust: similar to TBB, for the GPU (it can also use OpenMP or TBB if you do not have a GPU);
- Rth: to use Thrust from R;
- OpenBLAS.

(The author wrote Rdsml and Rth.)

A comparison of programming languages in economics
S.B. Aruoba (2014)

Julia, Python+Numba, Matlab+MEX, Mathematica have speeds comparable to C++/Fortran/Java, but functional languages (OCaml, Haskell, Scala) are worth a look.

A reliable effective terascale linear learning system
A. Agarwal et al. (2013)

Most machine learning algorithms can be implemented on a *data-centric computing platform* such as Hadoop using the *AllReduce* operation (arrange the nodes in a tree, use it to compute sums or weighted averages, *i.e.*, to aggregate the partial results), which has much less overhead than MapReduce. However, their implementation bypasses Hadoop's MapReduce (the nodes communicate between themselves via TCP), which may lead to reliability issues (do not expect the system to run for more than a few hours without failures).

Asynchronous functional reactive programming for GUIs
E. Czaplicki and S. Chong (2013)

FRP is programming with signals, *i.e.*, time-changing values (in Haskell, that would be a functor, `fmap: (a → b) → Signal a → Signal b`). Most FRP languages assume the signal changes continuously, and sample from it. Elm (a Haskell DSL) works with discrete signals (asynchronous FRP) and therefore avoids needless recomputations.

MDF

<https://github.com/ahlmss/mdf> (2013)

Data-flow programming in Python.

Clash of the lambdas
A. Biboudis et al. (2014)

Lambdas in Java 8 are mature and efficient. Scala is inefficient, *e.g.*, because of garbage collection or boxing/unboxing (collections are not specialized for primitive types). Optimizing frameworks (ScalaBlitz) help, but not enough: the gap is reduced from 2 orders of magnitude to 1.

Graph drawing in Tikz
T. Tantau (2013)

There are now graph layout algorithms in Tikz, implemented in Lua.

Managing schema evolution in NoSQL data stores
S. Scherzinger et al. (2013)

Schema migration in schema-less databases (NoSQL) are often ad hoc (dangerous, untested) data transformations, either eager (convert everything in one go) or lazy (old and new entries cohabit, they are only converted when accessed). A system-agnostic data migration language would be useful.

Locality-sensitive hashing scheme based on p-stable distributions
M. Datar et al. (2004)

To solve the *k*-nearest neighbour problem probabilistically, in high dimension:

- Find hash functions with a higher probability of collision when the points are close:

$$\text{distance} \leq r_1 \implies P[\text{collision}] \geq p_1$$

$$\text{distance} \geq r_2 \implies P[\text{collision}] \leq p_2;$$

- Apply many such hash functions to the data and examine the points with the most collisions.

Such hash functions can be obtained by projecting the points in a random direction and binning them:

- Choose $r > 0$;
- Pick $b \sim U(0, 1)$ and $a \sim F$, where F is an n -dimensional p -stable distribution;
- Let $h_{a,b}(v) = \left\lfloor \frac{a \cdot v + b}{r} \right\rfloor$.

A distribution F is p -stable if, for all n , for all $v_1, \dots, v_n \in \mathbf{R}$, if $X_1, \dots, X_n, X \sim F$ are iid, then $\sum_i v_i X_n$ and $(\sum |v_i|^p)^{1/p} X$ have the same distribution. The Cauchy distribution is 1-stable; the Gaussian distribution is 2-stable.

The development of hyperdual numbers for exact second-derivative calculations
J.A. Fike and J.J. Alonso (2011)

The first derivative of a function f is often approximated using

$$f'(x) = \frac{f(x+h) - f(x)}{h} + O(h)$$

$$f'(x) = \frac{f(x+h) - f(x-h)}{2h} + O(h^2),$$

but this is not numerically stable: there is a *subtractive cancellation error* problem, which prevents h from being too small (often, 10^{-4} to 10^{-6} is the best we can do). The complex step approximation

$$f'(x) = \frac{\text{Im } f(x+ih)}{h} + O(h^2)$$

addresses this problem: h can be very small (10^{-14}). But the problem reappears if you want the second derivative.

Instead of complex numbers, one can use other extensions of \mathbf{R} , such as the dual numbers $\mathbf{R}[\varepsilon]/(\varepsilon^2)$,

$$f(x + \varepsilon) = f(x) + f'(x)\varepsilon$$

or the *hyperdual numbers*, $\mathbf{R}[\varepsilon, \eta]/(\varepsilon^2, \eta^2, \varepsilon^2\eta^2)$,

$$f(x + \varepsilon + \eta) = f(x) + f'(x)\varepsilon + f'(x)\eta + f''(x)\varepsilon\eta.$$

The derivatives are exact, and there is no step size to choose.

That is easy to implement in languages with operator overloading (C++, Julia), but 10 times slower than the difference method.

***Unbounded spigot algorithms
for the digits of pi***
J. Gibbons (2005)

Good job interview question: implement a streaming algorithm to compute the digits of π , ad infinitum, using

$$\pi = \sum_{n \geq 0} \frac{(n!)^2 2^{n+1}}{(2n+1)!}.$$

The formula comes from

$$\frac{\pi}{4} = \arctan 1 = \int_0^1 \frac{dx}{1+x^2} = \sum \frac{(-1)^n}{2n+1}.$$

The series converges very slowly, but it is alternating, and taking the average of two consecutive partial sums gives a faster converging series – but it is still alternating, so we can use the same trick, again and again. This is the *Euler convergence acceleration transform*.

This transformation can also be motivated as follows: given

$$f(x) = \sum_{n \geq 0} (-1)^n a_n x^n,$$

show that

$$g(y) = f\left(\frac{y}{1-y}\right) = \sum_{n \geq 0} (-1)^n \Delta^n a_0 y^n,$$

where Δa is the forward difference of a , and compute $g(\frac{1}{2}) = f(1)$.

Here is a straightforward algorithm: find an upper and lower bound on the error,

$$s_n - \ell_n \leq \pi \leq s_n + u_n,$$

and use it to infer if the k th decimal of s_n is that of π – for this, you need arbitrary precision rationals.

***Computing extremely accurate quantiles
using t-digests***
T. Dunning

To compute a quantile of a datastream, approximately, one can:

- Sample from it, online, and take the quantile of the sample – for extreme quantiles, you only need to keep a sample of the tails;
- Bin the data into a set of centroids and counts, and collapse the centroids when there are too many of them (*t-digest*).

***The PH-tree – a space-efficient storage
structure and multi-dimensional index***
T. Zäschke et al. (2014)

Indexes for spacial data are often KD-trees (split the space in half, along an axis-aligned hyperplane, at each node), quad-trees (split the space in 2^n at each node) or R-trees (trees of bounding boxes). One can also use *prefix trees* (tries), by interleaving the different dimensions into a single bitstring. There is no need for rebalancing.

Nepotism and equity prices
G. Zhu (2014)

Nepotism (several family members being directors in the same company – in the US, this has to be reported in text form; the information can be extracted by looking for keywords such as “brother”, “father”, etc., used to build a social network and compute the usual network metrics) is detrimental to firm value, except when there is a large outside block holder.

Textual classification of SEC comment letters
J.P. Ryans (2014)

SEC comment letters are a good predictor of future negative abnormal returns (use a naive Bayes classifier), especially if they have been accessed by many investors (number of downloads).

***Efficient online summarization
of microblogging streams***
A. Alariu (2014)

A *word graph* (the nodes are words, the edges are bigrams, with weights) can be used to summarize a corpus (look for the highest-weight path). One can also use trigrams and let the weights decay (multiply by $1 - \varepsilon$ at each step).

***Looking for risk in words:
a narrative approach to measuring
the pricing implications of finance constraints***
M.M.M. Buehlmaier and T.M. Whited (2014)

Financially constrained firms (those having difficulty raising funds) can be identified from the text in the MD&A section of their 10-K filing, using the naive

Bayes algorithm (building the training set is problematic, though).

Finance constraints
M.M.M. Buehlmaier (2014)

One can estimate how financially constrained a company is by the textual analysis of its regulatory filings, using a Naive Bayes classifier. The training sets are questionable:

- A small, subjective manually-generated training set;
- Companies identified by a set of words known to be associated with delays resulting from the difficulty of issuing new equity;
- Idem for debt.

One could also check for the effect of pairs, triplets, quadruplets of words.

The price of silence: when no one asks questions during conference calls
S. Chen et al. (2014)

The number of questions asked by investors in earnings-related conference calls measures the quality of a firm's communication.

News-implied volatility and disaster concerns
A. Manela and A. Moreira (2013)

Use SVM regression to predict the VIX from front-page articles of the Wall Street Journal.

Portfolio selection with options and transaction
S. Malamud (2014)

Introducing options in your investment universe dramatically increases the number of assets, and the variance matrix becomes untractable – and, option traders would argue, largely irrelevant. Instead of a mean-variance portfolio, one can look for greek-efficient portfolios – with a high value for the greeks you want, and a small value for those you do not. [I would still use the mean-variance framework, and include the greeks as constraints, setting those we want to ± 1 , and those we do not to 0.]

Volatility and directional information-based trading in options

Generalization of the PIN model to option markets, accounting for two types of information, direction and volatility.

Why does the option to stock volume ratio predict stock returns?
L. Ge

Most option-implied measures only use the price: the volume, normalized by the stock volume, and decomposed into call/put, buy/sell, open/close, is also a

predictor of future returns. Opening and closing of long call positions are more informative than synthetic shorts.

CDS inferred stock volatility
B. Guo (2014)

Since both CDSs and OTM puts can be used to protect against downside risk, one can define a CDS-implied volatility. It is different from the option-implied one, and is a better predictor of future stock volatility.

Option listing and information asymmetry
J. Hu (2014)

Option listing improves market efficiency and reduces information asymmetry. (The study uses propensity score matching.)

Stock market ambiguity and the equity premium
A. Kagkadis (2014)

The dispersion of volume-weighted strike prices is a measure of market ambiguity (high ambiguity leads to high hedging demand with different beliefs, which leads to a higher dispersion of strikes). It is related to, but different from, other option-implied quantities (variance risk premium (VRP), smirk slope, risk-neutral variance, skewness, kurtosis, open-interest ratio (OTM puts/ATM calls, a measure of hedging pressure)). It complements the VRP. (Analyst forecast dispersion is another measure of ambiguity.)

Wealth transfers via equity transactions
R.G. Sloan and H. You (2013)

The option of a company to issue new shares or buy back shares when its stock is over- or under-priced should be included in its valuation. It corresponds to a wealth transfer from new to old investors.

Demand for crash insurance, intermediary constraints and stock return predictability
H. Chen et al. (2013)

New deep out-of-the-money S&P 500 put options are a good (negative) predictor of future (monthly) returns.

An option to cheat: an application of option theory to realize flipping in underpricing
J. Stojkovic (2013)

IPO flipping is the sale of an (undervalued) IPO stock on day one if/when the price jumps. It can be modeled as a perpetual American call option, with the IPO price as strike. The option price can be decomposed into the potential immediate profit, and the time value of waiting.

Does VIX truly measure return volatility?

K.V. Chow et al. (2014)

The current VIX computations (price of a portfolio of OTM put or call options, with weights inversely proportional to the square of the strike) are not really model-free (they assume a diffusion). It is a biased estimator of expected volatility, but it can be corrected.

Merton's model, credit risk and volatility skews

J. Hull et al. (2004)

Merton's model assess the credit risk of a company by considering its equity as an option on the assets – the spot is the value of the assets, the strike is the value of the debt, the expiry its maturity. Options on equity are therefore *compound options* on the assets – this explains the skew. One can use the option market to estimate the model parameters and compare the results with CDS spreads.

Where would the EUR/CHF exchange rate be without the SNB's minimum exchange rate policy?

M. Hanke et al. (2013)

Capped exchange rates (e.g., the floor on EUR/CHF) can be modeled as American options on the latent (uncapped) FX.

Option-implied volatility measures and stock return predictability

X. Fu et al.

The following option-derived quantities have some predictive power on future stock returns:

$$\begin{aligned} \text{IVSpread} &= \text{IV}_{\text{ATM, Call}} - \text{IV}_{\text{ATM, Put}} \\ \text{IVSkew} &= \text{IV}_{\text{OTM, Put}} - \text{IV}_{\text{ATM, Call}} \\ \text{AMB} &= \frac{1}{2}(\text{IV}_{\text{ITM, Put}} + \text{IV}_{\text{ATM, Call}}) - \frac{1}{2}(\text{IV}_{\text{ITM, Call}} + \text{IV}_{\text{ATM, Put}}) \\ \text{COMA} &= \text{IV}_{\text{OTM, Call}} - \text{IV}_{\text{ATM, Call}} \\ \text{POMA} &= \text{IV}_{\text{OTM, Put}} - \text{IV}_{\text{ATM, Put}} \\ \text{RVIV} &= \text{RV} - \frac{1}{2}(\text{IV}_{\text{ATM, Put}} + \text{IV}_{\text{ATM, Call}}). \end{aligned}$$

Jump and variance risk premia in the S&P 500

M. Neumann et al. (2014)

By estimating the physical and risk-neutral (option prices) SVCJ (stochastic volatility with contemporaneous jumps in returns and variance) model,

$$\begin{aligned} ds &= \mu dSdt + S\sqrt{V}dW_1 + Z_1 dN \\ dV &= \kappa(\theta - V)dt + \sigma\sqrt{V}dW_2 + Z_2 dN, \end{aligned}$$

one can define the following risk premia:

- Diffusive variance risk premium: $\kappa^{\mathbf{Q}} - \kappa^{\mathbf{P}}$;
- Price jump risk premium: $\mu^{\mathbf{Q}} - \mu^{\mathbf{P}}$;
- Variance jump risk premium $\theta^{\mathbf{Q}} - \theta^{\mathbf{P}}$.

They are related to macroeconomic uncertainty.

Risk-adjusted option-implied moments

F. Brinkmann and O. Korn (2014)

The (model-free) risk-neutral density can be computed from option prices; the physical density (and the physical moments) can be computed in the same way, using physical expected discounted payoffs instead of prices. Those physical prices can be computed from market prices and the utility function of a representative investor. A CRRA utility function can explain the variance risk premium (VRP),

$$\text{VRP} \stackrel{\text{def}}{=} E^{\mathbf{P}}[\text{variance}] - E^{\mathbf{Q}}[\text{variance}],$$

but not both the VRP and the skewness risk premium.

Pricing interest rate derivatives and computing pathwise Greeks in the extended Libor market model

T. Lee (2013)

There is no longer a single yield curve; the Libor market model (LMM) can be extended to this new multi-curve environment.

Expected bond returns and the credit risk premium

Z. Afik and S. Benninga (2014)

Do not confuse yield to maturity (computed from the promised cash flows) and expected bond returns (computed from the expected cash flows, *i.e.*, accounting for rating, rating transition matrix and industry recovery rate). The difference between the two, the credit risk premium, is (empirically) a simple function of rating and duration.

Asymmetry in stock returns: an entropy measure

L. Jiang et al. (2014)

Asymmetry tests usually rely on exceedance correlations

$$\begin{aligned} \rho_c^+ &= \text{Cor}(X, Y \mid X, Y \geq c) \\ \rho_c^- &= \text{Cor}(X, Y \mid X, Y \leq -c). \end{aligned}$$

Tests based on exceedance densities

$$\begin{aligned} f_c^+(x, y) &= f(x, y, \mid x, y \geq c) \\ f_c^-(x, y) &= f(x, y, \mid x, y \leq -c) \end{aligned}$$

and the “entropy”

$$S_c = \frac{1}{2} \iint_{RR^2} \left(\sqrt{f_c^+} - \sqrt{f_c^-} \right)^2$$

are more powerful.

Introduction to nonextensive statistical mechanics and thermodynamics
C. Tsallis et al. (2003)

Tsallis entropy (or q -entropy, or non-extensive entropy) generalizes entropy.

The exponential function e^x is a solution of $y' = y$; its inverse, $\ln x$, is additive: $\ln(xy) = \ln x + \ln y$; the entropy is

$$S = \sum_i p_i \ln \frac{1}{p_i} = \left\langle \ln \frac{1}{p_i} \right\rangle.$$

The q -exponential e_q^x is a solution of $y' = y^q$; its inverse,

$$\ln_q x = \frac{x^{1-q} - 1}{1 - q},$$

is pseudo-additive:

$$\ln_q(xy) = \ln_q x + \ln_q y + (1 - q) \ln_q x \ln_q y;$$

the q -entropy is

$$S_q = \sum_i p_i \ln_q \frac{1}{p_i} = \left\langle \ln_q \frac{1}{p_i} \right\rangle.$$

The characterizations of entropy (Shannon or Khinchin theorem) generalize to q -entropy, with one more term or exponent, e.g.,

$$S(A+B) = S(A) + S(B) + (1-q)S(A)S(B) \text{ if } A \perp\!\!\!\perp B$$

$$S(A+B) = S(A) + S(B|A) + (1-q)S(A)S(B|A)$$

Tsallis entropy is related to other generalized entropies, e.g.,

$$S_q^{\text{Renyi}} = \frac{1}{1-q} \ln \sum_i p_i^q = \frac{\ln[1 + (1-q)S_q]}{1-q}.$$

Realized coskewness of the VIX and S&P 500 and the equity premium
Z. Liu et al. (2014)

In factor models, besides volatility, idiosyncratic volatility, $\beta(\text{stock}, \text{market})$, one can also look at coskew(stock, market) (but it can be tricky to estimate – if you have high-frequency data, you can try the realized skewness). Coskew(VIX, S&P 500) is related to, but different from, the variance risk premium (VRP).

Which beta is best? On the information content of option-implied beta
R. Baule et al. (2014)

One can define many option-implied betas:

- Using implied volatility (IV) and historical correlation;
- Using IV and assuming constant correlation;
- Using IV and assuming some specific option-pricing model;

- Using IV and cross-correlation derivatives (if available);
- Using the implied moments: if $y = \alpha + \beta x + \varepsilon$, then

$$\beta = \sqrt{1 - \frac{\text{Var } \varepsilon}{\text{Var } y}} \left(\frac{\text{Var } y}{\text{Var } \varepsilon} \right)^{1/2} = \left(\frac{\text{Skew } y}{\text{Skew } \varepsilon} \right)^{1/3}$$

Option-implied betas based on the variance, and those that ensure that the market beta is one (for this, jointly estimate the betas for all the stocks) are more accurate.

Extremal dependence and contagion
R. Fry-McKibbin and C.Y.L. Hsiao (2014)

During crises, not only do the moments change (returns drop, volatility jumps), so do the *comoments*: for instance, $\text{Cor}(\text{ret}, \text{vol})$ changes sign, from negative (volatility skew) in normal times, to positive (volatility smile) in crises. One can devise *contagion tests* by looking at $\text{Cor}(\text{ret}_i, \text{vol}_j)$, $\text{Cor}(\text{ret}_i, \text{skew}_j)$, $\text{Cor}(\text{vol}_i, \text{vol}_j)$.

Modelling dependence structure and forecasting portfolio value-at-risk with dynamic copulas
M. Cerrato et al. (2014)

Look at the asymmetric dependence, e.g.,

- Threshold correlation,

$$\rho^- = \text{Cor}(X_1, X_2 \mid X_1 \leq x_1, X_2 \leq x_2),$$

where x_1, x_2 are the p -quantiles of X_1 and X_2 , and

$$\rho^+ = \text{Cor}(X_1, X_2 \mid X_1 \geq x_1, X_2 \geq x_2),$$

where x_1, x_2 are the $(1-p)$ -quantiles;

- Quantile dependence

$$\lambda^p = P[X_1 \leq x_1 \mid X_2 \leq x_2]$$

or

$$\lambda^p = P[X_1 \geq x_1 \mid X_2 \geq x_2];$$

- Tail dependence

$$\lambda^U = \lim_{p \rightarrow 1} \lambda^p$$

$$\lambda^L = \lim_{p \rightarrow 0} \lambda^p$$

between the long and short portfolios built from the following signals

- $\beta(\text{stock}, \text{market})$;
- $\text{coskew}(\text{stock}, \text{market}, \text{market})$;
- $\text{cokurt}(\text{stock}, \text{market}, \text{market}, \text{market})$.

To estimate the VaR, use the GAS (generalized autoregressive score) model.

Asymmetry in tail dependence of equity portfolios
E. Jondeau

To estimate tail dependence, prefer parametric methods (unless you really have a lot of data), e.g., using the multivariate non-central t distribution.

***Cornish-Fisher versus Gramm-Charlier:
an appraisal***
D. Maillard (2014)

Cornish-Fisher is a transformation of a Gaussian random variable

$$Y = X + (X^2 - 1)\frac{S}{6} + (X^3 - 3X)\frac{K}{24} - (2X^3 - 5X)\frac{S^2}{36};$$

if S and K are small, they are close to the skewness and excess kurtosis of Y .

Gram-Charlier is a transformation of the Gaussian density ϕ :

$$\psi(x) = \phi(x) \left(1 + \frac{S}{6} H_3(x) + \frac{K}{24} H_4(x) \right)$$

$$H_n(x) = (-1)^n e^{-x^2/2} \frac{d^n}{dx^n} e^{-x^2/2}$$

(this time, S and K are really the skewness and excess kurtosis). The domain of validity of the Cornish-Fisher transformation (the set of skewness-kurtosis pairs attainable) is much larger.

***Expansion of probability density functions
as a sum of gamma densities
with applications in risk theory***
N.L. Bowers (1966)

The idea behind the Gram-Charlier expansion of a pdf,

$$p(x) = \phi(x) + \sum_{n \geq 1} \dots = \sum_{n \geq 0} a_n H_n(x) \phi(x),$$

where the H_n are orthogonal polynomials wrt the Gaussian distribution ϕ , can be generalized to other reference distributions, e.g., for positive random variables, the Gamma distribution (and Laguerre polynomials).

***Robust series expansions
for probability density estimation***
M. Welling

Use robust moments

$$\left\langle (\alpha x)^n e^{\frac{1}{2}(1-\alpha^2)x^2} \right\rangle, \quad 1 \leq \alpha^2 \leq 2,$$

to define robust Gram-Charlier or Hedgeworth expansions.

Joining risks and rewards
H.J. Stein (2014)

When you need both the **P** and **Q** measures (e.g., for risk and pricing), use the same samples, but with different weights (*i.e.*, use importance sampling, as when pricing deep OTM options).

***Identifying jumps in financial assets:
comparison between nonparametric jump tests***
A.M. Dumitru and G. Urga (2011)

Review of many jump estimators or tests, e.g., those based on

$$\text{BV} = \sum |r_t r_{t-1}|$$

$$\sum \text{Min}(r_t, r_{t-1})^2$$

$$\sum \text{median}(r_t, r_{t-1}, r_{t-2})^2$$

$$\text{Max} \frac{|r_t|}{\text{BV}}$$

$$\frac{\sum_{t \equiv 0 \pmod{\delta}} |r_t + \dots + r_{t+\delta-1}|^m}{\sum |r_t|^m}$$

$$\sum R_t - r_t \text{ (ratio vs log-returns), etc.}$$

***Monitoring housing markets
for episodes of exuberance***
E. Pavlidis et al. (2013)

The ADF test can be generalized to distinguish between integrated $I(1)$ and explosive behaviours:

$$\Delta y_t = \alpha + \beta y_{t-1} + \sum_{i=1}^k \gamma_i \Delta y_{t-i} + \varepsilon, \quad t \in [T_1, T_2]$$

$$\text{ADF}_{T_1 T_2} = \frac{\beta_{T_1 T_2}}{\sigma(\beta_{T_1 T_2})}$$

$$\text{SADF}_{T_1} = \sup_{T_2 \geq T_1} \text{ADF}_{T_1 T_2} \quad \text{expanding window}$$

$$\text{GSADF}_w = \sup_{T_2 - T_1 \geq w} \text{ADF}_{T_1 T_2} \quad \text{window size at least } w.$$

***A compound multifractal model for
high-frequency asset returns***
E.M. Aldrich et al. (2014)

High-frequency returns (E mini S&P 500 futures contract), in trade space, away from prescheduled news announcements, are Gaussian. Intertrade duration can be modeled with an exponential distribution, conditional on a hidden state (k binary state variables, with varying degrees of persistence).

$$d_t \sim \text{Exp} \left(\lambda \prod_i M_{it} \right)$$

$$M_{i,t+1} = \begin{cases} M_{it} & \text{with probability } 1 - p_i \\ 2 - M_{it} & \text{with probability } p_i \end{cases}$$

$$M_{i0} = m_0 \in (0, 2)$$

A truncated version of this Markov switching multifractal duration (MSMF) model, $\text{Min}(d_t, d_t^0)$, where $d_t^0 \sim \text{Exp}(\lambda^0)$, gives a better fit.

When to sell Apple and the Nasdaq? Trading bubbles with a stochastic disorder model
A. Shiryaev et al. (2014)

Consider a geometric brownian motion with a change point in the trend,

$$dS_t = (\mu_1 \mathbf{1}_{t < \theta} + \mu_2 \mathbf{1}_{t \geq \theta}) S_t dt + \sigma dB_t$$

(the breakpoint, θ , is called a “moment of disorder” in quality control). Close a long (resp. short) position at

$$\tau_{\text{long}} = \underset{\tau \leq T}{\underset{\tau \text{ stopping time}}{\operatorname{Argmax}}} E[S_\tau]$$

$$\tau_{\text{long}} = \underset{\tau \leq T}{\underset{\tau \text{ stopping time}}{\operatorname{Argmin}}} E[S_\tau].$$

It can be estimated explicitly.

Empirical asset pricing: Eugene Fama, Lars Peter Hansen and Robert Shiller
J.Y. Campbell (2014)

Around the notion of stochastic discount factor.

The systematic risk of private equity
A. Buchnet and R. Stucke (2014)

To estimate the risk of a private equity fund, model its dividend payments as a stochastic process.

$$\text{Dividend yield} = 1 - e^{-\delta_t}$$

$$\delta_t = \delta_0 + z_t t$$

$$z_t \sim N(0, \sigma)$$

The valuation of M&A targets by relative indifference pricing
C. Mauch and S. Rostek (2013)

The *indifference price* is the price at which a given investor (initial wealth and utility function) is indifferent between holding and not holding the asset. The buying and selling (*i.e.*, long and short) indifference prices are different. Indifference pricing is relevant for incomplete markets, *e.g.*, for real options.

Return and risk of pairs trading using a simulation-based bayesian procedure for predicting stable ratios of stock prices
L.T. Gatarek et al. (2014)

When testing for cointegration, only the subspace of cointegration relations is well-defined. To single out a cointegration relation, some “normalization” is needed, *e.g.*, $\beta = \begin{pmatrix} \beta_1 \\ \beta_2 \end{pmatrix} = \begin{pmatrix} 1 \\ \beta_2 \end{pmatrix}$, or $\beta' \beta = I$, *i.e.*, $\beta = \begin{pmatrix} \beta_1 \\ \sqrt{1 - \beta_1^2} \end{pmatrix}$ (only the leverage changes). There are several rules to choose the size of the position on the spread $s_t = \beta_1 y_{1t} + \beta_2 y_{2t}$, *e.g.*, $-s_t$, $\text{sign } E_t[\Delta s_{t+1}]$ or $E_t[\Delta s_{t+1}] \times \text{sign } E_t[\Delta s_{t+1}]$ or a buy-and-hold strategy.

Financial contagion risk and the stochastic discount factor
L. Piccotti (2014)

Contagion risk (in the financial sector) can be estimated as follows:

- Start with bank returns, r_{it} ;
- Remove common risk factors (*e.g.*, Fama-French, estimated with a Kalman filter, assuming that the betas are random walks), and only look at the residuals e_{it} ;
- Regress those residuals against the sector residuals, with the bank of interest removed, $e_{it} = \beta_{it} e_{it} + \varepsilon_{it}$;
- Decompose the variance of the sector excess returns $\text{Var} \sum_i w_i e_{it}$ into a contagion contribution (the β_{it} , *i.e.*, the off-diagonal elements of $\text{Var } e_{\cdot t}$) and a residual term.

Explosive bubble modelling by noncausal process
C. Gouriéroux and J.M. Zakoian (2013)

Instead of a causal linear autoregressive process

$$y_{t+1} = \rho y_t + \varepsilon_{t+1}, \quad \varepsilon_t \text{ iid}$$

one can try to model financial time series with a *non-causal* AR process

$$y_t = \rho y_{t+1} + \varepsilon_{t+1}, \quad \varepsilon_t \text{ iid, Cauchy.}$$

[An AR(1) model is not convincing: try to add terms for 1-day, 1-week, 1-month, 1-year, *etc.*]

Stochastic areas of diffusions and applications in risk theory
Z. Cui

The area swept by a stochastic process below some threshold can be used to model default.

Extending time-changed Lévy asset models through multivariate subordinators
E. Luciano and P. Semeraro (2007)

To construct a multivariate Lévy process from a Gaussian one, use a multivariate subordinator, not a univariate one.

FARVaR
C.X. Cai et al. (2014)

To compute the value-at-risk, estimate the intraday density of returns (with a kernel estimator) and model the evolution of this density, from day to day, as a *functional autoregressive* (FAR) process.

Risk-adjusted time series momentum
M. Dudler et al. (2014)

Define risk-adjusted momentum as $\sum \frac{\log\text{-returns}_t}{\text{volatility}_t}$.

A Market-based funding liquidity measure
Z. Chen and A. Lu (2014)

The BAB (betting against beta) factor is the spread between (leveraged) low-beta stocks and (deleveraged) high-beta stocks. Its performance (low beta anomaly) can be explained by the inability of many investors to leverage their portfolio. But the beta is not a measure of funding liquidity: instead, one can combine size, idiosyncratic volatility, institutional ownership and analyst coverage – the BAB premium is higher for high-margin stocks. Appendix A lists 14 funding liquidity proxies.

Corporate news releases and equity vesting
A. Edmans et al. (2014)

CEOs time the release of corporate news to match their vesting equity.

Does liquidity beta predict mutual-fund alpha?
X. Dong et al. (2014)

The outperformance of a fund with a liquidity beta is not due to the liquidity premium, but to more trading opportunities in liquid times.

Policy announcements in FX markets
P. Mueller et al (2014)

Interest rate is a good FX investment signal, but only on scheduled FOMC announcement days. This can be explained by an agent model, in which agents learn the announcement effects in a Bayesian fashion.

Alliances and return predictability
J. Cao (2014)

Use alliance partners in your pairs trading strategy.

Post-split drift and post-earnings announcement drift: one anomaly or two?
L. Fengfei (2014)

Both stock splits and earnings announcements have a lasting effect on future returns, but the two phenomena may be distinct:

- The effects are real;
- They have the same duration, but
- A trading strategy using both outperforms one using only one.

[The conclusion is incorrect: the fact that the trading strategy performs better could come from the lower noise in the combined signal.]

International funding illiquidity
A. Vedolin (2014)

Country-specific funding illiquidity can be measured by the difference between market bond prices and theoretical bond prices (using the Svensson, Nelson-Siegel, or cubic spline model): large discrepancies mean that

arbitrageurs could not profit from the arbitrage opportunity.

Can information be locked-up? Informed trading ahead of macro-news announcements
Y. Tang (2014)

US macroeconomic announcements are often pre-released to the media under embargo agreements (lockup). Evidence (abnormal returns, order flow imbalance, from high-frequency data on index futures and ETFs, in the 30 minutes preceding the announcement) suggests that, for the FOMC (Federal Open Market Committee), this embargo is routinely breached – other government agencies manage to enforce it, though.

General purpose technologies, international technology diffusion, and the cross section of stock returns
W. Yang (2014)

Patents can be classified as general-purpose (computers, telecom, electronics) or special-purpose (chemical, medical, mechanical, etc.) The difference between the growth rate of general- and special-purpose patents is a non-diversifiable risk factors, that can be added to factor models (Fama-French, etc.)

Macro disagreement and the cross-section of stock returns
W. Li (2014)

High-beta stocks are more prone to speculative mispricing, and high dispersion (in market forecasts) leads to lower returns. This effect also exists for macroeconomic factors (industrial growth, inflation, etc.)

Liquidity risk and expected stock returns
L. Pástor and R.F. Stambauch (2003)

Stock liquidity can be defined as the volume coefficient in the regression

$$\text{return}_{t+1} \sim \text{return}_t + \text{sign}(\text{return}_t)\text{volume}_t.$$

The market liquidity is the equal-weighted average of the stock liquidities.

In search of distress risk
J.Y. Campbell et al. (2008)

Yet another bankruptcy model. [Why not a survival model? They already look at various horizons and the distance to default from Merton's model.]

The world price of political uncertainty
J. Brogaard et al. (2014)

Global political uncertainty (data from www.policy-uncertainty.com) affects the implied cost of capital of countries integrated with the global economy; local political uncertainty has the opposite effect (it can be defined as a binary variable indicating elections in a given

year – data from the World Bank database of political institutions). One can also use text data to measure political uncertainty:

- Proportion of articles about economic uncertainty;
- Residual of the regression of the domestic proportion against the global one.

A leverage-based measure of financial instability

A. Tepper and K.J. Borowiecki (2014)

Credit constraints, margin requirements and leveraged investors (their demand curve can become upward-sloping – to estimate it, assume they are optimistic and reinvest everything they gain, as much as possible) can make markets unstable. The stability condition (for a 4-agent model: leveraged investors, unleveraged investors, bank, central bank) can be written explicitly.

Aggregate short interest and return predictability
D.E. Rapach et al. (2014)

Detrended aggregate short interest helps predict future market returns.

Predictive systems under economic constraints
M. Bonelli et al. (2014)

Expected returns are not constant and can be modeled as

$$\begin{aligned} r_{t+1} &= \mu_t + u_{t+1} \\ x_{t+1} &= (1 - \lambda)x_\infty + \lambda x_t + w_{t+1} \\ \mu_{t+1} &= (1 - \beta)\mu_\infty + \beta\mu_t + v_{t+1} \\ \Sigma &= \text{Var}(u_t, v_t, w_t)'. \end{aligned}$$

Since the expected returns μ_t are unlikely to be negative, one can add this constraint, either with a Bayesian prior, or by reparametrizing the model, e.g., by using a square root process for μ_t .

Model uncertainty and expected return proxies
C. Jäkel (2013)

The implied cost of capital (internal rate of return in a dividend discount model – if you know the future dividends) is often used as a proxy for expected returns, but it is as imprecise.

Predicting the spread of financial innovations: an epidemiologic approach
I. Hull (2013)

The spread of financial innovations (new products: CDS, MBS, ABS, CDO, ETF, etc.) can be modeled with the SIR model. A 2-host SIR model (banks and creditors) can help monitor solvency problems.

Risk vs anomaly: a new methodology applied to accruals
J. Ohlson and P. Bilinski

Low accruals increase/decrease the probability of large positive/negative returns. (The “new methodology” is logistic regression...)

Strategic allocation to commodity factor premiums
D. Blitz and W. de Groot (2013)

Consider tercile commodity portfolios, for the following factors:

- Momentum (past 12-month return);
- Carry (annualized nearby future price / next nearby future price);
- Volatility (of daily returns, over the past 3 years)

The cross-sectional variation of volatility risk premia
A. González-Urteaga and G. Rubio (2014)

Instead of the index VRP (realized vol, minus model-free implied vol (MFIV)), look at the stock-specific one, and $\beta(\text{VRP}_{\text{stock}} \sim \text{VRP}_{\text{index}})$.

Convenient liquidity measure for financial markets
O. Danyliv et al.

There are already many definitions of liquidity: bid-ask spread, $|\text{returns}|/\text{ADV}$, long-term return variance / short-term return variance,

$$\frac{\text{high} - \text{low}}{\text{low}} \bigg/ \frac{\text{volume}}{\text{MCap}}.$$

Here is one more:

$$\log \frac{\text{Volume} \times \text{Close}}{\text{High} - \text{Low}}.$$

Colog asset pricing, evidence from emerging markets
Y. Dranev and S. Fomkina

Yet another measure of risk:

$$\text{Colog } X = E[X \log X] - E[X]E[\log X],$$

where X measures the loss beyond some threshold. One can also consider the colog utility:

$$U(x) = x - \lambda x \log x.$$

***Machines vs machines: high-frequency trading
and hard information***
Y. Huh (2014)

Hawkes's self-exciting model can be used to measure liquidity from high-frequency data (*i.e.*, how fast the intensity of the Poisson process reverts to its long-term value).

High-frequency trading both takes and provides liquidity, but the balance depends on information asymmetry – measure it by the proportion of transactions in the stock (say, AAPL) caused by a change in some index (sat QQQ).

Predictive power of aggregate short interest
E.J. Yu (2014)

Aggregate short interest can help predict cyclical GDP changes, up to four quarters ahead.

***Employee satisfaction, labor market flexibility,
and stock returns around the world***
A. Edmans et al. (2014)

Employee satisfaction only leads to higher returns in countries with a flexible job market (US, UK, but not Germany).

***Multi-scale representation
of high-frequency market liquidity***

A. Golub et al. (2014)

One can define another time scale (besides wall clock, volume clock, number-of-transactions clock) by looking at price changes beyond some threshold; time scales corresponding to different thresholds can be combined to define a multiscale market state, in $\{\text{up, down}\}^{\#\text{thresholds}}$.

***Predictability of bank stock returns
during the recent financial crisis***
W.S. Leung et al. (2014)

To predict the future returns of a bank, look at:

- Earnings;
- Non-performing loans;
- Loan-to-deposit ratio;
- Tier-1 capital ratio;
- Exposure to the structured finance market (off-balance sheet activities, ABX AAA index);
- Funding illiquidity risk (maturity mismatch).

The data for US banks comes from the bank regulatory database (“FRY5C form”).

Technical market indicators: an overview
J. Fang et al.

Technical analysis does not work – review of 93 indicators...

***Discretionary accrual models
and the accounting process***
X.G. Gómez et al. (2000)

Accruals should be included in the earnings: the cash flow alone is very noisy (its autocorrelation is negative), and accruals help smooth it. However, there is too much discretion in their computation: only part of them is informative.

Earnings = Cash flows + Good accruals + Bad accruals

The *non-discretionary accruals* have been defined as:

- Last year’s accruals;
- The average of the previous accruals;
- The fitted value of the following regression (divide by the previous assets and fit the models for each industry×year)

$$\text{Accruals} \sim \Delta(\text{Revenue} - \text{Receivables}) + \text{PPE}$$

$$\text{Accruals} \sim \Delta\text{Revenue} + \text{PPE} + \text{CFO}$$

$$\text{Accruals} \sim \text{Previous short-term accruals} + \text{Previous long-term accruals} + \Delta\text{CF}$$

where

$$\text{Short-term accruals} = \Delta((\text{Current assets} - \text{Cash}) - (\text{Current liabilities} - \text{Financing items}))$$

$$\begin{aligned} \text{Long-term accruals} = \\ - \text{Depreciation not in inventory} - \\ \Delta\text{Allowances. (?)} \end{aligned}$$

***Foreign ownership and real earnings
management: evidence from Japan***
J. Guo et al. (2014)

After the tightening of accounting rules in Japan (“big bang accounting reform”, in the late 1990s), companies have moved from accrual earnings management to real earnings management. This can be measured with the residuals of the following regression (divide by the previous assets and estimate for each industry×year pair, if there are at least 15 companies)

$$\begin{aligned} \text{Cash flow from operations} \sim \\ \text{Previous assets} + \text{Sales} + \Delta\text{Sales} \\ \text{Discretionary expenses} \sim \text{Previous assets} + \text{Sales} \\ \text{Production costs} \sim \\ \text{Previous assets} + \text{Sales} + \Delta\text{Sales} + \\ \text{previous } \Delta\text{Sales} \end{aligned}$$

where

$$\begin{aligned} \text{Discretionary expenses} &= \text{Advertising} + \text{R\&D} + \text{SGA} \\ \text{Production costs} &= \text{COGS} + \text{Inventory.} \end{aligned}$$

One can also add them:

$$\begin{aligned} \text{abnormal CFO} + \text{abnormal discretionary expenses} - \\ \text{abnormal production costs.} \end{aligned}$$

Firms with more foreign ownership are less manipulative.

***Performance matched
discretionary accrual measures***
S.P. Kothari et al. (2001)

Discretionary accrual measures, e.g., the residuals of the following regressions (divide by the previous assets, fit for each year×industry combination)

$$\text{Accruals} \sim \Delta\text{Sales} + \text{PPE}$$

$$\text{Accruals} \sim \Delta(\text{Sales} - \text{Receivables}) + \text{PPE}$$

$$\text{Accruals} \sim \Delta\text{Sales} + \text{PPE} + \text{Previous ROA}$$

$$\text{Accruals} - \text{Depreciation} \sim \Delta\text{Sales,}$$

rarely account for the relation between performance and accruals (a trend in performance leads to systematically positive/negative accruals). One can use *matching* (on year, industry, and previous ROA).

Kinetic component analysis
M. López de Prado and R. Rebonato (2014)

The authors have rediscovered structural models.

$$\text{acceleration} \quad a_{n+1} = a_n + \text{noise}$$

$$\text{velocity} \quad v_{n+1} = v_n + a_n + \text{noise}$$

$$\text{true price} \quad p_{n+1} = p_n + v_n + \frac{1}{2}a_n + \text{noise}$$

$$\text{observed price} \quad q_n = p_n + \text{noise}$$

(I think there is no $\frac{1}{2}a_n$ term in structural models, and R’s **StructTS** function only uses a first-order Taylor expansion, *i.e.*, assumes that the acceleration is zero.)

Those models can be fitted with a Kalman filter and, by choosing the amplitude of the noise, one can fine-tune the amount of smoothing.

Contrary to other smoothing methods, such as Fourier transform, wavelets, Hodrick-Prescott filter or local regression (lowess), which do not behave well at the ends of the sample, they are forward-looking, and provide forecasts and confidence intervals. For instance, market makers could use those forecasts to compute the acceptable interval for their quotes.

By looking if the acceleration is significantly different from zero, one can decide whether to follow a “momentum” strategy (strictly speaking, it should be called “inertia” strategy).

As usual, the article includes Python code.

***Reward-risk momentum strategies using
classical tempered stable distribution***
J. Choi et al. (2014)

Momentum strategies look at past performance but, instead of returns, one can consider other performance measures:

- VaR, CVaR, here estimated from and ARMA(1,1)-GARCH(1,1) model with classical tempered stable (CTS) innovations;
- Sharpe ratio, μ/σ ;
- Stable tail-adjusted return ratio (STARR), μ/CVaR , or an additive version of it, $\mu - \text{CVaR}$;
- Rachev ratio $\text{CVaR}(\text{gain})/\text{CVaR}(\text{loss})$.

Maximum drawdown, recovery and momentum
J. Choi (2014)

The returns over the past 6 months (or 6 weeks) can be decomposed into the sum of pre-peak, maximum drawdown, and recovery log-returns. In a momentum strategy, one can replace the past returns with various linear combinations of those three terms.

Persistent doubt: an examination of the performance of hedge funds
M. de la O González et al. (2014)

Hedge fund performance seems to be persistent: to check it, form quintile portfolios on various performance measures, such as

- Alpha, adjusted for everything you can think of (they used developed and emerging markets, size, bonds, credit, FX, commodities);
- The manipulation-proof performance measure (MPPM), $\Theta(A)$, *i.e.*, the certainty-equivalent monthly return (of the past 2 years of returns) for an investor with constant relative risk aversion (CRRA) $A = 3$;
- The excess MPPM, $\Theta_{\text{fund}}(A) - \Theta_{\text{Russell 2000}}(A)$;
- The doubt ratio, $\text{DR} = 2 + \Theta(2)/(\Theta(2) + \Theta(3))$.

Asymetric risks of momentum strategies
V. Dobrynskaya (2014)

The momentum anomaly can be explained by the CAPM with upside and downside betas: past winners have a lower β_+ and a higher β_- .

Bayesian analysis of bubbles in asset prices
A. Fulop and J. Yu (2014)

Bubbles can be described by regime-switching models (choose two among mean-reverting, unit root (random walk) and explosive root). Structural break models are similar, but their breakpoint is deterministic.

The authors suggest to model the price/dividend ratio (rather than the price) as a mean-reverting process, whose long-term mean follows a random walk, with an AR coefficient > 1 or < 1 depending on the regime, estimated with a particle filter.

emcee: the MCMC hammer
D. Foreman-Mackey et al. (2013)

The **Goodman-Weare sampler** uses the detailed balance rule, but the candidate distribution is inspired by differential evolution (DE):

- Consider n chains, X_1, \dots, X_n ;
- The candidate for X_k is $X_j + Z(X_k - X_j)$, where $Z \sim g$ is random, e.g., $g(z) \propto z^{-1/2} \mathbf{1}_{[a^{-1}, a]}(z)$ and $j \sim U(\llbracket 1, n \rrbracket \setminus \{k\})$.

The algorithm can be parallelized (but this changes the detailed balance condition) and is affine-invariant: it is not sensitive to different scales in the parameters.

emcee is a Python implementation.

GraphX: a resilient distributed graph system on Spark
R.S. Xin et al. (2013)

In a distributed environment, graph algorithms tend to be inefficient because data partitioning is often done on *edge cuts* (vertices are assigned to machines, edges span machines – it is a vertex-centric view of the graph). does not preserve locality. But graph partitioning with (random) *vertex cuts* (edges are assigned to machines, vertices span multiple machines – an edge-centric view) fares better.

GraphX (part of Spark) can easily implement the Pregel API (send-combine) or the Power Graph API (gather-apply-scatter).

Extreme learning machines: a survey
G.B. Huang et al. (2011)

“Extreme learning machines” are single-hidden-layer feed-forward neural networks in which the hidden layer is fixed and arbitrary – it seems to be another name for *echo state networks*, which can be seen as discrete support vector machines (with a random, rather than universal, kernel).

Variable selection using random forests
R. Genuer et al. (2012)

To account for groups of highly correlated explanatory variables, consider *nested random forests*, with an increasingly large number of variables.

Learning the parts of objects by non-negative matrix factorization
D.D. Lee and H.S. Seung (Nature, 1999)

Principal component analysis (PCA), vector quantization (VQ), nonnegative matrix factorization (NMF), independent component analysis (ICA) are all decomposition $V \approx WH$, with different constraints: orthogonal columns (rows) in H (W) for PCA; boolean W with exactly one 1 in each row for VQ; $W, H \geq 0$ for NMF. When used to reduce the dimension of a set of images (say, faces), they give qualitatively different results: PCA gives eigenfaces (not faces), designed to be combined; VQ gives prototypes (faces); NMF gives parts of images (the non-negative constraints only allow for additive reconstruction). On text data, the decompositions define topics: VQ only allows a single topic per text; PCA allows several, but these are “relative” topics, designed to be combined, and difficult to interpret; the independence assumption in ICA is inappropriate in this context.

When does the nonnegative matrix factorization give the correct decomposition into parts?
D. Donoho and V. Stodden

The nonnegative matrix factorization (NMF) $X = A\Psi$ can be interpreted geometrically: the rows of X are in the simplicial cone generated by the rows of Ψ , and this cone is in the first orthant. In particular, unless the cone is generated by rows of X “touches” the frontier of the orthant (e.g., the orthant itself, or an ice-cream cone tangent to the orthant), the decomposition is not unique: one can replace Ψ with a slightly wider cone. Separability and complete factorial sampling ensure unicity.

**Algorithms
for nonnegative matrix factorization
D.D. Lee and H.S. Seung**

A nonnegative matrix factorization (NMF) of an $n \times m$ matrix V (with nonnegative entries) is a decomposition $V \approx WH$ where W is $n \times k$ and H $k \times m$, with k small, and W and H have non-negative entries. By iterating

$$\begin{aligned} H &\leftarrow H \odot (W'V) \oslash (W'WH) \\ W &\leftarrow W \odot (VH') \oslash (WHH') \end{aligned}$$

(where \odot and \oslash are the elementwise multiplication and division), one can find a local minimum of $\|V - WH\|_2$ (it is actually a gradient descent with an adaptive learning rate). One can find a similar update rule to minimize the divergence $D(V \| WH)$, where

$$D(A \| B) = \sum_{ij} (A_{ij} \log \frac{A_{ij}}{B_{ij}} - A_{ij} + B_{ij}).$$

Alternating least squares (ALS) were not mentioned.

**Big data in asset management
T. Roncalli (2014)**

Machine learning methods can be applied to finance:

- Lasso regression can be used for hedge fund replication, or to hedge positions;
- Nonnegative matrix factorization (NMF) can be used to decompose returns into factors, with positive weights (this is not the classical NMF: we want a decomposition $R = WF$, with $W \geq 0$, but no sign constraint on R or F ; no algorithm is mentioned, but alternating least squares (ALS) should work);
- There is no satisfactory *sparse Kalman filter*, but the model

$$\begin{aligned} y_t &= x_t' \beta_t + \varepsilon_t \\ \beta_t &= \beta_{t-1} + \eta_t \end{aligned}$$

can be estimated with a penalty, as in the Hodrick-Prescott (HP) filter,

$$\begin{aligned} (\hat{\beta}_1, \dots, \hat{\beta}_n) &= \underset{\beta}{\operatorname{Argmin}} \sum_t \|y_t - x_t' \beta_t\|^2 + \\ &\quad \lambda \sum_{t,j} h(\beta_{tj} - \beta_{t-1,j}) + \\ &\quad \mu \sum_{t,j} h(\beta_{tj}) \end{aligned}$$

with $h(\varepsilon) = \|\varepsilon\|_1$ or $h(\varepsilon) = \|\varepsilon\|_2^2$.

**Finding large average submatrices
in high dimensional data
A.A. Shabalin (2009)**

Biclustering algorithms look for homogeneous submatrices (e.g., approximately equal rows, or columns, or elements, or rank statistics in rows, or in columns, or elements above a threshold, or well-fit by a 2-way anova, etc.) and can be seen as a form of *unsupervised exploratory data analysis*. The LAS model assumes that the data is constant on (possibly overlapping) submatrices), with additive noise. The log-likelihood of a $k \times \ell$ submatrix of the whole $m \times n$ matrix is

$$-\log \left[\binom{m}{k} \binom{n}{\ell} \Phi(-\text{average} \times \sqrt{\ell}) \right]$$

To account for overlap, the submatrix with the best score is subtracted from the data, and the algorithm is iterated. To find a good submatrix with prescribed size $k \times \ell$, take k rows at random, take the best ℓ columns, then the best k rows, and iterate until convergence; then fine-tune (k, ℓ) .

**Measures of causality in complex datasets
with applications to financial data
A. Zaremba and T. Aste (2014)**

Granger causality is a comparison of $P(X_t | X_{\leq t-1})$ and $P(X_t | X_{\leq t-1}, Y_{\leq t-k})$. For a VAR model, one can use *Geweke's measure*,

$$F_{Y \rightarrow X} = \log \frac{\operatorname{Var}[X_t | X_{\leq t-1}]}{\operatorname{Var}[X_t | X_{\leq t-1}, Y_{\leq t-k}]},$$

or apply the kernel trick to it.

The *transfer entropy* is

$$T_{Y \rightarrow X} = H(X_t | X_{\leq t-1}) - H(X_t | X_{\leq t-1}, Y_{\leq t-k})$$

where

$$H(U|V) = \sum_{uv} p_{uv} \log \frac{p_v}{p_{uv}}$$

is Shannon's conditional entropy.

**Are there bubbles in stock prices?
Testing for fundamental shocks
A. Velinov and W. Chen (2014)**

A VAR(p) model, for a stationary time series y_t (if it is not stationary, try with Δy_t),

$$y_t = \nu + A_1 y_{t-1} + \dots + A_p y_{t-p} + u_t,$$

can be written

$$A(L)y_t = \nu + u_t$$

where L is the lag operator and (if $A(L)$ is invertible) as an MA(∞) process (Wold decomposition)

$$y_t = \mu + \sum_{s \geq 0} \Phi_s u_{t-s} = \mu + \Phi(L)u_t.$$

While the VAR parametrization is well-defined, the MA one is not identified: one can multiply u_t by an invertible matrix:

$$y_t = \mu + \Phi(L)B\varepsilon_t = \mu + \Psi(L)\varepsilon_t.$$

The article uses two variables,

$$y_t = \Delta \begin{pmatrix} \log(\text{production}) \\ \log(\text{stock prices}) \end{pmatrix}$$

and (to identify the model) the restrictions

$$E[\varepsilon_t \varepsilon_t'] = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad \Psi = \begin{pmatrix} * & 0 \\ * & * \end{pmatrix}$$

(this is a **structural VAR** (SVAR) model). The two types of shock can be interpreted as fundamental and non-fundamental, and give a decomposition of the log-price into fundamental and non-fundamental components.

Downside volatility timing
I. Nolte and Q. Xu (2014)

Add (high-frequency, realized) downside risk to your alpha model or your risk forecasts (e.g., a heterogeneous autoregressive (HAR) model, $\sigma_{t,t+1} \sim \sigma_{t-1,t}^+ + \sigma_{t-1,t}^- + \sigma_{t-4,t} + \sigma_{t-22,t}$): it is more informative than volatility.

You can also try to decompose the risk into its jump and diffusion components (with the bipower variation).

***The economic value of realized jumps:
an asset allocation perspective***
I. Nolte and Q. Xu (2014)

Separating jumps from diffusion gives better volatility forecasts; they can be used in portfolio construction (“volatility timing”), either in the variance matrix in an optimization problem, or in a “parametric portfolio construction” (the portfolio weights are a linear function of some state variable, linked to the volatility components).

Volatility indices and state-preference pricing
Z.F. Liu (2014)

The VIX was originally computed from ATM options on the SP100 and the Black-Scholes formula. It is now computed from OTM SP500 options, but, although it no longer relies on the Black-Scholes formula, it is not completely model-free, ignores trading volume and includes illiquid options.

The article suggests a model-free approach (by constructing a “variance” option, that pays the squared log-returns) using only liquid vanilla options.

***Effects of financial crises on the long memory
volatility dependency of foreign exchange
rates: the Asian crisis vs the global crisis***
Y.W. Han (2014)

Long-memory, *i.e.*, the slow decay of the autocorrelation (processes between stationary and integrated) can be estimated with ARFIMA models (more precisely, for volatility, ARMA-FIGARCH) or by the local Whittle estimator (the asymptotic behaviour of the spectrum (periodogram) when $\omega \rightarrow 0^+$).

Omega risk model with tax
Z. Cui (2014)

Ruin theory models, such as the first hitting time

$$\tau = \inf\{t \geq 0 : X_t \leq 0\},$$

the deterministic grace period (Chapter 11)

$$\tau = \inf\{t \geq 0 : \forall s \in [t - \varepsilon, t] X_s \leq 0\}$$

or the stochastic grace period (omega risk model, $w(X_s)\mathbf{1}_{X_s \leq 0}$ is the intensity of a Poisson process)

$$\tau = \inf\{t \geq 0 : \int_0^t w(X_s)\mathbf{1}_{X_s \leq 0} ds > e\}$$

can be augmented with taxes (paid at rate γ when $X_t = \bar{X}_t$).

X_t = pre-tax value

U_t = after-tax value

$dU_t = dX_t - \gamma \bar{X}_t d\bar{X}_t$

\bar{X}_t = running maximum

***On a new index of riskiness:
theoretical results and some applications***
R. Resta and M.E. Marina (2013)

The riskiness of a gamble g can be measured by finding $\alpha = R_{AS}(g)$ such that $E[e^{-g/\alpha}] = 1$; this is monotonic wrt stochastic dominance. This can be generalized to $\alpha = I_\theta(g)$ such that

$$\frac{E[e^{-g-\cdot/\alpha} - 1]}{E[1 - e^{-g+\cdot/\alpha}]} = \theta.$$

Model risk of risk models
J. Danielsson et al. (2014)

To measure model risk, use several risk models (MA, EWMA, GARCH, t-GARCH, EVT, historical, etc.) and look at the ratio

$$\frac{\text{highest VaR (or ES)}}{\text{lowest}}.$$

The co-expected-shortfall is

$$\text{CoES} = E[X|M \leq M_\alpha],$$

where X are the stock returns, M the market returns, M_α the α -quantile of the market returns. The CoVaR is similarly defined.

On the measurement of economic tail risk
S. Kou and X. Peng (2014)

Median shortfall is the only “economically sound” (notion defined with a set of axioms) tail risk measure (yes, it is just a VaR).

The main problem (“elicitability”) with the expected shortfall (ES) is that, at least theoretically, you cannot check that your ES estimate is correct: something very bad could happen much farther in the tail, that would have no effect on the VaR, but a huge effect on the ES.

Power law and evolutionary trends in stock markets
P.V.S. Balakrishnan et al. (2007)

The power law exponent of stock trading volume has been increasing since 1965, suggesting a higher concentration of trades.

Rollover risk and volatility risk in credit spread models: a unified approach
S. Perrakis and R. Zhong (2013)

Credit risk is often estimated as a barrier option on the value of the firm, modeled as a random walk. The model can be improved by adding:

- The capital structure;
- Illiquidity risk – an illiquid bond market increases the *rollover risk*;
- Volatility risk – volatility is not constant (the article uses a CEV process).

Estimating stochastic volatility models using realized measures
J. Bekierman and B. Gribisch (2014)

Add the realized volatility to your GARCH or stochastic volatility model:

$$\begin{aligned}\text{return}_t &= e^{\lambda_t/2} \varepsilon_t \\ \log(\text{realized volatility}_t) &= \xi + \lambda_t + \sigma_1 u_t \\ \text{latent volatility} &= \lambda_t = \gamma + \delta \lambda_t + \sigma_2 \eta_t \quad ??? \\ \varepsilon_t, u_t, \eta_t &\sim N(0, 1).\end{aligned}$$

A user’s guide to the Cornish-Fisher expansion
D. Maillard (2012)

The Cornish-Fisher expansion is often considered as a black box: “compute the skewness and kurtosis of your distribution, plug them into the formulas, and retrieve the VaR and CVaR”. The expansion is actually very simple: a Gaussian random variable $Z \sim N(0, 1)$ can be transformed into a non-Gaussian one:

$$X = f(Z) = Z + \frac{S}{6}(Z^2 - 1) + \frac{K}{24}(Z^3 - 3Z) - \frac{S^2}{36}(2Z^2 - 5Z)$$

(understanding where this specific degree-3 polynomial comes from is less simple).

There are two common mistakes.

- To easily compute the VaR and CVaR of X from those of Z , f should be bijective: this imposes restrictions on the S and K parameters.
- The moments of X are not $(0, 1, S, 3 + K)$, but only asymptotically so, when $S, K \rightarrow 0$. In particular, what needs to be put in the formula is not the skewness and kurtosis, but the skewness and kurtosis *parameters* (the article fails to stress that the variance is affected by the same problem). The actual moments can be numerically transformed into the needed parameters.

Forward-looking measures of higher-order dependencies with an application to portfolio selection
F. Brinkmann et al. (2014)

Option prices can be used to estimate higher moments (skewness, kurtosis). In a multi-asset situation, the variance, skewness and kurtosis tensors can be modeled in a parsimonious way by assuming that the “higher correlations” (normalized covariance, coskewness, cokurtosis) are all equal, *i.e.*, besides the univariate parameters, there are only three parameters to estimate (ρ^{cov} , ρ^{coskew} , ρ^{cokurt}). Those higher moments can be used in portfolio optimization (take a 4th order Taylor expansion of the expected utility).

FVA explained: is there a solution?
D. Lu and F. Juan

When marking to market derivatives, one should also consider

- CVA (credit value adjustment), *i.e.*, the credit risk of the counterparty (CDS spread);
- DVA (debit value adjustment), *i.e.*, the credit risk of the bank itself;
- FVA (funding value adjustment), *i.e.*, the cost of funding the collateral for the derivative – uncollateralized derivatives are becoming rarer and rarer and the funding cost is not exactly the CDS spread.

Recovering from derivatives funding: a consistent approach to DVA, FVA and hedging
C.J. Gunnesson and A.F. Muñoz de Morales (2014)

CVA, DVA, FVA can be priced by replication.

KVA: capital valuation adjustment
A. Green et al. (2014)

Besides CVA, DVA, FVA, one can also include the cost of regulatory capital (KVA) in derivative valuation.

On multicurve models for the term structure
L. Morino and W.J. Runggaldier (2014)

To price forward rate agreements (FRA) and other fixed income products, you need a *multicurve model*,

with one curve for discounting, and one for the cash flows. [It had always shocked me to see people use the same curve.]

***Equity portfolio management
using option price information***
P. Christoffersen and X.N. Pan (2014)

Clear review of the use of options data for equity portfolio management:

- Smile slope = $\text{ivol}|K/S = 0.95 - \text{ivol}|K/S \approx 1$;
- $\langle \text{ivol} | \text{Call} - \text{ivol} | \text{Put} \rangle$;
- Model-free volatility, skewness, kurtosis;
- Exposure to VIX innovations, oil VIX (OVX), gold VIX (compute it yourself), copper VIX;
- Exposure to market skew;
- Exposure to VRP;
- Option-implied covariance matrix or, even, option-implied joint return distribution.

Dispersion trading in South Africa
S. Maze (2012)

A *dispersion trade* is long an index call, and short constituent calls; it is profitable if the constituents of the index are more volatile than the index.

***Option and accounting information: empirical
evidence in stock and derivative markets***
C.J. García Martín et al.

When forecasting the post-earnings announcement drift (PEAD), use options data (options volume/stock volume, open interest, etc.) if available.

***The price impact of option hedging
and the anomalous weekly reversal***
T. Wang (2014)

Hedging by option writers impacts prices, even for liquid underliers, especially around expiry, creating weekly reversals.

Identifying the drivers of predicted beta
J. Wand and J. menchero (MSCI, 2014)

One can compute betas from a factor model

$$r \sim N(\mu_0, V)$$

$$V = \text{eve}' + \Delta$$

$$\beta_i = \beta(r_i, w'r) = \frac{\text{Cov}(r_i, w'r)}{\text{Var}(w'r)} = \frac{V_{i, \cdot} w}{w'Vw}$$

and decompose it into factor contributions. One can do the same thing for the cross-sectional dispersion of the β 's.

Generalized risk-based investing
E. Jurczenko et al. (2013)

Minimum variance, maximum diversity, risk parity, etc. are special cases of the following optimization

problem:

$$\begin{array}{ll} \text{Find} & w \\ \text{To minimize} & \text{dispersion}_i \frac{w_i^\gamma}{\sigma_i^\delta} \frac{\partial \sqrt{w'Vw}}{\partial w_i} \\ \text{Such that} & w'\mathbf{1} = 1 \end{array}$$

i.e., trying to make those asset contributions equal, if possible.

***Equal-risk bounding is better than risk parity
for portfolio selection***
F. Cesarone and F. Tardella (2014)

The equal risk bounding (ERB) portfolio is the minimum risk portfolio among the risk parity portfolios built on a subsets of the assets:

$$\begin{array}{ll} \text{Find} & w \\ \text{To minimize} & \text{Max}_i w_i (Vw)_i \\ \text{Such that} & w'\mathbf{1} = 1, w \geq 0; \end{array}$$

it can also be written

$$\begin{array}{ll} \text{Find} & w, \lambda \\ \text{To minimize} & \lambda \\ \text{Such that} & \forall i w_i (Vw)_i \leq \lambda \\ & w'\mathbf{1} = 1, w \geq 0. \end{array}$$

***Efficiently combining multiple sources of alpha
in portfolio construction***
J. Menchero and J.H. Lee (MSCI, 2014)

Given a risk (or alpha) factor, one can define several portfolios. Let w_i be the weight of asset i in the market portfolio, with $\sum w_i = 1$. Let β_{ik} be the exposure of stock i to risk factor k , normalized: $\sum_i w_i \beta_{ik} = 0$, $\sum_i w_i \beta_{ik}^2 = 1$.

- The *simple factor portfolio* for factor k has weights $w_i \beta_{ik}$. (Thanks to the normalization) the factor returns can also be obtained by (univariate, time series) regression: $X_i = \alpha_i + \beta_{ik} F_k^{\text{simple}} + \varepsilon_i$.
- The *pure factor portfolio* for factor k has exposure 1 to factor k and exposure 0 to the other factors; the weights are the rows of $\beta^+ \text{diag}(w)$, where β^+ is the pseudo inverse of β ($\beta^+ = (\beta'\beta)^{-1}\beta'$ if the columns of β are linearly independent – it is a little more complicated otherwise, e.g., if you have world, country and sector factors).
- The *minimum volatility portfolio* among those with unit exposure to factor k .

***Alpha-risk factor misalignment:
does it pose a problem?***
J.H. Lee et al. (MSCI, 2013)

Portfolio optimization tends to maximize the exposure to the *residual alpha* – the part of the alpha not accounted for by the risk model –, assuming that it bears no risk. Since it does contain risk, and less information than the alpha, one can add a penalty for the exposure to this residual alpha to the optimization problem – but, quite often, this adjustment is not needed.

Diversified minimum variance portfolios
G. Coqueret (2014)

Regularization path of the minimum variance portfolio with an L^2 constraint.

Trilateral foreign exchange exposure
T.J. O'Brian (2014)

To compute (and hedge) the FX exposure of a firm in a trilateral situation (e.g., the firm and the customers use different currencies, and the price is in a third currency; two firms, from different countries, compete in a third country; firm, factory and market are in three different countries), consider unilateral shocks (*i.e.*, shocks, up or down, in one currency, leaving the other two fixed).

Pseudo-mathematics and financial charlatanism: the effects of backtest overfitting on out-of-sample performance
D.H. Bailet et al. (Notices of the AMS, 2014)

The dangers (and omnipresence) of overfitting in finance.

Significance testing in empirical finance: a critical review and assessment
J.H. Kim and P.I. Ji (2014)

Empirical finance is still in the statistical dark ages: people use conventional (arbitrary) significance thresholds, disregarding:

- Sample size;
- Economic significance (often, tests do not answer the question “is there something” but “do I have enough data to see it?”): do not test $H_0 : \beta = 0$ against $H_1 : \beta > 0$, but against $H_1 : \beta > \beta_1$ – if you do not want to choose β_1 , report a confidence interval for β ;
- Test power;
- Heteroskedasticity, autocorrelation, outliers;
- Expected losses.

One could use:

- Smaller thresholds (10^{-3} is fine in psychology);
- Bayesian methods, *i.e.*, check if

$$\frac{P(H_1|\text{data})}{P(H_0|\text{data})} = \frac{P(\text{data}|H_1) P(H_1)}{P(\text{data}|H_0) P(H_0)} > 1.$$

In addition, the publication bias is high and replicated studies almost inexistent. [I disagree: I see a lot of replicated studies – but they remain unpublished.]

Adaptive learning and survey data
A. Markiewicz and A. Pick (2013)

Homo economicus and his exact subjective probabilities should be replaced with *homo econometricianus*, who uses time series models fitted on real data (“adaptive learning”) and macroeconomic data.

Quantifying differential interpretation of public information
X.S. Sheng

By modeling analysts as Bayesian learners, blending their prior beliefs with their interpretation of new information, one can decompose the dispersion in their forecasts into a prior dispersion and the dispersion due to new information,

$$\text{Var}_{\text{new information}} = \frac{\text{Var } X_i^{\text{before}} - \lambda^2 \text{Var } X_i^{\text{after}}}{1 - \lambda^2}$$

$$X_i^{\text{after}} - X^{\text{after}} = \alpha + \lambda(X_i^{\text{before}} - X^{\text{before}}) + \varepsilon$$

Investor behavior and financial innovation: a case study on callable bull/bear contracts
X. Li et al. (2014)

Knock-out barrier options are cheap, volatile, and skewed – prospect theory can explain why investors like them (as a lottery), even though they lose money.

Bankruptcy sells stocks... but who's buying and why?
L. Coelho et al.

Bankrupt companies are actively traded, and often overpriced: they are used by retail investors as lottery stocks (high probability of a small loss, low probability of a large gain, *i.e.*, high skewness).

Pairs trading with copulas
W. Xie et al. (2014)

When implementing a pairs trading strategy (once you have identified the pair, e.g., via cointegration tests), one often just looks at the difference in normalized prices,

$$p_X(0) = p_Y(0) = 1$$

$$\Delta(t) = p_X(t) - p_Y(t)$$

$$\text{Trade when } |\Delta(t)| > 2\sigma_{\Delta(t)}.$$

Instead, one can estimate the copula of the returns, and the conditional probabilities (“mispricing indices”)

$$\text{MI}_t^{X|Y} = P[X_t < x_t | Y_t = y_t]$$

$$\text{MI}_t^{Y|X} = P[Y_t < y_t | X_t = x_t]$$

(where X_t are the returns and x_t the realized returns) and trade when $\sum_{s \leq t} \text{MI}_s^{X|Y}$ or $\sum_{s \leq t} \text{MI}_s^{Y|X}$ exceeds some threshold.

Improving pairs trading
T.R. Almeida (2011)

Pairs opening after a 1-sided shock are less profitable.

***Liquidity-adjusted price-dividend ratios
and expected returns***
B.G. Jang et al.

The price-dividend ratio is often assumed to be stationary: it can therefore be defined as a cointegration relation for $(\log(\text{price}), \log(\text{dividends}))$. But evidence suggests that it may not always be stationary: one can try to replace it with a cointegration relation for

$$(\log(\text{price}), \log(\text{dividends}), \log(\text{liquidity})),$$

where the USD trading volume can be used as a proxy for liquidity.

Random walks in dividend yields and bubbles
F. Bidian (2014)

A non-stationary dividend yield is not necessarily evidence of a bubble.

Estimating private equity market beta using cash flows: a cross-sectional regression of fund-market paired internal rates of return
Y. Jiang and J. Sáenz (2014)

To estimate the beta of private equity (PE):

- Compute the internal rate of return (IRR) of the PE investments (you need several of them, and you get an IRR for each);
- Compute the corresponding market IRRs (using the same cash flows, but invested in the market, with a non-zero final value);
- Regress.

[I am skeptical about the stability of this procedure: the market IRRs are weighted averages of market returns – they will be very, very similar, so we are almost regressing against a constant...]

***Peering inside the analyst “black box”:
how do equity analysts model companies?***
A. Markou and S. Taylor (2014)

Analysts value firms using the discounted cashflow model (DCF), with explicit cashflow forecasts (subjective, or from subjective forecasts of balance sheet items, or from subjective/historical growth rates thereof). The discount factor (weighted average cost of capital, WACC) is computed from the cost of debt, the cost of equity (equity risk premium, ERP), the tax advantage of debt, and the capital structure – some include preference shares and pension liabilities in the capital structure. The ERP is difficult to estimate – most use the CAPM. The terminal value and the time after which it is reached influence the result. The DCF is complemented by other approaches: EV/EBITDA, P/E, etc.

For more details, check Damodaran’s books.

***Changes in cash:
persistence and pricing implications***
J.Z. Chen and P.B. Shane (2010)

The changes in earnings can be decomposed into

$$\Delta \text{Earnings} = \text{Accruals} + \Delta \text{FCF}$$

$$\Delta \text{FCF} = \Delta \text{Cash} + \text{net distribution to debt holders} \\ + \text{net distribution to shareholders.}$$

The change in cash can be decomposed into a normal and an abnormal part,

$$\Delta \text{Cash} = \widehat{\Delta \text{Cash}} + \text{residual}$$

where the forecast $\widehat{\Delta \text{Cash}}$ comes from the model

$$\Delta \text{Cash} \sim \sigma_{\text{industry}}(\text{FCF}) + \\ \Delta \frac{\text{assets} - \text{BV}(\text{equity}) + \text{MV}(\text{equity})}{\text{assets}} + \\ \Delta \log(\text{assets}) + \Delta \text{FCF} + \\ \frac{\text{working capital} - \text{cash}}{\text{assets}} + \\ \Delta \frac{\text{debt}}{\text{assets}} + \Delta \frac{\text{R\&D}}{\text{assets}} + (\Delta \text{dividends} > 0) + \\ \Delta \frac{\text{cash outflow on acquisitions}}{\text{assets}} + \\ \Delta \text{Cash}_{t-1} + \text{Cash}_{t-1}.$$

Negative abnormal cash changes are persistent, and do not bode well for the company. Positive abnormal cash changes are not persistent, but such hubris is ignored by the market.

***When the use of positive language backfires:
the joint effect of language sentiment,
readability and investor sophistication
on earnings judgements***
H.T. Tan et al. (2013)

When readability is low, sentiment (*i.e.*, word choice) matters, but in opposite directions for naive and sophisticated investors.

R&D spillover and predictable returns
Y. Jiang et al. (2012)

R&D spending is an externality:

- Low R&D firms lag high R&D firms in the same industry;
- The surprises are higher for low R&D firms (in the same industry) that are not often found next to the leaders (in news, portfolios or analysts’ reports).

***What do we learn from two new
accounting-based stock market anomalies?***
S. Basu (2004)

Accounting anomalies (buy low NOA, sell short firms receiving a going-concern audit opinion, etc.) are consistent with *minimally rational markets*: the prices are

inconsistent with all investors being rational, but transaction costs are too high for rational investors to make a profit.

The roles of receivables and deferred revenues in revenue management
J. Zha (2014)

To detect manipulations, look at:

- $\Delta \text{receivables} \gg 0$ (fictitious sales, bill-and-hold);
- $\Delta \text{deferred revenue} \ll 0$ (get the cash early, ship the goods late).

Disentangling the accruals mispricing in Europe: is it an industry effect?
E. Basilico and T. Johnsen (2013)

Also look at:

- $\frac{\Delta \text{accounts receivables}}{\text{net operating assets}};$
 $\frac{\Delta \text{inventory}}{\text{net operating assets}};$
- Days of sales outstanding = $\frac{\Delta \frac{\text{receivables}}{\text{sales}}}{\frac{\text{sales}}{\text{receivables}}};$
- Days of inventory outstanding = $\frac{\Delta \frac{\text{inventory}}{\text{COGS}}}{\frac{\text{inventory}}{\text{COGS}}}.$

R in Finance 2014

Packages. Among the packages presented, beyond the usual `data.table` and `Rcpp` (with C++11 features), and the omnipresence of `shiny`:

- The next edition of *Modeling Financial Time Series with SPlus* ditches SPlus (and will contain a list of must-know R packages);
- `eventstudies` for the Patell test;
- `FlexBayes` fits hierarchical models (linear, logistic, Poisson, via MCMC);
- `ilmts` will provide Hurst exponent estimation and simulation of long (and intermediate) memory processes;
- `cds` implements the ISDA standard model for CDSs, *i.e.*, the standardized characteristics of the contract and the quoting conventions;
- The `pbo` package estimates the probability of back-test overfitting.

R engine. Recent or forthcoming performance improvements include:

- Bytecode compilation;
- Shallow duplication (since R 3.1.0);
- Reference counting (perhaps in R 3.2.0);
- Large vectors (> 16 GB);
- Parallelization: explicit parallelization works; C/C++ parallelization via OpenMP only works on Linux; implicit parallelization only works for a few functions;
- The `proftools` package will soon be available.

Portfolio construction. The `PortfolioAnalytics` package performs portfolio optimization (with ROI (`Rglpk`, `Rsymphony`, `quadprog`), random portfolios, `DEoptim`, `pso`, `GenSA`), for various types of objectives (mean, value at risk (VaR), expected shortfall (ES), standard deviation, expected utility) and constraints; the types of objective and constraints are apparently limited.

The `cccp` package will solve cone-constrained convex programs.

One should include taxes (in particular, “tax harvesting” effects in case of losses) in portfolio optimization: it can be very profitable to replace a stock with an equivalent one.

Let \mathbf{x} be the (random variable of) asset returns and $\tilde{\mathbf{x}} = (1 \ \mathbf{x}')'$. The inverse of

$$\Theta = E[\tilde{\mathbf{x}}\tilde{\mathbf{x}}'] = \begin{pmatrix} 1 & \mu' \\ \mu & \Sigma + \mu\mu' \end{pmatrix}$$

is

$$\Theta^{-1} = \begin{pmatrix} 1 + \mu'\Sigma\mu & -\mu'\Sigma^{-1} \\ -\Sigma^{-1}\mu & \Sigma^{-1} \end{pmatrix} = \begin{pmatrix} 1 + \text{sharpe}^2 & -\mathbf{w}' \\ -\mathbf{w} & \Sigma^{-1} \end{pmatrix}$$

where \mathbf{w} is the markowitz portfolio. The distribution of $\text{vech } \Theta^{-1}$ is asymptotically gaussian, and $\text{Var } \text{vech } \Theta^{-1}$ is easy to compute (from $\text{Var } \text{vech } \Theta$): it can be used to perform tests or compute confidence intervals on the Shape ratio or the portfolio weights. This can be generalized to constrained portfolios (e.g., the optimal portfolio with zero covariance wrt some reference portfolio).

To check if a signal has some predictive power on future returns, build the top and bottom quintiles, and match them (on industry, size, trading volume): if the effect disappears, it was caused by the imbalance between the portfolios. Coarsened exact matching is implemented in the `cem` package.

Cointegrated pairs do not remain so (use the `egcm` package for the tests).

Higher moments. `DEoptim` can account for higher moments in portfolio optimization.

The factor model $r_i = \sum_k b_{ik}f_k + e_i$ (with $E[r_i] = E[f_k] = E[e_i] = 0$, $f_k \perp e_i$, $e_i \perp e_j$ if $i \neq j$) can be used to decompose the higher moments of the portfolio returns.

$$E[(w'r)^2] = \sum_{ijkl} w_i w_j b_{ik} b_{jl} E[f_k f_l] + \sum_i w_i^2 E[e_i^2]$$

$$E[(w'r)^3] = \sum_{\substack{i_1, i_2, i_3 \\ k_1, k_2, k_3}} w_{i_1} w_{i_2} w_{i_3} b_{i_1 k_1} b_{i_2 k_2} b_{i_3 k_3} E[f_{k_1} f_{k_2} f_{k_3}] + \sum_i w_i^3 E[e_i^3]$$

$$E[(w'r)^4] = \dots$$

(I leave the fourth moment as an exercise to the reader: contrary to the second and third moments, the cross-products do not all disappear – you should have three

more terms.) Those higher-order tensors can be written as matrices using the Kronecker product

$$\begin{aligned} E[(w'r)^2] &= w'(BSB' + \Delta)w \\ E[(w'r)^3] &= w'(BG(B' \otimes B') + \Omega)(w \otimes w) \\ E[(w'r)^4] &= w'(BP(B' \otimes B' \otimes B') + Y)(w \otimes w \otimes w). \end{aligned}$$

Volatility models. The 2-state STAR model

$$y_t = [\lambda_t \phi_1 + (1 - \lambda_t)]' \begin{pmatrix} 1 \\ y_{t-1} \\ \vdots \\ y_{t-p} \end{pmatrix} + \varepsilon_t$$

smoothly switches between two AR models, ϕ_1 and ϕ_2 ; the state transition function $\lambda_t = \lambda(z_t)$ depends (via a logistic link) on exogenous variables z_t . It can be extended to a STARMAX model by allowing autoregressive dynamics in the state z_t .

One can use the bootstrap to estimate the precision of volatility indices (VIX, vega-weighted VIX (VVIX), liquidity- or elasticity-weighted VIX); check the `ifrogs` package for an implementation.

The `stochvol` package uses MCMC to fit stochastic volatility (SV) models: for time series modeling, regression with SV noise or factor models.

The `gpustcalibration` package uses GPUs to calibrate stochastic volatility models; it relies on `nloptr` and `DEoptim`.

Risk models. The `factorAnalytics` package can estimate risk factor models (time series, fundamental, statistical) and decompose the risk (standard deviation, VaR, ES) into risk factor contributions;

To estimate correlation, one can use shrinkage or, even better, weighted averages of shrinkage estimators.

When monitoring the volatility (or the VaR) of a portfolio, $\text{risk} = \sqrt{w'Vw}$ where $V = \beta v \beta' + \Delta$, one may want to decompose its changes into contributions of changes in weights w , changes in β , changes in v , changes in Δ . Graphically, one can look at:

$$\begin{aligned} \text{risk}(\text{portfolio}_{\text{now}}, \text{model}_t) &\sim t \\ \text{risk}(\text{portfolio}_t, \text{model}_{\text{now}}) &\sim t \\ \text{VIX}_t &\sim t \\ \text{VaR}_t^{99\%} - \text{VaR}_t^{95\%} &\sim t \end{aligned}$$

For stress-testing:

- Model the joint distribution of the risk factors and the stress factors (the stress factors may be in your risk model), either as a Gaussian or a mixture of Gaussians;
- Sample from the conditional distribution

$$\text{risk factors} \mid \text{stress factors}$$

for given values of the stress factors (−10%, −20%, −30%, etc.)

One can add the volume synchronized probability of informed trading (VPIN) to the Fama-French, momentum and liquidity factors; look at the beta of stock VPIN vs Market VPIN.

Performance measurement. To measure the performance of private equity (PE), use the cash flows to and from the fund, apply them to the benchmark, and look at $\log_{10}(\text{IRR}_{\text{PE}}) - \log_{10}(\text{IRR}_{\text{Market}})$ or

$$\frac{\text{final value}_{\text{PE}}}{\text{final value}_{\text{Market}}}.$$

Time series. To predict economic recessions, one can:

- Take high-frequency time series (e.g., daily index returns);
- Compute their spectrograms on a moving window (short-term Fourier transform (STFT), sometimes also called Gabor transform); one can notice more low-frequencies in expansion periods, and more mid-frequencies in recessions;

```
library(quantmod)
getSymbols( "^GSPC", from="1980-01-01" )
x <- log1p( as.vector( ROC( Ad( GSPC ) ) ) )
dates <- index(GSPC)
```

```
library( e1071 )
y <- stft(x, inc=1)$values
dates <- index(GSPC)
dates <- tail( dates, nrow(y) )
```

```
par(mar=c(2,1,1,1), xaxs="i")
image(
  dates, 1:ncol(y), y,
  col = rev(topo.colors(10)),
  axes = FALSE, xlab = "", ylab = ""
)
axis.Date( 1, dates )
box()
par(new = TRUE)
plot(
  dates, rowSums(y),
  type = "l", lwd = 3, axes = FALSE
)
```

```
# The patterns we see are just due
# to the volatility: they completely
# disappear if we normalize the signal
# in each window...
```

```
image(
  dates, 1:ncol(y), y/rowSums(y),
  col = rev(topo.colors(10)),
  axes = FALSE, xlab = "", ylab = ""
)
axis.Date( 1, dates )
box()
par( new = TRUE )
plot(
  dates, rowSums(y),
  type = "l", lwd = 3, axes = FALSE
)
```

- Consider those spectrograms as images, and model them as a 2-dimensional Gaussian process;
- Compute the *empirical orthogonal functions* (EOF) of the sequence of images (basically, a PCA): this gives variables with a potential predictive power on the current or future market state;
- Add low-frequency variables (GDP, perhaps also yield, etc.);
- Use *stochastic search variable selection* (SSVS) on those variables to find a parsimonious probit model, to predict the current or future state of the economy.

The `bcp` package detects change points (different means) in multivariate (Gaussian) time series, using bayesian methods. Use with log-returns (I would also try with their absolute value) for a few indices or currency pairs.

Tests. `robust::lsRobTest` provides tests on robust models (I often say that you should start to worry and pay attention to robust methods (e.g., `robust::lmRob`) when they yield significantly different results).

Text mining. When extracting sentiment from text, the position of the words is relevant: for instance, if a text starts with a lot of negative words and ends with a lot of positive words, it does not mean it is neutral. Use weighted measures of sentiment, with $\frac{1}{2}, \frac{1}{3}, \frac{2}{3}$ (1, x , $x(1-x)$), etc. as weights (they like $P_c(u) - (1-u^c)u^{3-c}$).

Networks. From the adjacency matrix A of a graph, one can compute the number of paths of length m between i and j as $[A^m]_{ij}$. The total number of paths between i and j , $[\sum_{m \geq 0} A^m]_{ij}$, may be infinite: instead, one can give less importance to longer paths, $[\sum_{m \geq 0} w_m A^m]_{ij}$, e.g., $[\exp A]_{ij}$. Many graph notions (centrality, communicability, etc.), usually computed from the adjacency matrix A , can be generalized and computed from $f(A)$ (with, e.g., $f = \exp$): the f -centrality $e'_i f(A) \mathbf{1}$ generalizes the degree, the f -communicability $f(A)_{ij}$ generalizes the number of paths. Check the `irlba` package (implicitly-restricted Lanczos method) to help compute those quantities on large, sparse matrices.

Infrastructure. The `RHIPE` package is an interface to Hadoop; `datadr` provides a simpler divide-map-reduce API, using either Hadoop (via `RHIPE`) or and in-memory key-value store. `treilliscope` applies the same ideas to treillis/lattice/faceted plots; it relies on “cognostics” (e.g., scagnostics, i.e., scatterplot cognostics) to navigate the huge number of panels.

The `rredis` package serializes/deserializes R objects to/from strings with `paste/substitute/deparsed`: it is slow for large objects (e.g., time series). `RapiSerialize` does the serialization/deserialization in C++; `RcppRedis` uses it, and can therefore efficiently deal with streaming data: for instance, C++ or Python would put the data to process in Redis, and R would read and process it.

OneTick is a tick data database, with online aggregation and complex event processing (CEP) in a GUI; the

node can be arbitrary R/Python/Java/C++ code: for instance, one could fit a state-space model (well, PCA) on a moving window to predict future returns.

CEM: Software for coarsened exact matching S.M.Iacus et al. (2009)

Coarsened Exact Matching (CEM) removes the sampling bias in observational studies: it temporarily coarsens each control variable (i.e., bins the observations and builds a histogram) and prunes the observations in the (multivariate) bins that do not have at least one control and one treated unit. The statistical analysis can then proceed on the remaining data (with weights inversely proportional to the bin sizes).

Asset Allocation with Higher Order Moments and Factor Models K. Boudt et al (2014)

An approach for identifying and predicting economic recessions in real-time using time-frequency functional models S.H. Holan et al. (2012)

Apparent criticality and calibration issues in the Hawkes self-excited point process model: application to high-frequency financial data V. Filimonov and D. Sornette (2013)

Hawkes processes (Poisson processes in which each event increases the background Poisson intensity, with an exponential or power law decay – there are several commonly-used such “kernels”) can be interpreted as branching processes (each event is either a mother event, exogenous, coming from the background intensity, or a daughter event, endogenous, coming from a previous event). The *branching ratio* is the average number of daughter events.

Goodness of fit can be assessed with a change of time, $\hat{\Lambda} = \int \hat{\lambda}$, which should give a Poisson process with $\lambda \equiv 1$.

The calibration of Hawkes processes is plagued by the following problems:

- Sensitivity to outliers (use a contamination model);
- Edge effects: missing mother events before the sample, missing daughter events after;
- Sensitivity to kernel misspecification: we often only care about the tail of the kernel, but its short-term behaviour also matters;
- Multiple extrema in the log-likelihood.

The microstructure of high-frequency data brings more problems:

- Overnight trading is not negligible, and it is different;
- The exchange only sends 1-second timestamps, and groups the ticks (to send fewer messages); The data provided tries to add miliseconds using the reception

time (ignoring latencies – problematic if they fluctuate), but there are still ties (one can try to add noise to reduce the bias);

- The data is not stationary, $\mu(t)$ is not constant: there are daily patterns (U shape) (estimate the pattern and remove it to get $\lambda \equiv 1$ – but this distorts the kernel) and announcement days are completely different (remove them);
- Regime switches (between different branching ratios, or different background intensities) are interpreted as excess clustering and bias the estimation.

An investigation of trades that move the BBO
Y. Huang et al.

The bid-ask spread is insufficient to measure liquidity: one can look into the depth of the order book by considering *strings*, *i.e.*, series of trades with non-increasing prices and computing the (average) number of trades, total volume, duration, log-return, volatility, beginning spread, beginning trade size, beginning price.

To test for variations between days or securities, one can use the intra-class correlation coefficient (ICC).

Investor networks in the stock market
R. Bilkdik et al. (2013)

While it is possible to develop an information network model and estimate it using (approximate) maximum likelihood from transaction data, this is not scalable. In a very empirical way, one can estimate the network by linking agents i and j if they trade the same asset, in the same direction, in a window of size τ , at least M times.

Agents with higher centrality trade earlier and earn higher returns.

A longitudinal analysis of asset return, volatility and corporate news network
G. Creamer et al. (2012)

Use a topic model (LDA, latent Dirichlet analysis) on a newsfeed, build a bipartite network of topics and companies (mentioned in the news items), reduce it to a network of companies (with the number of articles on the same topic as weights) and test for Granger causality between graph metrics (centrality, etc.) and returns or volatility.

A link mining algorithm for earnings forecast and trading
G. Creamer and S. Stolfo (2008)

Build a bipartite graph with directors (or directors and analysts) and firms as nodes, reduce it to a graph of firms (with the number of directors or analysts in common as weights): the network metrics (centralities, clustering coefficient) can help predict earnings surprises.

Trading networks
L. Adamic et al. (2010)

A simple limit-order book model (n brokers, a long liquidity taker, a short liquidity taker) suggests that order flow imbalance and size are visible on the network. Using transaction-level data, one can build a time-varying transaction network (e.g., on a 600-transaction window), look at network metrics

- Centrality (in-degree – out-degree);
- Absolute centrality;
- Assortativity (degree correlation);
- Clustering coefficient (comparison of the number of triangles and the number of connected triples);
- Size of the largest strongly connected component

and financial variables

- Amihud price impact;
- Bid-ask spread;
- Volatility (absolute value of the returns, squared returns or high – low);
- Intertrade duration;
- Trading volume;

Network metrics Granger-cause volume and intertrade duration.

The two faces of interbank correlation
K. Schaeck et al. (2013)

The correlation between banks can be decomposed into a diversification component (if the banks are very diversified, they are doing all possible banking activities, *i.e.*, they are all doing the same things – they are therefore exposed to the same sources of risk) and a residual component (containing, among others, the endogenic risk resulting from the relations between the banks).

$$\text{Commonality}_A = \text{Cor}(\text{returns}_A, \text{returns}_{\text{sector}})$$

$$\text{Diversification}_A = \text{Cor}(\text{returns}_A, \text{returns}_{\text{market}})$$

$$\text{Excess commonality}_A =$$

$$\text{residuals}(\text{Commonality} \sim \text{Diversification})_A.$$

If one knew the bank holdings, one could define commonality (resp. diversification) as the distance between the weights of the portfolio of bank A and the aggregate portfolio of the banking sector (resp., the market portfolio), and the excess commonality as the difference between the commonality and the minimum commonality possible for that level of diversification.

Filtering noise from correlation matrices
A. Izmailov and B. Shay (2013)

Random matrix theory (RMT) is often used to clean sample correlation matrices: since the asymptotic ($T \rightarrow \infty$, $N \rightarrow \infty$, $Q = T/N$ constant) distribution of the eigenvalues of the sample correlation matrix of a standard Gaussian random variable is known and bounded, one can discard all eigenvalues beyond the (asymptotic) maximum

$$\lambda_{\max} = (1 + Q^{-1/2})^2.$$

The article suggests a finite sample correlation (but this increases λ_{\max} , which is already very high) and measures the noise present in the correlation matrix by the “entropy”

$$\sum_i \frac{\lambda_i}{n} \log_2 \frac{\lambda_i}{n}.$$

Since, on the examples, the effect of filtering seems to be an increase in the “contrast” of the correlation matrix, one may want to compare with a simple coefficient-wise transformation, e.g., $x \mapsto x^\alpha$.

Determining the number of clusters/segments in hierarchical clustering/segmentation algorithms

S. Salvador and P. Chan

To estimate the number of clusters, consider some performance metric as a function of the number of clusters, and try to find the “knee” in its plot: $\text{Argmax}_i x_{i+1} - x_i$, $\text{Argmax}_i x_{i+1}/x_i$, $\text{Min}\{i : D^2(x)_i = x_{i+1} + x_{i-1} - 2x_i \geq c\}$, $\text{Argmax}_i D^2(x)_i$, $\text{Argmax}_i \text{res}(x \sim i)$, or the changepoint of a broken line fit to the data. If there is a lot of data, use the method again on $\llbracket 1, 2 \rrbracket$ and iterate until convergence.

The relative asset pricing model: towards a unified theory of asset pricing

A. Muraalidhar et al.

Advocacy for liability-driven investing (LDI): institutional investors (pension funds form a growing proportion of all investors) first define a “liability proxy portfolio”, describing their future liabilities (most do not do that seriously and settle for “60% equity, 40% bonds”) and then try to track or beat it. This can be modeled in a CAPM-like way,

$$E[X - X_0] = \beta E[M - L - X_0],$$

where X are the asset returns, X_0 are the risk-free returns, M are the market returns, L are the liability portfolio returns. The model can be augmented with more factors, à la Fama-French, and the presence of a reference point L accounts for prospect theory.

A robust capital asset pricing model

D. Ruffino (2014)

In mean-variance portfolio optimization

$$\hat{w} = \text{Argmax}_w \text{CE}[w'X] \approx \text{Argmax}_w w'\mu - \frac{1}{2}\lambda_1 w'V_1 w,$$

only the returns $X \sim N(\mu, V_1)$ are uncertain. In robust mean-variance optimization, μ and V_1 are also uncertain. It is possible to linearize the certainly equivalent into

$$\hat{w} \approx \text{Argmax}_w w'\mu_0 - \frac{1}{2}\lambda_1 w'V_1 w - \frac{1}{2}\lambda_2 w'V_2 w$$

where $\mu \sim N(\mu_0, V_2)$. (Note that the uncertainty on V_1 does not appear in this approximation.)

This is equivalent to the initial problem with V_1 replaced with $V_1 + (\lambda_2/\lambda_1)V_2$ – i.e., this looks like a shrinkage estimator.

The Fama-French three factors in the Chinese stock market

J. Xu and S. Zhang (2013)

The Fama-French model works well in China (higher returns for small or high-value stocks, higher R^2 when compared with the US), but pay attention to a few pitfalls:

- A large proportion of the shares are (still?) non-tradable;
- There are 4 markets (main Shanghai board, main Shenzhen board, SME, GEB – the last two, also in Shenzhen, are similar to the Nasdaq: you may, or not, want to include them);
- There are multiple share classes (A, B, H, foreign) – do not forget them when computing per-share quantities.

The determinants of convenience yields

M. Prokpczuk and Y. Wu (2013)

The carry cost is the difference between the future and spot prices. It corresponds to interest foregone, storage costs, inventory, insurance against unexpected demand, insurance against supply shocks, speculation, etc. – it can be interpreted as a convenience yield.

Rather than the spread future – spot, the convenience yield can be estimated from a model: the spot is a diffusion, the convenience yield is an Ornstein-Uhlenbeck process and it determines the spot trend). The convenience yield can be explained by:

- Global inventory levels;
- Hedging pressure (relative net/gross position for commercial traders);
- Volatility;
- Macroeconomic conditions: industrial production and inflation forecasts (from the BCEI).

Systematic tail risk

M.R.C. van Oordt (2013)

The tail beta, the sensitivity to extreme (say, beyond the 5% value at risk) market returns is persistent and a good predictor of losses during crises. However, there is no tail beta premium.

Patent- and innovation-driven performance in venture capital-backed IPOs

J. Cao et al (2013)

Patents (use the NBER patent database) are still a good sign.

***General purpose technologies
and the cross-section of stock returns***
P.H. Hsu and W. Yang

Classify patents as general-purpose (computers, telecom, electronics) or special-purpose (chemical, medical, mechanical, etc.). The difference between the growth rate of general and special purpose patents predicts industrial growth; it is a non-diversifiable risk factor, that can be added to your factor risk models (Fama-French, etc.).

***Blockholder exit threats
and financial reporting quality***
Y. Dou (2014)

The presence of blockholders (measured by the Herfindahl index of shareholders above 5%), increases financial reporting quality (measured by abnormal accruals, production costs, discretionary expenses, operating cash flow, where “abnormal” means “absolute value of the residuals of a regression against other financial variables, cross-sectionally, by industry), at least for liquid stocks.

***Environmental disclosure
and the cost of capital: evidence
from the Fukushima nuclear accident***
P. Bonetti et al. (2013)

Environmental disclosure (CO₂ emissions, etc.) is associated to a lower cost of capital (and a lower rise in cost of capital after accidents). It can be measured by: the existence of an environmental report, the inclusion of CO₂ emissions, the inclusion of a CO₂ emissions target, lower CO₂ emissions than the industry. The effect on the cost of capital can be estimated with *propensity score matching* wrt size, leverage, ROA, B/P industry.

Institutional presence
J. Sulaeman and C. Wei (2013)

Non-shareholder institutional observers improve corporate governance (and liquidity, cost of capital, information diffusion). It can be measured by the assets under management of institutional investors located in the region (US state) where the firm is headquartered.

Property theft and the cost of capital
J.D. Brushwood et al. (2013)

High state-level property crime leads to a higher cost of capital.

***Linguistic complexity in firm disclosures:
obfuscation or information?***
B.J. Bushee et al. (2013)

Linguistic complexity (measured by some linear combination of the average number of words per sentence, the average number of syllables per word, the proportion of “complex” words: Gunning fog index, Fleisch-Kincaid index) in manager-driven discourse is a sign

of obfuscation, but it is informative in analyst-driven discourse.

One can assess the relation with *information asymmetry*, measured by

- Amihud liquidity = $\frac{|\text{daily returns}|}{\text{dollar volume}}$;
- $\lambda_{GH} = 2(\lambda_1 + \lambda_2 \times \text{average size})$, where

$$\Delta p_t = \psi_1 \Delta D_t + \psi_2 (\Delta D_t \cdot \text{Size}) + \lambda_1 D_t + \lambda_2 D_1 \cdot \text{Size} + \text{noise}$$

p_t = price

D_t = sign(trade_t);

- λ_{MRR} in

$$\frac{\Delta p_t}{p_t} = \psi \Delta D_t + \lambda (D_t - \rho D_{t-1}) + \text{noise}$$

$$D_t = \text{noise} + \rho D_{t-1}.$$

Liquidity risk in credit default swap markets
B. Junge and A.B. Trolle (2013)

Market illiquidity can be measured by the difference between the price of an index CDS and its theoretical price, from the CDSes of its constituents. The corresponding index arbitrage portfolio is a *tradable liquidity factor*. It can be used in a multi-factor model, as we do for equities.

***Managing option trading risk with Greeks
when mental accounting matters***
H. Siddiqi

Many people consider call options as a surrogate for the underlying – they end up with biased Greeks and one can profit from them.

***Breaking bitcoin: does cryptocurrency
exchange activity lead to increased real activity
outside cryptocurrency exchanges?***
D. Vitt (2013)

One can use Bitcoin’s *perfect ledger* of all transactions to model the evolution of volume, price, number of transactions (with a distinction between hot (casinos) and cold (real economy) wallets), search frequency (Google trend), money supply with a VAR model and impulse-response plots.

***When finance meets physics: the impact
of the speed of light on financial markets
and their regulation***
J.J. Angel (2014)

The regulators have forgotten that information does not travel instantaneously (e.g., there are 4ms between Chicago and New York): rules such as “best execution” are actually unimplementable. Clock synchronization difficulties also prevents them from reconstructing what happened.

***ParadisEO-MOEO: a framework
for evolutionary multi-objective optimization***
A. Liefooghe et al. (2007)

ParadisEO is a C++ framework for multiobjective optimization, *i.e.*, for the estimation of the Pareto frontier. Here are some of the ideas used in those algorithms:

- Pareto ranking: a solution's rank is the number of solutions dominating it (rank-1 solutions are optimal, at least in the sample);
- Pareto front: one can group the candidate solutions into “fronts” of increasing Pareto rank, to preserve diversity;
- One can keep both an archive of Pareto optimal solutions and a current population; the strength of an archive solution is the number of population solutions it dominates; the strength of a population solution is the sum of the strengths of the archive solutions dominating it.

***The area under the ROC curve
and its competitors***
J. Hilden (1991)

There are a few variants of the ROC curve:

- OROC (ordinary ROC),

$$P(\text{positive}|D) \sim P(\text{positive}|\neg D);$$

- FROC (frequency-scaled ROC),

$$P(\text{positive}, D) \sim P(\text{positive}, \neg D);$$

- EUROC (expected utility ROC),

$$E[U(\text{treatment})|x, D] \sim E[U(\text{treatment})|x, \neg D]$$

The AUC can be interpreted as the probability of correctly distinguishing between a diseased (D) and a non-diseased ($\neg D$) patient, but it is not helpful for a single patient. The power of a diagnostic test (x) is better measured by its *diagnosticity*:

$$\text{Prior regret} = -\text{Max}\{E[U(T)], E[U(\neg T)]\}$$

$$\text{Posterior regret} = -\text{Max}\{E[U(T)|x], E[U(\neg T)|x]\}$$

$$\text{Diagnosticity} = \text{Prior regret} - E[\text{Posterior regret}]$$

***Use and misuse of the receiver operating
characteristic curve in risk prediction***
N.R. Cook (2007)

Do not use the AUC (or its generalization for survival data, the c statistic) for model selection

***Visualizing distributions
of covariance matrices***
T. Tokuda et al.

To visualize a distribution of covariance matrices (e.g., a prior), look at:

- Univariate distributions of the log-volatilities and the correlations (since distributions used as priors are often exchangeable, there are few of them to consider: $\log \sigma_1$ and ρ_{12});
- Bivariate scatterplots;
- Trivariate scatterplot of correlations

$$\begin{pmatrix} 1 & \rho_{12} & \rho_{13} \\ \rho_{12} & 1 & \rho_{23} \\ \rho_{13} & \rho_{23} & 1 \end{pmatrix};$$

- A hundred 50% equiprobability matrices for $N(0, \text{Var}(X_1, X_j))$;
- Histogram of the *effective variance* $|V|^{1/n}$ and the *effective dependence* $1 - |\text{cov2cor}(V)|^{1/n}$ (highlight samples with a high or low effective dependence in the other plots);
- The effective dependence of $V_{1:k,1:k}$ versus k .

Commonly-used priors are not as uninformative as we would like: for instance, for the inverse Wishart, ρ_{ij} is uniform, but (ρ_{ij}, ρ_{kl}) is not; even for a uniform correlation, the effective dependence depends on the size and converges to $1 - e^{-1}$.

Those plots are implemented in the **VisCov** R package.

***Trade interpretation and trade imbalances
in the European union: a network perspective***
G.M. Krings et al. (2013)

Flow, in a trade network, can be decomposed into symmetric, cyclic (often negligible) and acyclic components.

There are usually several acyclic flow graphs: choose the most diverse (maximize the sum of squared flows – Herfindahl index, *i.e.*, a generalized entropy). The acyclic graph can be decomposed into (single-source, single-destination) elementary flows: start with the nodes with no inflows as sources and no outflows as destinations (as in a topological sort), compute the maximum flow (not unique if there is a bottleneck), and choose the most diverse one.

Integration between two countries can be defined as trade/GDP.

One can also consider the random walk of a dollar on the trade network (PageRank without teleportation): the average commute time can be used as a distance; after multi-dimensional scaling (MDS), one can watch the time evolution of the network.

Political risk spreads
G. Bekaert (2013)

The political risk spread is the proportion of the sovereign spread explained by the *political risk rating* from the ICRG (international country risk grade), in a regression that also includes global macroeconomic conditions (high-yield spread), local macroeconomic conditions (GDP, GDP growth, inflation, budget, current account) and liquidity (incidence of zero daily bond returns).

One can also look at the components of the political risk rating.

Cluster PIN: a new estimation method for the probability of informed trading
Q. Gan et al. (2013)

The PIN (probability of informed trading) model

$$PIN = \frac{\alpha\mu}{\alpha\mu + \varepsilon_B + \varepsilon_S}$$

is difficult to fit. One can approximate it by considering the order imbalance $X_t = \text{Buy}_t - \text{Sell}_t$; its distribution is a mixture of three *Skellam distributions* (differences of independent Poisson variables), corresponding to the three regimes (no news, bad news, good news). It is not easier to fit, but one can use hierarchical clustering to approximate the three regimes; the resulting parameters can then be used as starting points for a more exact algorithm.

Short-horizon CEO incentives and abnormal stock returns, insider trading and earnings management
J.D. Chi et al. (2013)

Firms with short-horizon CEO incentives (data from S&P ExecuComp) and high short sales constraints (*i.e.*, with inefficient information dispersal, as measured by idiosyncratic volatility, short interest and size) are different: share price inflation and correction, greater earnings surprises, greater responses to earnings surprises, higher accruals, higher revenue for the CEO selling his shares.

To control for exogenous variables, the study uses *propensity score matching*: first, predict the probability that a firm has short-horizon CEO incentives, with a logit model from: incentive ratio (stock and option compensation, divided by total compensation), P/B , total assets (size), ROA, volatility of cash flow from operations, capital intensity (fixed assets / total assets), governance (institutional ownership, Gompers's governance index, percentage of independent directors

on the board, board size); then, compare the long- and short-horizon CEO incentive firms with a similar predicted probability of short horizon.

Lowball guidance and management's credibility
J. Chen (2013)

IBES provide management compensation term structure data.

Economic linkages inferred from news stories and the predictability of stock returns
A. Scherbina and B. Schlusche (2013)

Stock co-occurrence, in news, is informative: price shocks (after a bankruptcy, an oil spill, etc.) diffuse on that graph, making 1-day returns predictable.

Asset volatility
M. Correia et al. (2013)

Structural bankruptcy models (Merton) can be improved by better estimates of asset volatility:

- $\sigma = \lambda \sigma_{\text{Market Value}}$, where $\lambda = MV/(MV + \text{debt})$;
- $\sigma = \sqrt{\lambda^2 \sigma_{MV}^2 + (1 - \lambda)^2 \sigma_{\text{debt}}^2 + 2\rho \sigma_{MV} \sigma_{\text{debt}}}$, where ρ is shrunk towards to industry average and σ_{debt} is estimated from a representative bond;
- Replace σ_{MV} with the implied volatility (average the put and call volatilities), which is more forward-looking;
- The volatility of the RNOA (return on net operating assets), estimated from the inter-quartile range, from the quantile regression

$$RNOA_{t+1} \sim RNOA_+ + (RNOA > 0) + RNOA_- + \text{accruals} + \text{dividends} + (\text{dividends} > 0)$$

- The volatility of the seasonality-adjusted RNOA, $RNOA_t - RNOA_{t-4Q}$.

Instead of a probit model

$$\text{bankruptcy} \sim \text{leverage} + \text{past returns} + \text{market capitalization} + \text{volatility},$$

a *survival model* (predicting the time to bankruptcy) makes better use of the data.

Buffet's alpha
A. Frazzini et al. (2013)

Berkshire Hathaway's returns (at least the public stock portfolio part – the private equity part and the value of Buffet himself are difficult to replicate) can be replicated using market, size, value, low-beta and quality factors, with a 1.6 leverage – Berkshire have a low financing rate, thanks to their AAA rating, the use of insurance as liabilities, deferred taxes due to accelerated depreciation (free loans from the IRS), and the sale of derivatives.

A five-factor asset pricing model
E.F. Fama and K.R. French (2013)

The Fama-French model to explain excess returns can be extended by adding two more factors:

- Market excess returns;
- Returns of the quintile long-short size portfolio;
- Returns of the quintile long-short B/P portfolio;
- Returns of the quintile long-short profitability portfolio, where

$$\text{profitability} = \frac{\text{revenue} - \text{COGS} - \text{interest} - \text{SGA}}{\text{book equity}};$$

- Returns of the quintile long-short investment portfolio, where

$$\text{investment} = \frac{\Delta \text{assets}}{\text{previous assets}}.$$

The model is not sufficient to describe returns: the intercept is significantly different from zero – however, it is small, so it may not matter after all.

***The other side of value:
the gross profitability premium***
R. Novy-Marx (2012)

Another article on gross profits/assets.

***In short supply:
equity overvaluation and short selling***
M.D. Beneish et al. (2013)

Short selling facilitates information flow, and makes markets more efficient. Short selling constraints, e.g., lack of supply of shares to borrow, impede information flow: if you use the short interest ratio (SIR), consider correcting it for insufficient supply; the cost of borrow can be used as a proxy for supply.

(No mention of the *diversity* of supply.)

***Risk-averse reinforcement learning
for algorithmic trading***
Y. Shen et al.

Reinforcement learning can be made risk-averse: just replace the expected future reward with its expected utility, for some concave utility function.

***The meaning and use of the area under a
receiver operating characteristic (ROC) curve***
J.A. Hanley and B.J. McNeil (1982)

The area under the ROC curve can be interpreted as the probability that a randomly chosen pair of a positive and a negative observation is correctly identified; it can also be seen as a Wilcoxon statistic, which leads to sample size and power computations.

***Generating multi-asset arbitrage-free
scenario trees with global optimization***
A. Consiglio et al. (2013)

When generating scenarios for a stochastic optimization problem, one has to ensure that they are arbitrage-free. Checking if they are is a convex problem, but finding arbitrage-free scenarios that match given moments is a non-convex problem. It can be solved efficiently via a sequence of convex relaxations.

***How high frequency trading
affects a market index***
D.Y. Kenett et al. (2013)

This is not what the article is about, but the abstract suggested a study of the *term structure of beta*.

***Can Google Trends search queries
contribute to risk diversification?***
L. Kristoufek (2013)

Search volume, from Google trends (use the ticker, perhaps prefixed with “stock”), may be a proxy for risk and can be used in portfolio construction

$$\text{weight} \propto \text{search volume}^\alpha.$$

There are no comparisons with other measures of risk, with other weighting schemes (market capitalization), and the study was limited to the Dow Jones 30.

***Stochastic dominance tests
on the ASEAN40 index***
V. Aumeboonsuke (2011)

One can use stochastic dominance to compare investments or asset returns: increase the order until the difference becomes significant.

When to sell a Markov chain asset?
Q. Zhang (2013)

Computation, using the Bellman equation, of the optimal stopping time to sell a stock whose log-price follows a telegraphic process (random motion with two possible slopes, with slope changes determined by an (observable) 2-state Markov chain – equivalently, the slope changes are determined by a Poisson process).

***The fine structure of volatility feedback II:
overnight and intra-day effects***
P. Blanc et al. (2013)

Intraday and overnight returns can be modeled jointly; they behave and interact differently.

GARCH and FIGARCH models are special cases of

ARCH(∞):

$$\begin{aligned}\text{ARCH}(q) : \quad \sigma_t^2 &= s^2 + \sum_{\tau=1}^q K(\tau) r_{t-\tau}^2 \\ \text{GARCH} : \quad \sigma_t^2 &= s^2 + \sum_{\tau \geq 1} g e^{\tau/\tau_p} r_{t-\tau}^2 \\ \text{FIGARCH} : \quad \sigma_t^2 &= s^2 + \sum_{\tau \geq 1} g \tau^{-\alpha} e^{\tau/\tau_p} r_{t-\tau}^2\end{aligned}$$

Statistical inference of comovements of stocks during a financial crisis
T. Ibuki et al. (2013)

The Ising model can be used to model buy (+1) and sell (−1) decisions; the returns are $P(+1) - P(-1)$. The energy is

$$E = -\alpha \sum_{ij} S_i S_j - \beta \sum_i R S_i - \gamma \sum_i M S_i,$$

where $S_{i,k}(t) \in \{\pm 1\}$ is the decision of trader i at time t for asset k , $R = \frac{1}{N} \sum_i S_i(t-1)$ are the previous returns, $M = \frac{1}{K-1} \sum_{\ell \neq k} c_{k\ell} m_\ell$, $c_{k\ell}$ is the correlation between assets k and ℓ , m_ℓ is the behaviour of the average trader for asset ℓ .

The parameters α, β, γ can be estimated; their evolution over time can highlight regime changes; they can be used to forecast returns (e.g., currencies).

copulaedas: and R package for estimation of distribution algorithms based on copulas
Y. Gonzalez-Fernandez and M. Soto (2013)

Estimation of distribution algorithms (EDA) is a population-based global optimization algorithm:

- Start with a set of candidates, uniformly sampled in the feasible region;
- Fit a distribution (Gaussian or, as in this article, based on a multivariate copula or a vine copula);
- Sample a few candidates from this distribution;
- Replace some of the old candidates;
- Iterate.

(You may want to improve the candidates with a local search as they are generated.)

Similar software include: ParadisEO (C++) and MathEDA (Matlab).

Insider trading in Hong Kong: concentrated ownership versus the legal environment
J. Zhu et al. (2002)

Looking at Jensen's alpha (the intercept in the CAPM model) or comparing firms with their peers (build $3 \times 3 \times 3$ tercile portfolios on size, B/P and momentum) suggests that insider purchases are informative, while their sales are not. In contrast with the US, the effect is more pronounced for large (not small) companies.

Portfolio concentration and the geometry of co-movement
W. Phoa (JPM, 2013)

Diffusion maps are another dimension reduction technique (the article fails to compare it with principal component analysis (PCA), multi-dimensional scaling (MDS), independent component analysis (ICA), isomap, t-SNE, Kohonen maps, etc.):

- Compute the similarity matrix $1 + \text{Cor}(X)$;
- Divide each row by its sum, to have a probability transition matrix;
- Compute its first k eigenvectors, rescale them by the eigenvalues, and use their coefficients as coordinates.

One can estimate the *portfolio concentration* by computing the variance matrix Σ of the resulting cloud of points (using the portfolio weights) and looking at $\sqrt{\text{tr } \Sigma}$. One can estimate the *local concentration* with a kernel estimator.

This can be generalized to other measures of dependence (rank correlation, tail dependence, etc.)

An introduction to diffusion maps
J. de la Porte et al. (2008)

For the purpose of dimension reduction, small distances are more informative than large distances. Since multi-dimensional scaling (MDS) weighs them in the same way, it struggles at identifying non-linear, low-dimensional structures. Isomap uses the geodesic distance on a graph, but is not very robust to perturbations. Instead, one can consider a diffusion process (a random walk – this is very similar to the PageRank algorithm) on the complete graph, with transition probabilities

$$p(x \rightarrow y) \propto \exp - \frac{\|x - y\|^2}{2\sigma^2}.$$

Diffusion maps are projections to a lower-dimensional space coming from the spectral analysis of the transition matrix P (or P^t , after t steps) – note that this matrix is not symmetric. Those projections approximate the *diffusion distance*

$$D_t(i, j) = \sum_k |P_{ki}^t - P_{kj}^t|^2$$

(two points are close if they are similarly distant from any other third point).

Here are the computations: let K be the kernel matrix, $D = \text{diag}(K\mathbf{1})$ the (normalizing) density, $P = D^{-1}K$ the transition matrix; $Q = D^{1/2}PD^{-1/2}$ is symmetric and can be diagonalized $Q = SAS'$; $P = (D^{-1/2}S)\Lambda(D^{-1/2}S)^{-1}$ is also diagonalizable and $D^{-1/2}S = [\psi_0|\psi_1|\dots|\psi_n]$ are its right eigenvectors; send observation i to $(\lambda_1^t \psi_1(i), \dots, \lambda_k^t \psi_k(i))$ for some $k \in \llbracket 1, n \rrbracket$ and $t > 0$.

What is... Data Mining
M. Maggioni (2012)

Gentler presentation of diffusion maps.

Speaker identification using diffusion maps
Y. Michalevsky et al. (2011)

To use diffusion maps for classification tasks (e.g., speaker identification), one needs to project *new* observations on the submanifold, e.g., using the *Nyström extension*.

$$k(x, y) = \exp - \frac{\|x - y\|^2}{2\sigma^2}$$

$$d(i) = \sum_j k(x_i, x_j)$$

$$p(i, j) = \frac{k(x_i, x_j)}{d(i)}$$

The right eigenvectors ψ_k satisfy $P\psi_k = \lambda_k\psi_k$, *i.e.*

$$\psi_k(i) = \frac{1}{\lambda_k} \sum_j p(i, j)\psi_k(j).$$

That formula can be generalized to project any point z , not just one of the x_i :

$$d(z) = \sum_j k(z, x_j)$$

$$p(z, x_j) = \frac{k(z, x_j)}{d(z)}$$

$$\psi_k(z) = \frac{1}{\lambda_k} \sum_j p(z, j)\psi_k(j).$$

[There may be a confusion, in this article or in others, between eigenvectors and singular vectors, and/or between the matrices $D^{-1}K$ and $D^{-1/2}KD^{-1/2}$.]

Diffusion maps
R.R. Coifman and S. Lafon (2006)

Original article on diffusion maps, in a continuous context. One can define a *family* of diffusions (a diffusion is a continuous analogue of a random walk) as

$$k_\sigma(x, y) = \exp - \frac{\|x - y\|^2}{2\sigma^2}$$

$$d_\sigma(x) = \int k_\sigma(x, y) dy$$

$$k_{\sigma,\alpha}(x, y) = \frac{k_\sigma(x, y)}{d_\sigma(x)^\alpha d_\sigma(y)^\alpha}$$

$$d_{\sigma,\alpha}(x) = \int k_{\sigma,\alpha}(x, y) dy$$

$$p_{\sigma,\alpha}(x, y) = \frac{k_{\sigma,\alpha}(x, y)}{d_{\sigma,\alpha}(x)},$$

with $\alpha = 0, \frac{1}{2}$ or 1 (there are three parameters: α , σ and t , the number of steps in the random walk). With $\alpha = 1$, the distribution of the points on the submanifold has no influence.

**Diffusion maps and coarse-graining:
a unified framework for dimensionality
reduction, graph partitioning
and data set parametrization**
S. Lafon and A.B. Lee (2006)

For large datasets, one can aggregate the data and control the discrepancy on the diffusion distances.

Diffusion maps for signal processing
R. Talmon et al. (2013)

Diffusion maps can be used in signal processing:

- For single-channel source localization, one can record white noise from various angles, compute the corresponding diffusion map, notice that its first component ψ_1 corresponds to the location (angle), and project any new recording onto it.
- To identify repeating, transient interference (keyboard noises, etc.), one can compute the diffusion map of the frames of the signal and notice that they form two clusters: a compact one, with the interference, and a more diffuse one, with the signal (speech). The interference samples can be averaged (the speech samples are too different: averaging them is destructive).
- Non-local filtering averages a signal x with nearby signals: $\hat{x} \propto \sum_i \bar{k}(x, x_i)x_i$; the kernel \bar{k} used can come from the diffusion distance:

$$\bar{k}(x, y) = \exp - \frac{D_t^2(x, y)}{2\varepsilon^2}.$$

To build diffusion maps, the Euclidian distance is not always the best choice. Consider:

- Euclidian distance in feature space;
- Intrinsic distance: cluster the data, compute the covariance C_i of each cluster i , use the Mahalanobis distance

$$d(x, y) = \frac{1}{2}(x - y)'(C_{\text{cl}(x)}^{-1} + C_{\text{cl}(y)}^{-1})(x - y).$$

- Local PCA models: use dimension reduction, but only locally, to remove the noise when computing small distances (they matter more than large distances).

The diffusion map can be computed from the singular value decomposition (not checked). Let K be the kernel matrix, $D = \text{diag}(K\mathbf{1})$ the (normalizing) density, $P = D^{-1}K$ the transition matrix, $P = U\Lambda V'$ its singular value decomposition, $V = [\psi_0|\psi_1|\dots|\psi_n]$ its right singular vectors, $\Lambda = \text{diag}(\lambda_0, \lambda_1, \dots, \lambda_n)$ its singular values; send observation i to $(\lambda_1^t\psi_1(i), \dots, \lambda_k^t\psi_k(i))$ for some $k \in \llbracket 1, n \rrbracket$ and $t > 0$.

Applications of machine learning to finance
Z. Cazalet and R.L. Dao

Lasso regression can be used to replicate hedge funds with a parsimonious portfolio.

The *non-negative matrix factorization* (NMF)

$$A = BC$$

with $\forall i, j, k \ A_{ij}, B_{ik}, C_{kj} \geq 0$, A square, B and C rectangular and small can be used as an alternative to principal component analysis (PCA) or independent component analysis (ICA), with log-prices (not price returns); stocks can be clustered using the corresponding factors.

When fitting classification models (probit, etc.), try ensemble methods such as *bagging* or *boosting*.

The *Hodrick-Prescott* (HP) filter is a low-pass filter with an L^2 penalty on the second derivative,

$$\underset{y}{\operatorname{Argmin}} \frac{1}{2} \|y - x\|_{L^2}^2 + \lambda \|D_2 x\|_{L^2}^2.$$

One can use an L^1 penalty instead: the L^2 penalty tends to “oversmooth” the signal and the L^1 penalty tolerates isolated singularities.

Add support vector machines (SVM), with cross-validation, to your toolbox. They can also be used to smooth a signal [not clearly explained].

Experiments in conditioning risk estimates with quantified news
C. Kantos (Northfield, 2013)

Risk models are backward-looking, but they can be adjusted with contemporaneous data. GARCH models are sometimes used for this, but they do not deal well with announcement days. One can use intraday volatility, cross-sectional volatility, implied volatility (VIX if the stocks does not have a liquid options market), variation in news sentiment. Only the factor and stock-specific variances are adjusted, not the exposures or the correlations.

[Data sources: Ravenpack, Alexandria, Market Psych, Thomson Reuters, Recorded Future (sentences in the future tense).]

Cointegration strategies for asset allocation
D. diBartolomeo (Northfield, 2013)

Cointegration can provide “active returns with passive management”: find a portfolio (or a continuously-rebalanced strategy) with price P such that $P - \text{Price}(\text{index} + 3\%)$ be stationary – for hedge fund returns, use $P - \text{Price}(10\%)$. This can be described as “liability-driven investing”. The results are more robust than modern portfolio theory. VAR (vector autoregressive) models are the other traditional way of incorporating non-contemporaneous structure in time series.

An innovative look at corporate credit risk
S. Malinak (Northfield, 2013)

There are many ways of estimating the probability of default:

- Structural models (Merton, KMV): the value of the assets of a company can be modeled as a geometric random walk (estimate its volatility from the volatility or implied volatility of the stock and the capital

structure; somehow estimate its drift) and one can compute the probability that the value of the assets will drop below that of the debt (Black-Scholes formula – barrier options seem to make more sense, but simpler vanilla options actually perform better);

- Accounting models (Altman, Ohlson, etc.);
- Forward-looking accounting models, with analyst estimates instead of past reported values (when available);
- Text mining from company filings, transcripts, news feeds or broker research (the data has to be cleaned of compliance and commercial verbiage, and a sentiment lexicon specific to that kind of document is needed).

Incorporating commodities in the multi-asset-class portfolio risk assessment
D. diBartolomeo (Northfield, 2013)

Adding commodities to a risk model is not as straightforward as it may seem:

- There are too many of them: one should use a factor model, e.g., by clustering commodities into agricultural, energy, precious metals, industrial metals, performing a principal component analysis (PCA) in each cluster, and retaining the first two components (as suggested by random matrix theory (RMT));
- The correlations (between commodities, between commodities and other asset classes) are very volatile (the confidence intervals are very large, and often contain 0), even after *GARCH correction*;
- There is a lot of overlap with other asset classes: instead of adding the commodity factors to the model, one can express them using the factors already there – since it works, it suggests that, except perhaps for agricultural commodities, commodities hardly add any diversification to a portfolio.

Liquidity planning tools and strategy capacity for equity markets
D. diBartolomeo (Northfield, 2013)

The risk of a portfolio increases with size. To estimate it, decide on a *liquidation policy* (cost of liquidating $x\%$ in n days in a normal/crisis situation), compute the volatility of the portfolio, convert it to a value at risk (VaR), add the liquidity costs (from your transaction cost model), and convert the corrected VaR back to a volatility.

Quality minus junk
C.S. Asness et al. (2013)

The discounted cash flow model

$$\text{Price} = \sum_{n \geq 0} (1+r)^{-n-1} d(1+g)^n = \dots = \frac{d}{r-g},$$

where d is the next dividend, $(1+r)^{-1}$ the discount

factor, and g the growth rate, can be written

$$\begin{aligned} P/B &= \frac{d/B}{r-g} \\ &= \frac{\frac{\text{Profit}}{\text{Book value}} \times \frac{\text{Dividends}}{\text{Profit}}}{r-g} \\ &= \frac{\text{Profitability} \times \text{Payout ratio}}{\text{Required return} - \text{Growth}}; \end{aligned}$$

this suggests to combine various measures of profitability, payout (shareholder friendliness), required return (safety) and growth, in the hope that the errors will average out. A quality indicator can be constructed by adding the z -scores (rank the stocks, divide the rank with the number of stocks, apply the Gaussian inverse cumulative distribution function) of various financial ratios falling in those categories:

- Profitability: GP/A (gross profit to assets), ROE (return on equity), ROA (return on assets), CFOA (cash flows over assets), gross margin, accruals;
- Growth: change in those factors over the past 5 years;
- Safety: Altman z -score, Ohlson model, beta, leverage, ROE volatility;
- Payout: new equity, new debt, payout-to-profits (dividends paid and shares repurchased, divided by sales minus COGS (cost of goods sold)).

Quality is persistent (high autocorrelation, leading to low-turnover strategies).

The *price of quality*, *i.e.*, the slope of the regression $\log(P/B) \sim \text{quality}$ (one could use the z -score instead of a logarithm; one can define the price of each quality component similarly) is lower during bubbles.

Value investing: the use of historical financial statement information to separate winners from losers
J.D. Piotroski (2002)

Value portfolios often contain many poorly performing stocks, their performance coming from a small number of strongly performing stocks. They can be improved with a quality measure such as the Piotroski score, a sum of binary variables measuring profitability (ROA, CFO, change in ROA, accruals), capital structure (change in leverage, change in liquidity (current ratio), new equity issuance), efficiency (change in gross margin, change in turnover). This works best for stocks with inefficient information dispersion (low volume/float, market capitalization, number of analysts, media coverage, availability of earnings forecasts, etc.).

Most of the performance is gained around earnings announcements.

Financial statement analysis also separate winners from losers in Brazil
A.B. Lopes and F.C. Galdi

Even in emerging countries such as Brazil, the Piotroski score can improve value portfolios.

Change in cash-holding policies and stock return predictability in the cross section
W.R. Sodjahn (2013)

The change in cash holdings (cash/assets) has predictive power on future returns, especially for low cash/assets firms, even after controlling for size, P/B, momentum, growth, liquidity (current ratio) and idiosyncratic volatility (standard deviation of the Fama-French residuals).

The accrual anomaly
P.M. Dechow et al. (2011)

Cash earnings are more persistent than accrual earnings. Many investors focus on earnings rather than cash: accruals, *i.e.*, the piece of earnings made up by accountants, do not seem to be correctly priced. High accruals are a good predictor of inventory write-downs, SEC enforcement actions, etc.

Earnings manipulations and expected returns
M.D. Beneish et al. (2013)

The M-score is a refinement of Sloan's accruals: it combines accruals with changes in receivables/sales, gross margin, proportion of other assets, sales, depreciation rate, SGA/sales, leverage. It predicts changes in accruals and the futures returns, even after controlling for size, momentum, value and accruals.

The detection of earnings manipulations
M.D. Beneish (1999)

Construction of the M-score, a probit model to predict manipulation (future SEC accounting enforcement action or media coverage) for non-financial US firms in the late 1980s.

Financial ratios and the probabilistic prediction of bankruptcy
J.A. Olson (1980)

The Ohlson model, a refinement of the earlier Altman model, is a logit model to predict the bankruptcy of US industrial firms in 1970–1976 using the following variables: size, liabilities/assets, current ratio, net income/assets, cash flow from operations/liabilities, change in net income. (There are 3 more variables, but they are not significant: working capital/assets, liabilities \geq assets (to allow for discontinuities), negative net income for the past 2 years.)

The quality dimension of value investing
R. Novy-Marx (2013)

Review of many quality measures – Graham score, Grantham quality (high ROE, low ROE volatility, low leverage), Greenblatt's return on invested capital (EBIT/tangible capital), Sloan's accruals, Piotroski's score, Novy-Marx gross profit/assets ratio – and how they can be combined with value factors (E/P, B/P,

EBIT/EV, where the enterprise value EV is market capitalization + liabilities – cash).

The tree of LIFO
R. Cahan et al. (DB, 2012)

Many accounting-derived investment signals have been suggested, capturing accounting manipulations (e.g., difference between cash and accrual earnings), overinvestment, return on capital, distress, etc. Classification trees (CART) can combine those factors, capturing non-linearities (default models do not distinguish between low-default-risk assets; many signals show an “inverted U” pattern, *i.e.*, extreme values are bad) and conditional payoffs (e.g., default models that do not include volatility work better for high-volatility stocks; different sectors (financials...) behave differently) and avoid overfitting through pruning.

Fitting them on a 5-year window captures changing market conditions and investor preferences (leverage is good/bad in risk-seeking/adverse environments).

The model can be used as a “prescreen” for non-quant investors, or as an overlay, a long-only or a long-short strategy.

Using link mining for investment decisions: extending the Black-Litterman model
G. Creamer (2013)

Directors and companies form a bipartite network. Many social network statistics (degree, degree centrality, closeness centrality, betweenness centrality, (normalized) clustering coefficient), etc. – measured on the bipartite graph, or the graph of directors, or the graph of companies) estimate in how many pies board members have their fingers, *i.e.*, they gauge corporate governance. [No recent data available.]

Analysts following companies (IBES data) can be used in a similar way.

Understanding hedge fund alpha using improved replication methodologies
J. Chen and M.L. Tindall (2013)

Hedge fund indices can be replicated using penalized regression (lasso) or state space models (linear models whose coefficients follow a random walk, with independent errors). Methods known to be suboptimal (stepwise regression, principal component regression, partial least squares (PLS)) are indeed suboptimal. (The authors do not list the factors retained by the model and their coefficients – they tend to be very noisy and rather unusable.)

The factors used also contain option-like assets:

- Buy-write index (buy the S&P 500 and write a (covered) near-term call);
- Synthetic call (buy a 3-month ATM call and sell it one month later; do not use market prices (?) but the Black-Scholes formula, with the VIX as implied

volatility, the 3-month T-bill as risk-free rate, and the S&P 500 dividend yield);

- Synthetic put.

Regularized hedge fund clones
D. Giamouridis and S. Paterlini

Two methods have been proposed to replicate hedge funds:

- Moment replication: try to match the second, third and fourth moments of the distribution of hedge fund returns and hope that the first moment (the returns) will follow;
- Factor replication.

Adding an L^1 penalty to factor replication

$$\begin{array}{ll} \text{Find} & \beta \\ \text{to minimize} & \|r - F\beta\|_2^2 + \lambda \|\beta\|_1 \\ \text{such that} & \mathbf{1}'\beta = 1 \\ & -1 \leq \beta \leq 1 \end{array}$$

creates smaller portfolios, with a lower turnover (an L^2 penalty would also reduce the turnover), and therefore a lower implementation cost.

Hedge fund replication: putting the pieces together
V. Weber and F. Peres (2013)

Hedge fund style classification labels have little value (the entropy of the conditional probabilities $P[\text{cluster}|\text{style}]$, where the clusters come from the k -means algorithm, is high).

Hedge funds can be replicated (even if we account for transaction costs and liquidity constraints) from a set of *dynamic risk factors* (rule-based trading strategies) and various regression techniques (ordinary least squares (OLS), weighted least squares (WLS), lasso, BIC model selection):

- Dollar-neutral equity portfolios (e.g., Topix vs S&P 500);
- Carry strategies (within each asset class, go long markets in backwardation, go short markets in contango);
- Equity risk parity;
- Long-short momentum strategies (for each asset class);
- Long currency futures;
- High yield (there are no corporate bonds, but one can use a portfolio of government bonds and equities, matching the duration and the equity beta).

Hedge fund returns should be *corrected for autocorrelation*.

Alpha factors in risk models
(M. Brown, CQAsia 2013)

Try to include your alpha, or its components, in the risk model – but if you already had similar risk factors, remove them. (Some people also suggest to rotate

the risk model to make it orthogonal to your alpha, so that the optimization reduces the risk orthogonal to your alpha, without reducing your alpha.)

Flight to safety
(T. Marsh, CQAsia 2013)

The “flight to safety” is problematic: since markets have to clear, if investors want to sell risky positions, someone else has to be willing to buy them – or, rather, the price has to drop enough for someone to be willing to buy them.

The market can be modelled with 10 investors, with varying risk aversions, 5 assets, with known expected returns, volatilities and correlations, in quantities and prices such that everyone holds an optimal portfolio and markets clear. After a crisis, the prices have changed, and the investors no longer hold an optimal portfolio; in addition, their risk tolerance has dropped, and their estimates of expected returns, volatilities and correlations have changed. Can they rebalance their portfolios? How should prices change to allow markets to clear?

Wealth transfer
(H. You, CQAsia 2013)

New equity issues (resp. share repurchase) are bad (resp. good) for existing investors: they should be included when computing the value of the firm.

Generalized risk-based investing
(T. Michel, CQAsia 2013)

Equal-weighted, minimum risk, risk parity, maximum diversification (all examples of “smart betas”, *i.e.*, alternatively-weighted indices) and equal-weighted portfolios are special cases of

$$\forall i, j \quad \frac{w_i^\alpha}{\sigma_i \beta} \text{MCR}_i = \frac{w_j^\alpha}{\sigma_j \beta} \text{MCR}_j$$

for various values of α and β .

An innovative look at corporate credit risk
G. Bonne (CQAsia 2013)

There are several models to estimate the probability of default:

- Structural (Merton) models, based on leverage, volatility of assets, drift of assets;
- Ratio analysis (works better with analyst forecasts instead of reported values);
- Text mining (using filings, transcriptions of meetings with investors, etc.) – the general sentiment lexicons do not work well in this context
- Combined models.

Generating Alpha from event-based investing
(D. Pope, CQAsia 2013)

Event studies should not limit themselves to computing the average return around an event, but should use a portfolio approach, trying to actually design and implement a strategy around those events.

- The announcement of activist investing raise the price two or three weeks before and after the announcement (13D filing, when they own more than 5% of the company).
- After a CEO change, accompanied with an improvement in quality (say, return on assets (ROA) ratio) in the next six months, the price rises for one year; the effect is less pronounced with CFOs (they are more often poached).
- There is a positive (resp. negative) reaction to dividend initiations and increases (resp. decreases).

The momentum of complicated firms (conglomerates) lags that of their peers.

Quant in Asia
(B. Lau, CQAsia 2013)

One can measure overcrowding as follows: take 120 factors, combine them in random ways, look at the performance of the corresponding strategies, and compare the portfolios in the top 10% – there is some overlap, but not that much.

Gearing into reverse
C. Natividade (DB, 2013)

The variance ratio

$$\text{VR}(q) = \frac{\text{Variance}(\text{returns on intervals of size } q)}{q \times \text{Variance}(\text{returns on intervals of size } 1)}$$

(for a random walk, it is a constant function of q) suggests there is a short-term (30 minutes to 2 hours) reversal. The reversal is more pronounced for assets with a low correlation to the VIX.

Colours of trend
C. Natividade et al. (DB, 2013)

How to build a trend-following strategy:

- Use trend (time series momentum) rather than (cross-sectional) momentum if your universe has few assets;
- Add liquidity constraints (e.g., 1% of the average daily volume);
- Compute each signal for 9 different window sizes, and aggregate them (unweighted average, first principal component, or using a sentiment indicator – more weight to recent value in adverse market conditions);
- Combine all the strategies, e.g., with equal weights, mean-variance optimization, equal-risk contribution, maximum diversification, residual momentum (regress the strategy returns against the first two principal components of the asset returns, rank the (cumulated?) residuals);

- For the variance matrix needed by the mean-variance optimization, use a regime-specific variance matrix (from the sentiment indicator);
- Fine-tune the rebalancing frequency;
- There is no evidence that stop-loss rules improve the strategy.

The signals used are the following direction signals (in $\{\pm 1\}$):

- **Velocity:** $\text{EWMA}(X, a) - \text{EWMA}(X, b)$ (you can use a Hodrick–Prescott filter instead of the exponential-weighted moving average, or any low-pass filter);
- Aggregate correlation;
- Auto-regression;
- Naive direction: $X_t - X_{t-a}$;

and strength signals (in $[0, 1]$ – they can be used as trade size or leverage):

- Hurst exponent;
- Mann-Kendall test;
- Auto-turbulence;
- Technical analysis recipes (RSI, VHF, etc.).

Pairing singles

C. Natividade (DB, 2013)

Pairs trading can be seen as a trend-following strategy for several assets:

- The two assets have started to diverge and we expect them to continue to diverge;
- The two assets are usually close, but they have started to diverge; we expect them to converge soon (cointegration was not mentioned).

Clock-watchers

C. Natividade (DB, 2013)

With the volume clock instead of the wall clock (divide the day into 96 blocks of equal volume, corresponding to 15 minutes of average volume), trend-following strategies (e.g., Mann-Kendall test; short- versus long-term moving average (5 vs 25 blocks); trend-following with structural-break-test-induced stop-loss) are less volatile.

Machine (un)learning

C. Natividade (DB, 2013)

Try the following machine learning algorithms:

- Ordinary least squares;
- Support vector machines (SVM);
- Penalized regression (not mentioned);
- Gaussian process regression (in R: `gptk`, `kernlab`, etc.);
- Recurrent neural nets (RSNNS in R, `neurolab` or `pybrain` in Python);
- Deep neural nets (not mentioned, and difficult to implement);
- Regime switching models (hidden Markov models, HMM);

to predict future returns from the following features:

- Velocity;
- Acceleration;
- **Mann-Kendall test:**

$$\sum_{j-i \in \{3, 5, 10, 20, 30\}} \text{sign}(x_j - x_i)$$

- **Auto-turbulence:**

$$(y_i - \mu)' \Sigma (y_i - \mu)$$

$$\Sigma = \text{Var } y$$

$$\mu = E[y]$$

$$y_t = (x_t, x_{t-1}, \dots, x_{t-30})$$

(you can restrict y_t to the components with a significant correlation with x_t);

- Volatility (3-month, exponentially weighted).

Switching styles

K. Chen and C. Natividade (DB, 2012)

There are three main FX strategies:

- **Carry:** buy (sell) the three G10 currencies with the highest (lowest) money market rate; rebalance every 3 months;
- **Momentum:** buy (sell) currencies that appreciated (depreciated) the most over the past year; rebalance every month (this works well when the volatility is either low or high);
- **Valuation:** buy (sell) the three cheapest (dearest) currencies (for the purchasing power parity, PPP); rebalance every 3 months.

Here are a few ways of combining them:

- Style momentum: increase the weight of the best-performing one;
- **Moment optimization** (generalizations of the minimum variance portfolio – but you need robust estimators of higher comoments: L -moments, shrinkage, etc.): maximize

$$E[X] - \lambda_1 \text{Var } X + \lambda_2 \text{Skew } X - \lambda_3 \text{Kurt } X;$$

- Other general portfolio construction procedures: maximum diversification, equal risk, etc.
- Regime switching, using a market sentiment indicator.

The **sentiment indicator** is the first principal component of the following factors:

- VIX;
- MSCI Financials/MSCI World;
- Difference between 30Y and 2Y asset swap spreads;
- Average of USD, EUR, JPY 3M5Y swaption volatilities;
- TED spread (interbank rates vs treasury bills);
- Spread between BAA corporate bonds and 10-year treasuries;
- Non-financial CDS spreads;
- FX implied volatility (CVIX);

- FX volatility slope (1Y vs 1M);
- FX volatility skew;
- Emerging markets sovereign risk.

***Nineteen dubious ways to compute
the exponential of a matrix,
twenty-five years later***
C. Moler and C. Van Loan (2003)

There are many algorithms to compute the exponential of a matrix, with problems regarding reliability (the precision of the result should be known, a warning should be issued if it is insufficient), stability, accuracy, efficiency: series methods (Taylor, Padé), scaling and squaring ($e^A = (e^{A/m})^m$, where $e^{A/m}$ is computed with a series), rational approximation (good if the eigenvalues are negative), ODE solvers (general solvers are very inefficient, but the algorithms can be specialized to this special case), characteristic polynomial (if you know it, e^{tA} is a polynomial in A), eigenvalues, matrix decompositions ($A = SBS^{-1}$, with B diagonal, Jordan, triangular or block-diagonal – find a good compromise between “close to diagonal” and “well-conditioned”: the blocks correspond to nearly-confluent eigenvalues), Trotter’s formula ($e^{B+C} = \lim_{n \rightarrow \infty} (e^{B/m} e^{C/m})^m$, with $B = (A + A')/2$, $C = (A - A')/2$, and e^A , e^C are computed using their eigenvalues), Krilov spaces ($\text{Span}\{v, Av, A^2v, \dots, A^mv\}$, with m small).

In R, use the `expm` package.

The *pseudo-spectrum* can help explain the behaviour of the matrix exponential:

$$\begin{aligned}\Lambda_\varepsilon(A) &= \{z : \|(zI - A)^{-1}\| \geq \varepsilon^{-1}\} \\ &= \{z : z \in \Lambda(A + E), \|E\| \leq \varepsilon\} \\ &= \{z : \|(A - zI)v\| \geq \varepsilon, \|v\| = 1\} \\ &= \{z : \|(zI - A)^{-1}\| \geq \varepsilon^{-1}\}.\end{aligned}$$

There are nice pseudospectra plots on the Pseudospectra gateway website.

***Visualizing and inspecting
large datasets with tableplots***
M. Tennekes et al. (2013)

The *tableplot* is very similar to the *lensplot*, but the rows correspond to aggregated values, not individual observations (for qualitative variables, it is a stacked area plot, for quantitative variables, just the plot of the average in each bin – use 100 bins).

An alternative to `describe` for data exploration: `tabplot`, `tabplotGTK`; use `ff`, `LaF` for larger datasets.

***DAKS: an R package for data analysis
methods in knowledge space theory***
A. Ünlü and A. Sargin

Item response theory (IRT) (`1tm`, `mokken` in R) is used in psychometrics to model (students’) abilities and (tests’) difficulties. Knowledge space theory (KST) fulfills the same role, but is deterministic and based on the

notion of partial order (on the set of skills: $i \rightarrow j$ if skill i entails skill j). The basic local independence model (BLIM) is a probabilistic KST, accounting for a non-zero probability of careless error and lucky guess (for each item). The inductive item tree analysis (IITA) algorithm builds a sequence of partial orders (start with $i \sqsubseteq_0 j$ if $j \rightarrow i$ has no counter-examples; then $i \sqsubseteq_L j$ if $j \rightarrow i$ has at most L counter-examples and does not add any non-transitivity to \sqsubseteq_{L-1}) and pick that closest to the data, *i.e.*, minimizing $\sum_{i \neq j} (b_{ij} - b_{ij}^*)$, where b_{ij} is the number of counter-examples of $j \rightarrow i$ and b_{ij}^* their expected number.

***Mining the web for the “voice of the herd”
to track stock market bubbles***
A. Gerow and M.T. Keane

Vocabulary uniformity in financial articles (FT) (smaller set of verbs – only positive ones; smaller set of nouns – focus on a smaller set of market events) can help detect crises: use the (windowed geometric mean of the) exponent in the power law distribution of word frequency. Verbs work better. In the bull market prior to a crisis, the distribution of frequencies of positive verbs is different (as measured by the Kullback-Leibler divergence) from the long-term distribution.

***Modeling movements in oil,
gold forex and market indices using
search volume index and twitter sentiment***
T. Rao and S. Srivastava (2012)

Google search volume (use a list of words, suggested by the “related searches”, and reduce the dimension with principal component analysis (PCA)) and twitter sentiment (same keywords) can predict future weekly returns (GLD, WTI, DJIA, Nasdaq, EUR), with “95% accuracy” (sic) – even though the sentiment estimator itself is only 80% accurate.

Critical truths about power laws
M.P.H. Stumpf and M.A. Porter (2012)

All too often, the omnipresence of power laws:

- Lacks statistical support;
- Lacks a mechanistic explanation: it could just be due to the central limit theorem and the aggregation (sum) of heavy-tail random variables;
- Provides no new insight.

A guide to vehicle routing heuristics
J.F. Cordeau et al. (2002)

List of a few VRP algorithms: Clarke-Wright savings heuristic, sweep algorithm (rotate a ray centered at the depot), adaptive memory (a kind of genetic search), and various tabu algorithms (random tabu duration, penalized objective, removal of unlikely (*i.e.*, long) edges, etc.).

***A new flexible direct ROC regression model
Detection of cardiovascular risk factors
by anthropometric measures***
M.X. Rodríguez-Álvarez et al. (2010)

The dependence of the ROC curve on covariates can be modeled with a GLM or GAM model (ROC-GLM, ROC-GAM).

Data stream mining: a practical approach
A. Bifet et al. (2011)

MOA is a Java library for machine learning on streaming data, an online analogue of Weka. Contrary to Vowpal Wabbit, it only allows a small number of features (hundreds), focuses on algorithms with theoretical guarantees, (mainly decision trees and ensemble methods), and can deal with time-changing models (*concept drift*).

1. Hoefding trees (VFDT, very fast decision trees) only look at each observation once, and split a node if the information gain and/or the difference between the best and the next best variable to split on exceeds some threshold (computed from *Hoefding's inequality*); this requires storing sufficient statistics at each node. To save memory, some nodes can be deactivated. To save time, the information gains are only computed every 200 observations. Quantitative variables can be approximated by histogram (quantile) summaries or a Gaussian approximation.

For prediction, one can use the majority class of a leaf, or use the sufficient statistics stored in that leaf in a naive Bayes classifier, or use whichever method worked best for that leaf in the past.

To estimate performance, use measures robust to unbalanced classes, such as *Cohen's kappa*.

2. Online bagging estimates several models in parallel (a small number, to keep resource usage low), including each observation $\text{Pois}(1)$ times (offline bagging corresponds to a binomial distribution, whose limit is a Poisson distribution). To improve online bagging:

- Include each observation $\text{Pois}(\lambda)$ times, with $\lambda > 1$, to increase weight diversity;
- Output a random class (sampled according to the predicted probabilities), instead of the majority one.

Online boosting is similar, but with $\text{Pois}(\lambda_{i,m})$ instead, for observation i and model m , with $\lambda_{i,1} = 1$, and $\lambda_{i,m+1}$ computed from $\lambda_{i,m}$ depending on whether observation i is classified properly by model m . Online boosting does not perform as well as online bagging, especially in the presence of changes.

Instead of separate models, *option trees*, *i.e.*, trees with option (non-deterministic) nodes (both branches are taken) are more memory-efficient.

Ensembles of classifiers of different sizes (say, 2^n , for various values of n – when the size exceeds the threshold, either delete the root (the oldest node) and all its children except one – or delete everything and start

afresh) perform better: smaller trees adapt quickly, and larger trees perform better when there is no change (use weights proportional to the inverse of the square of the error rate, estimated with an exponential moving average).

To avoid overfitting, one can use depth-limited trees, or trees built on distinct subsets of the attributes (all k -element subsets) and combined with a (softmax) neural network, trained alongside the trees.

3. To account for concept drift, one can:

- Fit the model on a moving window;
- Review the previous decisions, at each node, and check if we would still make the same decision;
- Check if the error rate decreases (it should, as long as the data-generation process does not change).

The data in the moving window can be used, not only to detect change, but also to update or refit the model. The windows can be:

- A fixed window of size W (reference) and the last W observations;
- The last W observations and the W observations immediately before;
- All the possible partitions of the previous W observations into two windows.

This last idea can be improved (ADWIN):

- Only consider $\log W$ windows (the past $\lfloor c \rfloor$, $\lfloor c^2 \rfloor$, $\lfloor c^3 \rfloor$, etc. observations);
- Use an approximate data structure (exponential histogram) to store the data needed;
- Instead of an actual statistical test, use a threshold, derived from Hoefding's inequality.

This can be combined with a Kalman filter. For Hoefding trees, look for changes at each node, but adjust the threshold for multiple testing.

***Introduction to stream:
a framework for data stream mining***
J. Forrest et al.

stream is an R package for machine learning on data streams, focusing on clustering (cluster the data into a large number of micro-clusters, online, then cluster the micro-clusters into macro-clusters, offline). The interface allows for other mining tasks (classification, itemset mining), but there is no implementation yet. The clustering algorithms from MOA are available.

***A general framework for observation-driven
time-varying parameter models***
D. Creal et al. (2008)

GAS (generalized autoregressive score) models are a unified framework to describe GARCH-like models (observation-driven models, *i.e.*, the time-dependence of the parameters comes from lagged, observed values –

as opposed to, say, stochastic volatility)

$$y_t \sim p(y|y_1, \dots, y_{t-1}; f_1, \dots, f_{t-1}; x_1, \dots, x_t; \theta)$$

$$f_t = \omega + \sum_i A_i s_{t-i} + \sum_j B_j f_{t-j}$$

$$s_t = S_{t-1} \frac{\partial \log p}{\partial f_{t-1}}$$

$$S_{t-1} = I \text{ or } S_{t-1} = E_{t-1} \left[\frac{\partial \log p}{\partial f_t} \frac{\partial \log p'}{\partial f_t} \right]^{-1}.$$

(This can be seen as a kind of smoothed or shrunk Kalman filter.)

Structural and topological phase transitions on the German stock exchange
A. Sienkiewicz et al. (2013)

The minimum spanning tree (MST) computed from the correlation of stock returns changes with time, sometimes a scale-free network (the degree distribution is a power law), sometimes a star-like network (idem, with one outlier).

Coupling between time series: a network view
S. Mehraban et al. (2013)

Some of the properties of a time series can be read from its visibility graph: the vertices are the timestamps, and there is an edge between i and j if $\forall k \in]i, j[$,

$$y_k < y_i + \frac{k-i}{j-i}(y_j - y_i).$$

It can be generalized to pairs of time series (normalize them both first): edge between i and j if

$$\forall k \in]i, j[\quad y_k \leq y_i + \frac{k-i}{j-i}(x_j - x_i)$$

or

$$\forall k \in]i, j[\quad y_k \geq y_i + \frac{k-i}{j-i}(x_j - x_i).$$

Dynamics of episodic transient correlations in currency exchange rate returns and their predictability
M. Žukovič (2013)

One can look for predicability in financial time series by testing if the correlation $C_{xx}(s)$ or the bicorrelation $C_{xxx}(r, s)$ of the log-returns

$$C_{xx}(r) = E[x_t x_{t-r}]$$

$$C_{xxx}(r, s) = E[x_t x_{t-r} x_{t-s}],$$

estimated on a moving window, is zero.

Dancing links
D.E. Knuth (2000)

Dancing links, *i.e.*, the remark that it is easy to remove *and add back* an element in a doubly-linked list, can be used to efficiently keep track of the current state in depth-first (backtracking) search. For instance, in the *exact set cover* problem (given a boolean matrix, find a set of rows with exactly one 1 in each column), one can encode the matrix as two doubly-linked lists (rows and columns), and descending in the tree just removes a column and one or several rows. This can be used in many satisfaction problems:

- Packing pentominoes on a chessboard: one row for each possible position of each individual pentomino, one column for each chessboard square, 1 if it is occupied;
- The n -queen problem: one row for each possible queen position, one column for each row, column or diagonal, 1 if it is controlled;
- Sudoku: one row for each possible decision of the form “digit i in (k, l) ”, columns for constraints: “there is a number in (k, l) ”, “there is an i in row k ”, “there is an i in column l ”, “there is an i in square m ”.

Will central counterparties become the new rating agencies?
C. Kenyon and A. Green (2012)

Overreliance on central counterparties could be as bad as overreliance on rating agencies: through collateralized trades, they transform credit risk into liquidity risk, but sharp price changes (that exceed the buffer in the margin account) and invalid prices (from previous transactions (we want future transactions) or from a model) still pose problem – seek more diverse price sources.

Network analysis of correlation strength between the most developed countries
J. Miśkiewicz (2012)

Instead of looking at the minimum spanning tree of a correlation matrix, *i.e.*, start with an empty graph and progressively add the most important edges, if they do not create cycles, until the graph is connected, do the opposite: start with a complete graph and delete the least important edges as long as the graph remains connected (the result is not a tree). [The first part of the article is a very confusing estimator of $\text{Cor}(\log x, \log y)$.]

Early prediction of movie box office success based on Wikipedia activity big data
M. Mestyan et al. (2013)

Editor activity of a Wikipedia entry is yet another (crowdsourced) data source, after Twitter and Google.

Deep learning via hessian-free approximation
J. Martens (2010)

Newton's method to minimize f approximates the objective as $q_\theta(p) = f(\theta) + \nabla f(\theta)'p + \frac{1}{2}p'Bp$ and minimizes it by solving $\nabla f(\theta) + Bp = 0$. Instead of exactly minimizing this second order Taylor expansion, minimize it approximately by a few conjugate gradient (CG) steps – the whole hessian B is not needed, only a few products Bp are (*truncated Newton*).

The article also lists a few modifications, useful for neural networks: damping (do not move too far: the quadratic approximation should remain good), back-propagation to compute products with the (Gauss-Newton approximation of the) hessian, mini-batches (large, and constant during the CG runs), termination condition for the CG, *no* backtracking (in the CG runs, keeping the parameter corresponding to the best value of f , as opposed to the last value, *i.e.*, the best value of q_θ), preconditioning (change of variables), start each CG iteration in the direction of the previous one.

**A practical guide
to training restricted Boltzmann machines**
G. Hinton (2010)

Advice on setting the many, many parameters in *contrastive divergence* (with a concise, but clear explanation).

**Deep neural networks for acoustic modeling
in speech recognition**
G. Hinton et al. (2012)

Review article on deep neural networks, Gaussian-Bernoulli restricted Boltzmann machines (GRBM), contrastive divergence.

High frequency trading and mini flash crashes
A. Golub et al. (2012)

Most mini flash crashes have a regulatory origin (intermarket sweep orders, ISO: the order is executed on the exchange with the best price first, which can deplete the order book (if the exchange is less liquid) and expose stub quotes).

Discrete optimization
P. Van Hentenryck (Coursera, 2013)

Lively overview of several approaches to optimization problems; as in the real world, for the programming assignments you are not told which algorithms will work for a given problem – your first ideas are likely to fail.

0. The first attempt to solve an optimization problem is often a *greedy algorithm*. For instance, for the traveling salesman problem, you can start at a node, take the nearest neighbour, and iterate; you could also (that is better) start with a 2-element cycle, add a vertex in the best position, and iterate. For the set cover problem (often represented as a binary matrix, one element per column, one set per row), you can take the sets in order, until all the elements are covered; better, you can take the largest sets first; even better, you can take the sets with the largest number of uncovered elements first – you can also simplify the problem, e.g., by removing dominated sets or checking if there are sets that have to be taken (because there is an element that is only in this set).

The knapsack problem can be solved exactly by *dynamic programming* (let $O_{j,k}$ be the value of the optimal solution with capacity k and items $\llbracket 1, j \rrbracket$) or (depth-first, best-first, etc.) *branch and bound* (to find a bound, relax the problem by removing the capacity constraint or, better, by replacing $x \in \{0, 1\}$ with $x \in [0, 1]$).

1. *Constraint programming* keeps track of the set of possible values (“domain”) of each variable, and tries to reduce those sets by “propagating the constraints”. For instance, in the 8-queen problem, “propagating the constraints” means “marking the cells that are no longer available”. It could be called “branch-and-prune”.

From an implementation point of view, a constraint is often an object with two methods, **satisfied?** and **propagate**; it only interacts with the domain store – constraints do not interact with one another.

There are dedicated **constraint propagation** algorithms for each type of constraint. For instance, to propagate an arithmetic constraint over integers $\sum a_i x_i = 0$, one can isolate one variable $x_i = \sum_{j \neq i} a_i^{-1} a_j x_j$ and find a lower and upper bound on x_i from the lower and upper bounds on the other x_j (a few iterations may be needed).

Most constraint programming languages or libraries allow reification (transforming a condition into a binary variable) and the use of decision variables as array index – these make constraint propagation a bit trickier.

Global constraints, e.g., **allDifferent**, could be expressed with elementary constraints, but if the solver is made aware of them, it can exploit their special structure (e.g., detect infeasibility earlier, or prune more) – sudoku can be solved efficiently in this way.

Scheduling problems often use more complicated global constraints.

The domains are usually intervals (bounds consistency), but one could consider arbitrary sets instead (domain consistency – more computationally expensive).

If the problem has a symmetry, symmetry-breaking constraints can reduce the search space a single coset.

For instance, a balanced incomplete block design (BIBD) is a $v \times b$ binary matrix with r ones in each row, k ones in each column, such that the scalar product of any 2 rows is ℓ . (This is used in experiment design and software testing: b new features, v tests, each with k features, each feature appearing r times, each pair of features is tested ℓ times.) The symmetries (row and column permutations) can be removed by requiring that the rows (and columns) be in lexicographic order.

Since constraints do not communicate with each other, *Redundant constraints* can speed up the computations: you could add the sum of the constraints, or (better), a linear combination of the constraints, with coefficients 1, α , α^2 , etc.; you could also find some less obvious property of the solution.

For instance, in the car sequencing problem (the cars to build have different option, but at most a out of b consecutive cars can have option o), the cars with a given option cannot be all at the end: there is a minimum number of them in each interval $[0, k]$ – these redundant constraints help the solver realize early that a partial solution is infeasible; it links the capacity and demand constraints.

If you have two very different models, you can give them both to the solver, and link them with constraints (*dual modeling*); for instance, for the 8-queen problem, there is one queen in each column, and we want to find the corresponding row numbers, but conversely, there is one queen in each row, and we want to find the corresponding column numbers.

The implementation of global constraints often relies on graph algorithms. For instance, for the `allDifferent` constraint, feasibility can be checked by the existence of a maximum matching in the bipartite graph of variables and values. (Feasibility is a special case of constraint propagation: it either leaves the domains unchanged, or sets them all to \emptyset .)

When exploring the tree of possible assignments, there are several strategies to choose which variable to instantiate and which value to set it to: often, the most-constrained variable (smallest domain and/or largest number of constraints) leads to earlier failures and more pruning. For instance, for the Euler knight problem, you can start in a corner, and then do the other corners. Instead of choosing the variable and then its value, you can do the opposite, *i.e.*, choose the value and then the variable (e.g., in the perfect square packing problem). Instead of choosing an actual value, you can just reduce the domain, e.g., by halving it – that is a weaker commitment (magic square, car sequencing).

2. For large problems, local search, which only provides a local optimum, is a scalable alternative to exact methods – but you need to pay close attention to the definition of the neighbourhoods, to how you explore them (randomly, exhaustively, heuristically), and implement them as efficiently as possible,

The simplest neighbourhood corresponds to changing

the value of a single variable, e.g., for a satisfaction problem (you are trying to minimize the number of breached constraints), choose a variable that appears in the largest number of violated constraints and a new value to minimize the number of violations.

The next simplest neighbourhood swaps the values of two variables – in particular, if there is an `allDifferent` constraint. For instance, in the TSP problem, the 2-opt neighbourhood corresponds to swapping two edges; it can be generalized to 3-opt (remove 3 edges and rewire the nodes to have another tour – contrary to 2-opt, there are many possible rewirings) or k -opt (Lin-Kerningham).

If the the number of breached constraints is too coarse a measure of how bad a solution is, you can use the “degree” of violation instead, e.g., in an arithmetic constraint, the difference between the lhs and the rhs.

When using local search to solve a constrained optimization problem, you can solve a sequence of satisfiability problems (e.g., for graph colouring, look for a solution with k colours, and progressively decrease k – you can use the solution with $k + 1$ colours, with one colour removed, as a starting point for the search for a solution with k colours), or build a sequence of feasible solutions (e.g., maximize $\sum_i |C_i|^2$, where C_i is the set of vertices with colour i , using Kemp chains to move from one feasible solution to another), or explore both feasible and infeasible solutions, by adding a penalty for breached constraints to the objective (e.g., change the colours of one node at a time and minimize $\sum 2b_i |C_i| - \sum |C_i|^2$, where b_i is the number of bad edges in colour i – it turns out that, in this example, local minima are feasible).

Heuristics, e.g., simulated annealing (with restarts, reheats, and perhaps even a tabu list) can help escape local minima.

Tabu search keeps a list of the last k states to avoid visiting them again; instead of the whole state, you can make some property of the state (especially if the state is complex), or the (inverse of the) move (e.g., swapping the values of variables i and j) tabu. There are many variants: aspiration (accept a tabu move if it is better than everything seen so far), intensification (store high-quality solutions and return to them periodically), diversification (when there has been no progress for some time, diversify the current state, e.g., by setting some of the variables to random values), strategic oscillation (change the proportion of time spent in the feasible and infeasible regions), *late-acceptance hill-climbing* (compare the candidate solution with the solution n steps earlier – only one comparison, and keeping the value of the solutions suffices) etc.

3. Mixed integer programs (MIP) can be solved by branch-and-bound, using a linear relaxation, and branching on the most fractional variables. Reformulating the problem can make the relaxation closer to the actual problem. For instance, the constraint $x \neq y$

the node you want to put in the fringe is already there is not sufficient, you also need to update its cost). The heuristic often comes from a relaxation of the problem.

2. Constraint satisfaction problems are similar (single agent, deterministic actions, fully observed state, discrete state space), but the state is not arbitrary: it is defined by variable assignments.

A binary constraint satisfaction problem (each constraint involves two variables) can be represented by a graph, with variables as vertices and constraints as edges (if the constraints are not binary, use a bipartite graph, with two types of nodes, variables and constraints). BFS does not perform well because it only considers actual solutions in the last layer; DFS fares slightly better, but it only realizes it made a mistake when the solution is complete. *Backtracking search* checks the constraints as early as possible to prune the search tree; it can be improved by changing the variable order (most constrained first), or the value order. It can be improved further by propagating the constraints via *arc consistency*: (for binary constraints) for each arc in the constraint graph, check if for each value x in the tail there is a valid value y in the head; reprocess the arcs if you remove something from their head. This can be generalized to k -consistency (each assignment of $k - 1$ variables can be extended to an assignment of all k) – 3-consistency (path consistency) is sometimes used.

The structure of the problem can help: independent sub-problems can be solved independently; if the constraint graph is a tree, process the variables in topological order to make them consistent, and assign them in the reverse order; if the graph is a tree after removing a small number of nodes, do an exhaustive search on those nodes and use the tree algorithm for the others (cutset conditioning); consider “mega-variables” (subproblems), overlapping to ensure consistency, and forming a tree (they should satisfy the running intersection property).

Iterative improvement algorithms can also be used: local search (e.g., the *min-conflict heuristic* changes a variable to the value that violates the fewer constraints – it works very well for the n -queen problem, $n = 10^7$); simulated annealing; genetic algorithms.

3. Adversarial search, *i.e.*, two-player, perfect-information, zero-sum, deterministic games (zero-sum means that there is only one utility function, one player tries to maximize it, the other tries to minimize it) uses the same ideas: the value of a state is the best achievable outcome from that state, against an optimal adversary (*minimax*); it is sometimes possible to prune the search tree (alpha-beta pruning). It is needlessly pessimistic against a non-optimal adversary (e.g., the PacMan ghosts move randomly). If there are resource limits, go down the tree as far as possible in the allotted time, and use an evaluation function, usually some linear combination of features, (if it is sufficiently deep, it should work well). Since the agent replans at each step, infinite loops (thrashing) are possible (decide on

plan A and go left, then decide on plan B and go right, etc.).

4. Expectimax replaces the worst-case in Minimax with the average case, *i.e.*, the uncertainty does not come from a perfect adversary, but from chance (equivalently, the adversary acts randomly). The values in the leaves are utilities, and the players maximize their expected utility.

5. In a Markov decision process (MDP), the effect of the agent’s actions are not deterministic. Formally, an MDP is the datum of a set S of states, a set A of actions, transition probabilities $T_{s,a,s'}$, rewards $R_{s,a,s'}$ and a start state. The aim is to maximize the expected (discounted) reward.

By introducing chance nodes for (s, a) pairs (q -states), one can use expectimax:

$$V(s) = \text{Max}_a Q(s, a) \quad \text{Max node}$$

$$Q(s, a) = \sum_{s'} T_{s,a,s'} (R_{s,a,s'} + \gamma V_{s'}) \quad \text{Chance node.}$$

The corresponding tree is huge, has a lot of redundancies, but we only want an optimal policy $S \rightarrow A$.

The value $V_k(s)$ of a state if the game ends after k steps can be computed iteratively (*value iteration*); the values V_k converge to V , but the policy usually converges faster.

Policy iteration starts with an arbitrary policy, computes the value of the states under that policy, finds the optimal policy for those values (expectimax, 1 step), and iterates until convergence.

6. Reinforcement learning tries to solve an MDP without knowing it:

- Passive reinforcement learning starts with a policy π and learns the corresponding state values (policy evaluation);
- Temporal difference learning directly learns the state values (at each step, update the estimated value of the state you are leaving), but not allow the the corresponding optimal policy (the rewards and the transition probabilities are needed);
- *Q-learning* does the same thing, but with the Q -values; it converges to the optimal policy, even if you do not follow it (off-policy learning).

To explore the state space, one could follow the current policy with probability $1 - \epsilon$ and act randomly otherwise (ϵ -greedy) or, better, explore areas whose badness has not been established yet (boost the Q -values by adding $k/\text{number of visits}$).

If there are too many states, approximate them by a set of features, and estimate the Q -values with linear combinations of features.

Semantic hashing

R. Salakhutdinov and G. Hinton (2007)

Deep neural networks (stacked restricted Boltzman machines (RBM)) whose deepest layer has a small

number of binary variables can model word count vectors more accurately than latent semantic analysis (LSA, *i.e.*, SVD-based low-dimensional approximations of the word-document co-occurrence matrix); the values of those binary vectors can be used as a semantic hash: texts that differ by only a few bits are similar.

***Do arbitrage-free prices
come from utility maximization?***
P. Siorpaes (2012)

In an incomplete market with no arbitrage, no-arbitrage prices (of non-traded assets) form intervals. For a given utility-maximizing investor, the set of threshold prices (sell if above, buy if below) is a sub-interval. As the investor's endowment varies, these intervals cover the no-arbitrage one.

***Forecasting intraday volatility
in the US equity market.
Multiplicative component GARCH***
R.F. Engle and M.E. Sokalska (2011)

Intraday volatility can be modeled as a product of three factors, $r_{it} = \sqrt{h_t} s_i q_{ti} \varepsilon_{ti}$:

- Daily volatility (from a factor risk model) h_t ;
- Deterministic diurnal volatility pattern $s_i = E[r_{it}^2/h_t]$
- GARCH residual volatility q_{ti} .

The results are more stable if you pool the stocks by industry.

***The European debt crisis:
defaults and market equilibrium***
M. Lagi and Y. Bar-Yam (2012)

Long-term sovereign interest rate and debt/GDP ratio are linked, and their evolution can help defaults (one can compute a market-implied critical debt/GDP ratio).

***Modeling dependence with C- and D-vine
copulas: the R-package CDVine***
E.C. Brechmann and U. Schepsmeier (2013)

Vine copulas describe the dependence between n variables with $n(n-1)/2$ bivariate copulas, using Bayes's formula

$$f(x_1, \dots, x_n) = f(x_1)f(x_2|x_1) \cdots f(x_n|x_1, \dots, x_{n-1}).$$

The K-function (Kendall function) is

$$k(t) = P[C(U, V) \leq t].$$

The *K-plot* plots the sample versus the theoretical K-function. The λ -function is

$$\lambda(t) = t - P[C(U, V) \leq t];$$

one can plot it (λ -plot, with the sample and theoretical λ -functions) or use it to reduce the copula fitting

problem to a curve fitting problem (for parameter estimation or goodness-of-fit tests).

$$F_i = \frac{1}{n-1} \sum_{j \neq i} \mathbf{1}_{x_j < x_i}$$

$$G_i = \frac{1}{n-1} \sum_{j \neq i} \mathbf{1}_{y_j < y_i}$$

$$H_i = \frac{1}{n-1} \sum_{j \neq i} \mathbf{1}_{x_j < x_i, y_j < y_i}$$

$$\chi_i = \frac{H_i - F_i G_i}{\sqrt{F_i(1-F_i)G_i(1-G_i)}}$$

$$\lambda_i = 4 \operatorname{sign}[(F_i - \frac{1}{2})(G_i - \frac{1}{2})]$$

$$\times \operatorname{Max} \{(F_i - \frac{1}{2})^2, (G_i - \frac{1}{2})^2\}$$

One can also look at the χ -plot, $\chi_i \sim \lambda_i$, where χ_i can be interpreted as a local measure of dependence ("local correlation") and λ_i as the signed distance to the median.

The CDVine package also provides tests and estimators.

The fine-structure of volatility feedback
R. Chicheportiche and J.P. Bouchaud (2012)

The quadratic generalization of the GARCH model (QARCH)

$$\sigma_t^2 = s^2 + \sum_{\tau > 0} L_\tau r_{t-\tau} + \sum_{\tau, \tau' > 0} K_{\tau, \tau'} r_{t-\tau} r_{t-\tau'}$$

accounts for a dependence of the volatility on the sign of the past returns (linear term) and effects at different time scales (off-diagonal terms). Special cases include:

- The effect of both 1- and 2-day returns;

 squares of the returns
on those intervals

- The effect of the previous 1-, 5-, 20-day returns;

 squared returns

- Trends

 squared returns

 products

or

 products

***Beyond implied volatility:
extracting information from option prices***
R. Cont (1997)

In an incomplete market, the *state price density* (SPD) is not unique; to choose one, take that that minimizes hedging risk (for a given option) among all probability densities that give arbitrage-free prices (or among all densities, if hedging risk is more important than absence of arbitrage), or that closest to the historical density.

To estimate the SPD, use the option prices (or the volatility smile):

- Taylor expansion of the logarithm of the Fourier transform (cumulants, Edgeworth expansion);
- Hermite expansion of both the SPD and the payoff;
- Kernel estimator of the call option prices C to compute the density

$$e^{r(T-t)} \frac{\partial^2 C}{\partial K^2}$$

- Maximum entropy distribution under the constraints that the market prices are fair (without further constraints, it is often multimodal);
- Implied binomial trees (unstable);
- Mixture of log-normals (thin tails).

As an application, one can assume that the volatility is a function of the price, $\sigma = \sigma(S)$, estimate this function, compute the corresponding SPD, compare with another estimator (say, a kernel estimator), and use the difference as an investment signal.

The article also stresses the difference between expectation pricing (what accountants do) and no-arbitrage pricing.

Measuring capital market efficiency: global and local correlations structure
L. Kristoufek and M. Vosvrda (2012)

A low fractal dimension indicates herding; fractal dimension D and Hurst exponent H can be combined to form a “market efficiency measure”.

$$\begin{aligned} r_{xx}(0) - r_{xx}(\tau) &\underset{\tau \rightarrow 0}{\propto} \tau^{4-2D} \\ r_{xx}(\tau) &\underset{\tau \rightarrow \infty}{\propto} \tau^{2H-2} \\ r_{xx}(\tau) &= \text{Mean}_t[x_t x_{t+\tau}] \end{aligned}$$

Calibration of optimal execution of financial transactions in the presence of transient market impact
E. Busseti and F. Lillo (2012)

Finding the trading strategy (how much to trade in each 5-minute period, using the information available at that time, to trade a total quantity X during the day) to “minimize” the execution cost (the difference between the profit if everything had been traded at the open price and the actual profit – it is a random variable, so by looking at its expectation and variance, one can build a whole efficient frontier of trading strategies) can be formulated and solved as a quadratic problem.

Introduction to nloptr: an R interface to NLOpt
J. Ypma (2013)

NLOpt is a set of optimization algorithms, for constrained or unconstrained, global or local, gradient-free or not:

- Dividing rectangles (DIRECT, StoGO): not unlike Lipschitz optimization (if f is Lipschitz with constant k , then $\forall x \in [a, b] \ f(x) \geq f(a) - k(x - a)$,

- $f(x) \geq f(b) - k(b - x)$; by refining the intervals one can build a piecewise lower approximation of f), but without the knowledge of the Lipschitz constant;
- Controlled random search (CRS) with local mutation, improved stochastic ranking evolution strategy (ISRES): population-based random Nelder-Mead;
- Multi-level single linkage (local search, with many random or low-discrepancy restarts, that tries to avoid points leading to already-visited extrema);
- Constrained optimization by linear approximations;
- Bounded optimization by quadratic approximations;
- Principal axis (Brent);
- Nelder-Mead, Subplex;
- Method of moving asymptotes (MMA);
- Sequential quadratic programming (SLSQP);
- L-BGFS;
- Augmented Lagrangian (to turn a constrained optimization problem into a sequence of unconstrained ones).

An effective implementation of the Lin-Kernighan traveling salesman heuristic
L. Helsgaun

The 2-opt move for the traveling salesman problem (remove 2 edges and rewire in the only possible way) can be extended to k -opt moves (remove k edges and rewire in one of the many possible ways). The Lin-Kernighan heuristic uses the same idea, but extends a $(k - 1)$ -opt move into a k -opt move, but limits the choice of the k -th edge to the edge after the $(k - 1)$ st edge.

The traveling salesman problem: a case study in local optimization
D.S. Johnson and L.A. McGeoch (1995)

Among other algorithms, here are two heuristics to address the problem. The Clarke-Wright savings heuristics starts with a star path (return to the starting point after visiting each city) and progressively joins “nearby” cities. The Christofides heuristics constructs a minimum spanning tree, finds a minimum-length matching of its vertices of odd-degree (producing a graph all of whose vertices have even degree), and finds a Euler tour.

The late-acceptance hill-climbing heuristic
E. Burke and Y. Bykov (2012)

A variant of hill-climbing, as fast as, easier to implement than, and more robust than simulated annealing: keep a queue of past values; accept a candidate if it is better than the current solution or the solution in the queue L steps ago; put the candidate in the queue if it is better than the current solution.

The late-acceptance hill-climbing algorithm for the magic square problem
Y. Bykov

Another application of LAHC, to *magic frames* (to build a large magic square, constrain the problem some

more, and look for nested magic squares – the magic frame problems are smaller and independent).

(But there are constructive magic square algorithms: Siamese method, LUX method.)

The vehicle routing problem **T.G. Hinton (2010)**

Heuristics to solve the traveling salesman problem (TSP) include:

- The minimum spanning tree (MST) (pre-traversal order, after choosing a root);
- The *Christofides heuristic*: build the MST, find a minimum matching of the odd-degree vertices, find a Eulerian tour (*i.e.*, it visits all edges) of the resulting graph (all the vertices now have even degree), prune it to have a tour;
- Local search with k -opt neighbourhoods (remove k edges and rewire the graph into a tour in all possible ways); to speed up the search, use a neighbourhood list (only consider the $k = 40$ closest nodes of each node); with simulated annealing, select the starting temperature so that the average probability of accepting a detrimental move be 0.75.

Here are a few heuristics to solve the vehicle routing problem (VRP):

- Local search with λ -interchange neighbourhoods (swap λ vertices between two routes);
- n -opt- k : pick k routes, remove n edges, rewire in all possible ways;
- Iterated tour partition: solve the TSP problem, pick a node, start there, follow the tour until full capacity, start another tour, iterate until the end;
- Clarke-Wright (CW) heuristic (agglomerative greedy algorithm): start with 1-city routes, merge two routes, iterate – the routes to merge are those with the CW savings:

$$s(i, j) = c_{0,i} + c_{0,j} - c_{i,j}$$

or their modified version

$$s(i, j) = c_{0,1} + c_{0,j} - \lambda c_{i,j} + \mu |c_{0,i} - c_{0,j}| + \nu \frac{d_i + d_j}{\bar{d}}$$

where \bar{d} is the average demand and $\lambda, \mu, \nu \in [0, 2]$ are chosen by exhaustive search (they try to avoid “ring routes” and favour large demands). It can be randomized: sort the possible moves from best to worst and take the i th one with probability $\frac{1}{q} \mathbf{1}_{i \leq q}$ or $p(1-p)^i$.

Factors on demand **A. Meucci (2010)**

Factor risk models are often used to both estimate and decompose risk. One can use different factors for estimation and attribution: given the joint distribution of (F, Z) or (X, Z) (often, simulated data), find d to minimize the discrepancy (variance, R^2 , VaR, etc.) between $R(X)$ and $d'Z$.

For instance:

- Statistical estimation factors (random matrix theory, RMT) and industry attribution factors.
- $X = Z$ = stock returns and $R(X)$ = price of an option on this stock defines “non-linear delta”

$$\underset{d}{\text{Argmin}} \text{CVaR}(\text{option returns} - d \times \text{stock return})$$

- Use detailed, regional (numerous) estimation factors and (fewer) global attribution factors;
- Style analysis (maximize the R^2 between the portfolio returns and a linear combination of reference strategies)
- Risk attribution to the alpha components: use portfolios associated to the components of the alpha as attribution factors and minimize the variance of the residuals.

Risk management **for central bank foreign reserves** **ECB (2004)**

3. Foreign reserves management is similar to assets and liabilities management (ALM), evaluated on a tree modeling the evolution of short rate and exchange rates, with a few differences:

- The portfolio is often separated into liquid and non-liquidity-constrained parts;
- Choosing a base currency is problematic;
- Constraints of the form

$$\text{reserves} \geq 12\text{-month debt repayments} + \text{imports}$$

are imposed on the liquid portfolio;

- If the distribution of final wealth is not satisfactory, it can be “shaped” by adding (several) value at risk (VaR) constraints.

4. Foreign reserves are often excessively constrained. If you can tolerate short-term underperformance, add corporate bonds; relaxing the (liquidity, currency, duration, credit) constraints, and allowing for a larger universe, moves the efficient frontier: you can gain 1.5% in expected returns or risk – assuming that your estimates of the various market parameters are correct. However, as you diversify your portfolio, measuring risk becomes trickier.

7. The conflicting targets, wealth preservation (in the home currency) and liquidity preservation (ability

to pay in foreign currencies), call for different benchmarks. One can use robust (worst-case) optimization

$$\underset{w' \geq 0}{\text{Max}} \underset{s, b}{\text{Min}} [w' \mu - \lambda_{s, b} (w - w_b)' V_s (w - w_b)]$$

to address multiple benchmarks b , multiple scenarios s (normal and hectic, with the same correlation, but different volatilities, estimated with robust (shrinkage) estimators), and different “weights” (risk aversions) $\lambda_{s, b}$ in each case. The problem can be reformulated as a linear problem with quadratic constraints. For non-Gaussian returns, directly optimize the expected utility with a set of scenarios.

10. To account for counterparty risk (credit risk), do not simply look at the credit ratings, but check:

- The probability of default $P[\text{default}]$;
- The expected and unexpected loss (given default),

$$\text{EL} = E[\text{loss}|\text{default}]$$

$$\text{UL} = \sigma[\text{loss}|\text{default}];$$

- The portfolio expected loss $\sum_i \text{EL}_i$, the portfolio unexpected loss

$$\text{UL}' \rho \text{UL}$$

where ρ is either the default correlation (“default” is a Bernoulli random variable) or the correlation of the asset returns.

As usual, the expected and unexpected portfolio loss can be decomposed into a sum of contributions and/or used in portfolio optimization.

13. Instead of decomposing the risk (ex ante), one can decompose the *change* in risk (ex post), either as

$$\begin{aligned} \Delta \text{VaR} = & \text{VaR}(w_t, p_{t-1}, t-1) - \text{VaR}(w_{t-1}, p_{t-1}, t-1) \\ & + \text{VaR}(w_{t-1}, p_t, t-1) - \text{VaR}(w_{t-1}, p_{t-1}, t-1) \\ & + \text{VaR}(w_{t-1}, p_{t-1}, t) - \text{VaR}(w_{t-1}, p_{t-1}, t-1) \\ & + \text{rest} \end{aligned}$$

or

$$\begin{aligned} \Delta \text{VaR} = & \text{VaR}(w_t, p_t, t) - \text{VaR}(w_{t-1}, p_t, t-1) \\ & + \text{VaR}(w_{t-1}, p_t, t-1) - \text{VaR}(w_{t-1}, p_{t-1}, t-1), \end{aligned}$$

where w are the portfolio weights, p the market data (prices) and t the time. This helps understand why the risk limits are breached – to avoid blindly selling positions.

17. To decompose the risk of a portfolio, use risk factors directly interpretable by portfolio managers (even if they are not independent – for a more modern approach, check Meucci’s *factors on demand*). For instance, for a fixed income portfolio, use use shift, slope and curvature factors; for an equity portfolio, use size, value (P/E, P/B, dividend yield) and momentum (earnings revisions, price reversals, earnings torpedo (high expected earnings and price drop)) factors.

18. The performance of a fixed income portfolio can be decomposed into time, curve and spread (*i.e.*, benchmark) components:

$$\begin{aligned} \Delta &= P(t, t) - P(t-1, t-1) \\ &= B(t, t) - B(t, t-1) && \text{time} \\ &\quad + B(t, t-1) - B(t-1, t-1) && \text{curve} \\ &\quad + \text{rest} && \text{spread} \end{aligned}$$

where

$P(\text{curve}, \text{time})$ = portfolio value

$B(\text{curve}, \text{time})$ = benchmark value

19. The PnL of fixed income portfolios can be decomposed into benchmark, duration, allocation and selection components, where “duration” captures the effect of the difference between the duration of the benchmark and that of the portfolio. The factors used to explain the PnL should be portfolio-dependent.

20. Liquidity crises can be modeled as follows:

- Random inflows and outflows occur daily, and have to be addressed by the overnight tranche of the portfolio;
- If the overnight tranche exceeds some threshold ON^* , the excess is moved to the weekly tranche;
- If the weekly tranche exceeds some threshold W^* , the excess is moved to the optimized portfolio;
- Every week, the overnight tranche is replenished, up to the target ON^* , from the weekly tranche.

Using simulations (e.g., the cashflows follow an autoregressive (AR) process) one can estimate the probability of a liquidity crisis, as a function of the target levels ON^* and W^* .

21. Choose your benchmark wisely: if it only depends on one parameter, duration, and if high duration means high returns, choose the maximum duration so that

$$\text{VaR}_{95\%} \geq \frac{1}{2} \times \text{risk-free returns}$$

(or some other threshold – the reference rate could be a constant rate, or a short-term rate minus a spread).

***The expectation maximization algorithm:
a short tutorial***
S. Borman (2009)

Let x denote the observed data, z the hidden data and θ the parameters to estimate. We want to maximize

$$L(\theta) = \log p(x|\theta) = \log \sum_z p(x, z|\theta),$$

iteratively. The improvement brought by θ on the pre-

vious estimate θ_n is

$$\begin{aligned}\Delta(\theta|\theta_n) &= L(\theta) - L(\theta_n) \\ &= \log \sum_z p(x, z|\theta) - \log p(x|\theta_n) \\ &= \log \sum_z p(z|x, \theta_n) \frac{p(x, z|\theta)}{p(z|x, \theta_n)} - \log p(x|\theta_n) \\ &\stackrel{\text{Jensen}}{\geq} \sum_z p(z|x, \theta_n) \log \frac{p(x, z|\theta)}{p(z|x, \theta_n)} - \log p(x|\theta_n) \\ &= \sum_z p(z|x, \theta_n) \log \frac{p(x, z|\theta)}{p(z|x, \theta_n)p(x|\theta_n)}.\end{aligned}$$

Since $L(\theta) \geq L(\theta_n) + \Delta(\theta|\theta_n)$, with equality if $\theta = \theta_n$, a value of θ that improves the right handside will also improve the left. After dropping the terms constant with respect to θ , we end up maximizing

$$\sum_z p(z|x, \theta_n) \log p(x, z|\theta) = E_{Z|X, \theta_n}[\log p(x, z|\theta)].$$

The single formula

$$\theta_{n+1} = \underset{\theta}{\operatorname{Argmax}} \sum_z p(z|x, \theta_n) \log p(x, z|\theta)$$

is traditionally (and confusingly) decomposed into E and M steps:

- Compute the conditional probabilities $p(z|x, \theta_n)$, one for each value of z (E step);
- “Compute” the function $\sum_z p(z|x, \theta_n) \log p(x, z|\theta)$ – it is a function of θ (E step);
- Find the value θ_{n+1} of θ that maximizes it (M step).

The generalized expectation maximization (GEM) algorithm does not use $\theta_{n+1} = \underset{\theta}{\operatorname{Argmax}} \Delta(\theta|\theta_n)$ but merely $\theta_{n+1} \in \{\theta : \Delta(\theta|\theta_n) > 0\}$; this is sufficient to ensure convergence.

A quasi-Newton acceleration for high-dimensional optimization algorithms H. Zhou et al. (2009)

The EM (expectation-maximization) iteration can be written $x_{n+1} = F(x_n)$ and (hopefully) converges to a fixed point of F . One can replace it with Newton’s method to solve $G(x) = 0$, where $G(x) = x - F(x)$: $x_{n+1} = x_n - G'(x_n)^{-1}G(x_n)$, i.e.,

$$x_{n+1} = x_n - (I - F'(x_n))^{-1}G(x_n).$$

To facilitate the inversion, one can use a low-rank approximation of $F'(x_n)$. The *quasi-Newton method* uses another approximation of $F'(x)$: sufficiently close to the fixed point x_∞ ,

$$F^2 x_n - F x_n \approx F'(x_\infty)(F x_n - x_n).$$

The smallest matrix $\widehat{F'(x_\infty)}$ satisfying those equations for the last q observations is an estimate of $F'(x_\infty)$.

The speed of Shor’s algorithm J.V. Burke et al. (2007)

Shor’s r -algorithm is a generalization of steepest descent ($\gamma = 0$) and conjugate gradient ($\gamma = 1$) to find a minimizer of a (non-necessarily smooth) function f

$$\begin{aligned}x_{n+1} &= x_n - t_n B_n B_n' f'(x_n) \\ t_n &= \underset{t}{\operatorname{Argmin}} f(x_{n+1}) \\ r_{n+1} &= B_n'(f'(x_{n+1}) - f'(x_n)) \\ B_{n+1} &= B_n(I - \gamma r_{n+1} r_{n+1}')\end{aligned}$$

with good performance for non-smooth functions (in this case, f' is a subgradient).

The R Journal (2013)

This issue contains more articles than usual; among others: `RTextTool` provides a unified interface to supervised classification algorithms for text processing (`svm`, `glmnet`, `maxent`, `sldca`, `ipred::bagging`, `caTools::LogitBoost`, `randomForest`, `nnet`, `tree`); “generalized simulated annealing” (`genSA`) may be faster than `DEoptim` or `rgeoud`; `ftsa` analyzes functional time series (e.g., a yield curve, a volatility surface); qualitative comparative analysis (QCA) is another name for association rules analysis in the social sciences (small datasets), often with fuzzy sets; many packages to manipulate maps (`ggmap`, `osmar`, `OpenStreetMap`, `RGoogleMaps`); applications of sparse matrices (`Matrix`) to fit GEE models and spatial probit models; etc.

To promote/enable reproducibility and productionalization, the R package manager should account for versioning (version dependencies are currently declared, checked, but not used), like Gentoo or NPM – but this would require the ability to install and load, simultaneously, several versions of the same package.

The generalized simulated annealing algorithm in the LEED search problem E.R. Correia et al.

Generalized simulated annealing (GSA) is simulated annealing on \mathbf{R}^D , with the following visiting distribution

$$g(\Delta x) \propto \frac{1}{\left(1 + (q-1) \frac{(\Delta x)^2}{T^{2(3-q)}}\right)^{\frac{1}{q-1} + \frac{D-1}{2}}},$$

cooling scheme $T(t) \propto t^{1-q}$ and acceptance probability

$$p(\Delta E) = \left(1 + (q-1) \frac{\Delta E}{T}\right)^{-\frac{1}{q-1}}.$$

Fast simulated annealing ($q = 2$, Cauchy visiting distribution) performs well.

Here are some of the topics mentioned:

- Instead of finding the portfolio weights maximizing the expected utility, one can smooth the expected utility and look for the center of a region (in the portfolio weights space) where it is high: *probabilistic utility* formalizes this idea and computes the expected weights w for the distribution

$$p(w) \propto \exp E[\text{utility}(\text{wealth}(w))];$$

- Part of the volatility smile is due to numeric imprecisions (far from the strike, the price is almost independent of the implied volatility);
- On a toy model of asset returns (say, ARMA), one can explicitly compute the Sharpe ratio of simple strategies (say, a moving average);
- Markov chains can model the evolution (survival) of exchange-traded derivatives, by looking at their (\log_{10} -binned) volume;
- Performance attribution;
- Implied expected returns can be computed from a *set* of mean-variance optimal portfolios, e.g., capital-weighted (market), equal-weighted ($1/N$), equal risk contribution, maximum diversification ($w' \sqrt{\text{diag } V} / \sqrt{w' V w}$), and risk efficient (the tangency portfolio, under the assumption that the returns are proportional to the downside deviation);
- The high-frequency-based volatility (HEAVY) model

$$h_t = \text{Var } r_t = \omega_1 + \alpha_1 V_{t-1} + \beta_1 h_{t-1} + \lambda r_t^2$$

$$\mu_t = E[V_t] = \omega_2 + \alpha_2 V_{t-1} + \beta_2 \mu_{t-1}$$

r_t : (daily) returns

V_t : realized volatility, measured from high-frequency data;

- Change-point analysis on a time series of independent observations can be performed using cluster analysis (agglomerative or divisive) with time constraints (to ensure that the clusters are contiguous – this is not unlike key detection in music), by maximizing

$$\mathcal{E}(X, Y, \alpha) = 2E|X - Y|^\alpha - |X - X'|^\alpha - |Y - Y'|^\alpha;$$

this is implemented in the **ecp** package;

- Cluster risk portfolios assign the same risk contribution to each cluster (either user-defined clusters, e.g., asset classes, or those resulting from some clustering algorithm), and then to each asset inside each cluster;
- Many models predict the yield curve or the S&P 500 from economic variables; combining them, with weights inversely proportional to the past performance (mean squared error, with older values discounted more), improves performance – but penalized models, with all the variables, do even better;
- Network analysis of interbank overnight loans, from SEC filings, can identify those whose failure can lead to a crisis (high centrality);

- Communities in a venture capital (VC) network influence performance;
- Remortgaging can be formulated as a game between lender and borrower;
- Crashes can be predicted with the log-linear power law (LPPL) model;
- Behavioural portfolios (or goal-based optimal portfolios) are mean-variance optimal portfolios, with a constraint on the value-at-risk.

The estimation of covariance matrices was a recurring topic:

- Factor models can also be used to decompose the cross-sectional volatility;
- When estimating a variance matrix, rescale the volatility with the (smoothed) VIX to make it stationary;
- Use robust correlation estimators (MCD for market outliers, robust pairwise correlation for specific risk outliers): to avoid believing in diversification when it is not there; for dynamic alerts (plot the Mahalanobis distance versus time with a (say) $\pm 3\sigma$ band);
- Principal volatility component (PVC) analysis looks for no-ARCH portfolios (not unlike independent component analysis, which looks for non-Gaussian portfolios);

A few new packages were presented: **RND** to estimate the risk-neutral density from option prices, **modopt** (not currently available) to specify optimization (and even stochastic optimization) problems as strings (unfortunately not as expressions, as Matlab's CVX allows), **greek**s, **MTS** (unavailable) for sparse modeling (sparse parametrization or penalized estimation) of multivariate time series (VAR, VARMA, etc.).

From a programming point of view, besides **Rcpp** (to access QuantLib functions or objects not available in **RQuantLib**, to use linear algebra libraries such as **Armadillo**), **quantstrat** (to build and test investment strategies), or **data.table**, **rzmq** (an interface to ZeroMQ, an easy-to-use and language-agnostic networking library) and **scidb** were also mentioned.

Efficient indexation

An alternative to cap-weighted indices

N. Amenc et al. (2010)

Compute the *tangency portfolio* by assuming that the returns are proportional to the (rank of the) downside risk (since investors require higher returns to invest in riskier stocks) and using principal component analysis to estimate the variance matrix; shrink towards the $1/N$ portfolio by adding minimum and maximum weight constraints, $1/2N \leq w \leq 2/N$; do not rebalance every quarter but only when the absolute value of the changes in weights exceed 50%.

Scalable robust covariance

and correlation estimates for data mining

F.A. Alqallaf et al. (2002)

Robust estimators of the variance matrix are often

computationally intensive ($O(e^{dn^2})$):

- Minimum covariance determinant (MCD): take 90% of the data (at random), compute the covariance matrix, iterate, keep the matrix with the smallest determinant;
- Minimum volume ellipsoid (MVE): take 90% of the data, find the smallest ellipsoid containing those points, iterate, keep the ellipsoid with the smallest volume (MCD can be seen as a constrained MVE: the ellipsoids are those defined by the sample mean and variance);
- Fast MCD: instead of taking a different, random, independent sample at each iteration, take the 90% of the data with the smallest Mahalanobis distance.

Faster estimates can be obtained by using robust pairwise correlation estimators (but you need to fix the correlation matrix afterwards):

- Rank correlation;
- Find the robust scale s_j and location m_j of each variable j ,

$$\sum_i \psi\left(\frac{x_{ij} - m_j}{s_j}\right) = 0,$$

where ψ is the Huber function $\psi(x) = \text{Min}(\text{Max}(-c, x), x)$ or the sign function $\psi(x) = \text{sign}(x)$ and take the correlation $\text{Cor}(y_{.j}, y_{.k})$ of the transformed data $y_{ij} = \psi\left(\frac{x_{ij} - m_j}{s_j}\right)$ (Huber correlation, quadrant correlation).

Propagation of outliers in multivariate data F. Alqallaf et al.

The contamination models used to develop robust estimators rarely include *componentwise outliers* – the resulting estimators have a poor breakdown, in high dimension, in presence of such outliers.

Portfolio optimization with mental accounts S. Das et al. (2010)

It is easier for investors to specify, for each of their goals (retirement, bequest, etc.) the minimum success probability than the overall risk aversion. Each goal corresponds to a subportfolio, optimized with a value-at-risk (VaR) constraint. Under a Gaussian assumption, those portfolios are mean-variance efficient; if short sales are allowed, the resulting portfolio is still optimal (if they are not, you only lose a few basis points).

Options and structured products in behavioural portfolios S. Das and M. Statman (2013)

Options have a role to play in behavioural portfolios (VaR-constrained portfolios), even if they are overpriced (by up to 20%).

Threshold cointegration: overview and implementation in R M. Stigler (2012)

The cointegration relation can be written in VECM (vector error correction model) form,

$$\Delta Z_{t+1} = c + \lambda' Z_t a + B \Delta Z_t + \varepsilon,$$

where $\lambda' Z_t$ are the cointegration relations (e.g.,

$$\lambda = \begin{pmatrix} 1 \\ -\beta \end{pmatrix}, \quad Z_t = \begin{pmatrix} X_t \\ Y_t \end{pmatrix}$$

and a is the mean-reversion speed). It can be extended to a threshold model by having the mean-reversion speed a depend on the current regime (the regime could correspond to the position of $\lambda' Z_t$ wrt some thresholds). This is implemented in the `tsDyn` package.

The misleading value of measured correlation B.M. Damghani et al. (2012)

Correlation is rarely a good measure of how linked two assets are, and cointegration should often be preferred. For instance, its assumptions (linear, synchronous, no outliers) are seldom satisfied; it is not valid if the spread between two underlyers follows a mean-reverting process (e.g., WTI and Brent – if you have a notion of “spread”, correlation is a bad idea), or for companies sharing the same, fixed-size market, or for commodities with an equity mirror (e.g., oil and BP), or for assets with contagion/domino effects (credit derivatives), or for overlays.

Instead of replacing the correlation model

$$\begin{aligned} \frac{dx}{x} &= \sigma_1 dW_1 \\ \frac{dy}{y} &= \sigma_1 \rho dW_1 + \sigma_2 \sqrt{1 - \rho} dW_2 \quad dW_1 \perp dW_2 \end{aligned}$$

with the cointegration (Ornstein-Uhlenbeck) one

$$\begin{aligned} \frac{dx}{x} &= \sigma_1 dW_1 \\ \frac{dy}{y} &= \theta(\mu + x - y)dt + \sigma_2 dW_2 \quad dW_1 \perp dW_2 \end{aligned}$$

one could try a hybrid model

$$\begin{aligned} \frac{dx}{x} &= \sigma_1 dW_1 \\ \frac{dy}{y} &= \theta(\mu + x - y)dt + \sigma_2 dW_2 \\ \text{Cor}(dW_1, dW_2) &= \rho. \end{aligned}$$

Improving portfolio selection using option-implied volatility and skewness V. DeMiguel (2012)

With a continuum of option prices, one can compute the model-free implied volatility (MFIV)

$$\text{MFIV}_{[t,T]} = \sqrt{EQ[e^{-r(T-t)} R_{[t,T]}^2]}$$

(or the other implied moments) and, assuming that MFIV/realized volatility is constant, forecast the future realized volatility – it is a better forecast of future volatility than historical volatility. Use implied volatility and implied skewness (either the model-free implied skewness, defined as the MFIV, or the spread between the IV computed from puts and calls) in your alpha to increase performance (Sharpe ratio, etc.)

***High-quality topic extraction
from business news explains
abnormal financial market volatility***
R. Hisano (2012)

Analysis of a huge set of business news suggests that news do have an impact on trade *volume*: for the news associated to a given company, discard all stock-related news, use *latent Dirichlet analysis* (LDA) for form 100 topics (sets of words, each word is in exactly one topic), and use penalized regression to try to predict future returns.

***Factor-risk-constrained mean-variance
portfolio selection: formulation
and global optimization solution approach***
S. Zhu (2011)

Constraints on the contribution of risk factors to the portfolio risk (a quadratic term) make the portfolio optimization problem non-convex. For up to a few hundred assets, it is amenable to branch-and-bound, with a semi-definite relaxation.

Measuring financial market stress
K.L. Kliesen and D.C. Smith (2010)

One can build a “financial stress index” by looking at (weekly) interest rates (government bonds with various maturities, TIPS, corporate bonds with various credit ratings), spreads (Libor-OIS, TED), and indices (emerging market bonds, VIX, bond volatility, equities) and taking the first principal component (of the demeaned, normalized time series) (the coefficients (“loadings”) are only estimated once, when the index is first constructed; they do not change with time).

***Stability analysis of financial contagion
due to overlapping portfolios***
F. Caccioli et al. (2012)

When banks hold diversified portfolios, those portfolios overlap; a bankruptcy triggers a flash sale and a devaluation of the assets, thereby impacting other banks. Contagion is made worse by overcrowding (ratio of the number of banks by the number of assets).

***Cascading failures in bipartite graphs:
model for systemic risk propagation***
X. Huang et al. (2013)

Idem.

***A model of market limit orders
by stochastic PDEs, parameter estimation,
and investment optimization***
Z. Zheng and R.B. Sowers (2012)

The limit order book can be modeled with a (system of) *stochastic PDEs* for mid-price (a function of time) and volume (a function of price and time – positive volumes for supply, negative for demand, and the volume at the mid-price is zero).

***Keynes meets Markowitz: the tradeoff
between familiarity and diversification***
P. Boyle et al. (2009)

Knightian uncertainty (uncertainty about the parameters of probability distributions) can be introduced in portfolio construction as follows: asset returns are Gaussian, $X \sim N(\mu_0, V)$; their variance V is known but their mean μ_0 is not; we only have an estimate $\mu \sim N(\mu_0, A)$, whose precision (ambiguity, A) is known; the investor wants to maximize the expected returns, with penalties for risk and ambiguity. The article uses a robust optimization instead:

$$\text{Max}_w \text{Min}_{\mu_0} \left\{ w' \mu_0 - \lambda_1 w' V w, \frac{(\mu - \mu_0)^2}{\text{diag } A} \leq \lambda_2 \right\}.$$

***Improved performance by constraining
portfolio norms: a generalized approach to
portfolio optimization***
V. DeMiguel et al. (2007)

Adding an L^2 penalty to the portfolio optimization problem

$$\text{Min}_w \{ w' V w + \lambda \|w\|_2^2, w' \mathbf{1} = 1 \}$$

is equivalent to shrinking the covariance matrix V to $V + \lambda I$; one can equivalently use a hard constraint

$$\text{Min}_w \{ w' V w, w' \mathbf{1} = 1, \|w\|_2 \leq \nu \}.$$

Adding an L^1 constraint $\|w\|_1 \leq \ell$ restricts the leverage to ℓ ($\ell \geq 1$, e.g., 1.3 for 130/30 portfolios).

Applying the conjugate gradient algorithm to the $1/N$ portfolio to minimize the variance produces a sequence of $N - 1$ “partial minimum variance portfolios”.

***Stock return serial dependence and
out-of-sample portfolio performance***
V. DeMiguel et al. (2010)

Use a VAR (or NAR – non-parametric auto-regressive – *nearest neighbour regression*, using the 50 days closest to today’s performance) model to build a momentum portfolio (use the conditional variance and mean, $V, \mu | X_{t-1}$; it will also capture lead-lag relations; you may want to add an L^1 constraint (or penalty) to reduce turnover.

The adaptive lasso and its oracle properties
H. Zou (2006)

Prefer the adaptive lasso (the coefficients of the L^1 penalties are variable-specific, e.g., $\lambda/\hat{\beta}_{ols}^\gamma$, with $\gamma > 0$) to the lasso: it makes variable selection consistent. In R, it is implemented in `lqa::adaptive.lasso`.

A kernel statistical test of independence
A. Gretton et al.

Covariance is not sufficient to test for independence, but in a universal reproducing kernel Hilbert space (RKHS), it is. “Universal” means dense in $\mathcal{C}_b(X, \mathbf{R})$ – in practice, you will choose a kernel and hope that it is not too far from universal. The norm of the covariance operator is

$$\text{HSIC} = E[k(x_1, x_2)\ell(y_1, y_2)] + E[k(x_1, x_2)]E[\ell(y_1, y_2)] - 2E_{x_1, y_1}[E_{x_2}[k(x_1, x_2)]E_{y_2}[\ell(y_1, y_2)]]$$

and it can be estimated as

$$\frac{1}{m^2} \text{tr}(KHLH)$$

where

m = number of observations

$k_{ij} = k(x_i, x_j)$

$\ell_{ij} = \ell(x_i, x_j)$

$$H = I = \frac{1}{m} \mathbf{1}\mathbf{1}'$$

k, ℓ : kernels on X and Y .

One can compute the asymptotic distribution of this estimator under the null hypothesis $P_{xy} = P_x P_y$ and estimate the critical value for a statistical test (or to convert the test statistic to a p -value).

New approaches in visualization of categorical data: R package extracat
A. Pilhöfer and A. Unwin (2013)

Use barcharts overlaid with mosaic plots (`rmb`) and interactive (iWidgets, iPlots) parallel graphs (`cpcp`), with the variables and values reordered to reduce overplotting.

Visualizing association rules: introduction to the R-extension package arulesViz
M. Hahsler and S. Chelluboina

Here are a few ways to visualize association rules:

- Plot confidence, support, lift, number of items using two variables as coordinates and a third as colour;
- Plot the rules as a matrix, with the antecedent (lhs) on the x axis and the consequence on the y axis, reordered with the `seriation` package and/or clustered with the Jaccard distance

$$d(X_i, X_j) = 1 - \frac{|X_i \cap X_j|}{|X_i \cup X_j|};$$

- Graphs (with itemsets, or items, as nodes);
- Parallel plots, etc.

Time-frequency dynamics of the biofuels-fuels-food system
L. Vacha et al. (2012)

To study *one* time series x , one can look at its continuous wavelet transform

$$W_x(u, s) = \int x(t) \frac{1}{\sqrt{s}} \bar{\psi}\left(\frac{t-u}{s}\right) dt.$$

To study two time series x, y , one can look at the cross-wavelet transform

$$W_{xy}(u, s) = W_x(u, s) \overline{W_y(u, s)}$$

or, separately at the *wavelet coherence coefficient* (“time and frequency correlation”)

$$R^2(u, s) = \frac{|S[s^{-1} W_{xy}(u, s)]|^2}{S[s^{-1} |W_x(u, s)|^2] S[s^{-1} |W_y(u, s)|^2]}$$

where S is some (2-dimensional) smoothing operator, and the wavelet phase

$$\phi_{xy}(u, s) = \arg W_{xy}(u, s).$$

GillespieSSA: Implementing the stochastic simulation algorithm in R
M. Pineda-Krch (2008)

Population dynamics (predator-prey, SIR, etc.) are often modeled as coupled ordinary differential equations (ODE), but this is only valid for large populations. For small populations, a stochastic model is needed – *stochastic simulation algorithms* (SSA) are a generalization of the simulation of a Poisson process, modeling the state changes (alive/dead, susceptible/infected/resistant) of the individuals; they can be exact or (faster) approximate.

GrassmannOptim: an R package for Grassmann manifold optimization
K.P. Adragano et al. (2012)

Gradient-based optimization can be used on manifolds other than \mathbf{R}^n – for instance, many constrained optimization problems looking for a set of orthogonal vectors are unconstrained optimization problems on the Grassmannian (e.g., the first eigenvectors, independent components, or other dimension reduction problems).

Graphical models with R: Tutorial
S. Højsgaard (2012)

The `gRbase`, `gRain`, `gRim` packages provide functions to build, use, fit graphical models (or discrete variables, *i.e.*, log-linear models).

***An improved algorithm
for matching large graphs***
L.P. Cordella et al.

To find an isomorphism between two graphs, grow an isomorphism between subgraphs (adding edges outgoing from the subgraph, or incoming if there are no outgoing edges, or other vertices if there are no edges to/from the subgraph), backtracking when needed. The VF2 algorithm is implemented, for instance, in Python's NetworkX module.

McKay's canonical graph labeling algorithm
S.G. Hartke and A.J. Radcliffe

To test if two graphs are isomorphic, one could try all possible permutations, or the permutations (of the vertices) that preserve some vertex invariant, such as the degree (or the centrality, etc.). The degree is too coarse an invariant, but it can be propagated: first, partition the edges by degree; then, for each node, look at the number of edges to each part of the partition – this gives a finer partition; iterate until the partition stabilizes (equitable partition). When you reach an equitable partition, split by removing an element (non-deterministically) from one of the parts (deterministically). The smallest leaf of the resulting search tree (the partitions are ordered) is a canonical isomorph of the graph.

The algorithm is implemented in *nauty*.

It is not known if the graph isomorphism is NP-complete.

Clustering with qualitative information
M. Charikar et al. (2004)

Here are some algorithms to cluster the vertices of a graph whose edges are labeled “agree” or “disagree”:

- Take a binary decision variable x_{ij} for each edge, with $x_{ij} = 0$ if i and j are in the same cluster; the condition $x_{ij} = x_{jk} = 0 \implies x_{ik} = 0$ can be written $x_{ik} \leq x_{ij} + x_{jk}$; minimize

$$\sum_{i,j \text{ agree}} x_{ij} + \sum_{i,j \text{ disagree}} (1 - x_{ij});$$

truncate the solution of the linear relaxation at $2/3$ and $1/3$, one cluster at a time;

- Associate a vector v_i to each vertex: maximizing

$$\sum_{i,j \text{ agree}} v_i v_j + \sum_{i,j \text{ disagree}} (1 - v_i v_j)$$

subject to $v_i v_i = 1$ and $v_i v_j \geq 0$ is a semi-definite relaxation of the previous problem.

***On the identifiability
of the post-nonlinear causal model***
K. Zhang and A. Hyvärinen (2009)

The PNL (post-nonlinear) model $x_2 = f_2(f_1(x_1) + e_1)$ is not identifiable in general (e.g., in the Gaussian case)

but is, in many special cases (e.g., if f_1 is not invertible). It is not directly useable beyond two variables: first use conditional independence tests to find the Markov equivalence class of directed acyclic graphs (DAG), then use the PNL model two variables at a time, to identify the unresolved causal relations.

***Dynamic decentralized any-time
hierarchical clustering***
H.V.D. Parunak et al.

Ant clustering (each ant picks up items and drops them when it is close to similar items) can be seen as a distributed variant of k -means. It can be generalized to produce a hierarchical clustering: start with a random tree (with the data in the leaves) and move nodes (if they are too dissimilar to their siblings) or merge them (if their children are very dissimilar). (This is just a local search algorithm, but an easy-to-parallelize one.)

***Parable: a parallel random partition based
hierarchical clustering algorithm
for the MapReduce framework***
S. Wang and H. Dutta

To cluster a large dataset on Hadoop:

- Split the data at random and compute a hierarchical clustering on each node;
- Choose one of the trees as a template;
- Align all the other trees to it: swap two children of the root if doing so makes them more similar to the two children of the root of the template, continue recursively with the other nodes;
- Output the resulting tree: the shape is that of the template, but the leaves contain *sets* of observations rather than individual observations.

***Probabilistic latent variable models
for distinguishing between cause and effect***
J.M. Mooij

The direction of a causal relation between two random variables X and Y can be inferred by comparing the two models

(E is not observed) using Bayesian model selection.

***A quick and gentle guide
to constraint logic programming via ECLPSe***
A. Niederliński (2011)

The book starts with a clear description of the differences between constraint logic programming (CLP) and its ancestor, Prolog: they are syntactically similar, they explore the same tree, but CLP prunes it more efficiently. Prolog only gives up a branch (a partial instantiation, or grounding, of the decision variables)

when a constraint (involving ground variables) is violated. CLP keeps track of the domain of each variable (usually, as an interval of integers – but it could also be an arbitrary finite set of integers) and, after each instantiation, propagates the constraints – for instance, if you know that $x + y = z$, $x, y \in \llbracket 0, 3 \rrbracket$, $z \in \llbracket 5, 9 \rrbracket$, you can deduce that $x, y \in \llbracket 2, 3 \rrbracket$, $z \in \llbracket 5, 6 \rrbracket$ – this prunes a lot of branches. In addition, CLP offers more choice for the search strategy: branch-and-bound (Prolog is designed for satisfaction problems and requires dirty, non-declarative tricks), variable choice heuristic (e.g., most constrained), value choice heuristic (e.g., minimum, maximum, middle, random), random restarts, timeout, etc. CLP also differs from operations research (OR), which is limited to continuous and binary variables.

The rest of the book is a long list of examples for the ECLPSe open source CLP system, but most of the language features are used without any explanation.

```

```

Similarity evaluation on tree-structured data R. Yang et al. (2005)

The edit distance between trees (number of relabeling, delete and insert operations needed to transform one into the other) can be computed with dynamic programming. Alternatively, one can use the string edit distance between the preorder (or post-order) traversal sequences, or various histogram distances (height, degree, label). Here is another histogram: transform the tree into a binary tree

make it complete, and consider the histogram (empirical distribution) of the binary branches

(they can be seen as 3-grams for binary trees).

OpenTURNS reference guide

OpenTURNS is a C++ *reliability* library, often used from Python, *i.e.*, a list of methods used by engineers to propagate uncertainty in their computations and identify the main sources of those uncertainties.

First, the input variables can be described, as a joint probability distribution, using empirical cumulative

distribution functions (ecdf), kernel smoothing, correlation, rank correlation, common parametric distributions, copulas, mixtures (via the Fourier transform), classical or Bayesian estimators, tests and plots for goodness of fit, etc.

Then, one propagates uncertainty: either as $[\min, \max]$ intervals, analytically, or by solving optimization problems, or by simulations with quasi-random numbers (low discrepancy sequences, or Latin squares (design of experiments) – Latin squares are fixed-length multivariate low discrepancy sequences); or as location-dispersion pairs, or quantiles, estimated by Monte carlo simulations or Taylor expansions.

To approximate the probability of some event $[g(X) \leq 0]$, transform X to make it rotationally invariant (isoprobabilistic (Nataf, Rosenblatt) transformation – if $X \sim N(\mu, C'C)$, just use $X \mapsto C^{-1}(X - \mu)$) and approximate the event $[g(X) \leq 0]$ with a half-plane (FORM: first order reliability method) or a ball (SORM). The probability can also be approximated with Monte Carlo simulations.

Finally, the importance of each input variable on the uncertainty of the output can be estimated, for instance, if $Z = h(X)$, with a Taylor expansion

$$\begin{aligned} \text{Var } Z &\approx \nabla h(\mu_X) \text{Var } X \nabla h(\mu_X)' \\ &= \sum_i \nabla_i h(\mu_X) \text{Var } X \nabla h(\mu_X)' \end{aligned}$$

or, simply, with $\text{Cor}(Z, X_i)$, $\text{lm}(Z \sim X_i)$, $\text{pCor}(Z, X_i)$, rank correlation, $\partial \text{RI} / \partial \theta$, etc.

Instead of the Taylor expansion, given

$$\begin{array}{ccc} \mathbf{R}^n & \xrightarrow{h} & \mathbf{R}^m \\ & \nwarrow X \quad \nearrow Y=h(X) & \\ & \Omega & \end{array}$$

one can use the *functional chaos expansion*: the expansion of h over a basis of orthogonal polynomials (“polynomial chaos”) wrt f_X (only keep the “first” coefficients – since there are many indices, you can tweak the notion of “first”, e.g., using the L^p pseudonorm, for $p < 1$, of the indices).

LOF: Identifying density-based local outliers M.M. Breunig et al. (2000)

One can use the ideas behind density-based clustering (DBSCAN) to define the degree of outlier-ness of a

point p ,

$$\text{LOF}_k(p) = \frac{1}{k} \sum_{q \in N_k(p)} \frac{\ell_k(q)}{\ell_k(p)}$$

$$\ell_k(p) = \frac{1}{k} \sum_{q \in N_k(p)} d_k(p, q) \quad \text{local reachability density}$$

$$d_k(p, q) = \text{Max}\{d_k(q), d(p, q)\} \quad \text{reachability distance}$$

$$d_k(p) = \text{distance to the } k\text{th nearest neighbour.}$$

Being local, the method still works if the data has clusters of different densities. Fraud detection is the most prominent application of outlier detection.

A scalable and efficient outlier detection strategy for categorical data A. Koufakou et al. (2007)

Here are a few ideas to detect outliers in categorical data:

- Greedy algorithm to identify observations whose removal reduces the entropy the most;
- Observations containing few frequent item sets (FIS)

$$\text{FPOF}(x) \propto \sum_{\substack{F \in \text{FIS} \\ F \subset x}} \text{Support}(x)$$

$$\text{FIS} = \{I : |\text{Support } I| > n\}$$

- Observations containing many infrequent itemsets

$$\text{Otle}(x) = \sum_{\substack{I \subset x \\ |\text{Support } I| \leq n}} \frac{1}{|I|}$$

- Observations containing rare values for most variables (*i.e.*, consider the variables separately)

$$\text{AVF}(x) = \frac{1}{m} \sum_i f(x_i)$$

where $f(x_i)$ is the proportion of points in which the i th variable has value x_i .

Frequent pattern growth (FP-growth) algorithm. An introduction F. Verhein (2008)

The *apriori* algorithm for frequent item set (FIS) mining

$$L_1 = \{\text{frequent items}\}$$

$$= \{\{x\} : \text{Support } \{x\} \geq n\}$$

$$C_{k+1} = \{a \cup \{x\}, a \in L_k, \{x\} \in L_1, x \notin a\}$$

$$L_{k+1} = \{c \in C_{k+1} : \text{Support } c \geq n\}$$

is expensive (double loops to compute the candidates C_k and the frequent k -item sets L_k).

The FP-growth algorithm processes the data into an *FP-tree*:

- Compute the support of each item;
- For each transaction, sort the items by decreasing support;
- Build the corresponding *prefix tree*, storing the support of each prefix in the nodes, with links between identical items.

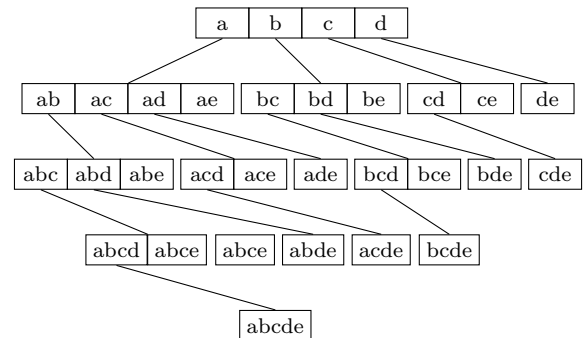

Using the FP-tree to extract frequent itemsets is trickier:

- Start with the least frequent item;
- If it is sufficiently frequent, consider the subtree it defines, update the counts for the conditional FP-tree and discard the leaves (the item itself);
- Process this conditional FP-tree recursively;
- Discard the item and iterate with the next least frequent item, until the tree is empty.

Efficient implementations of Apriori and Eclat C. Borgelt (2003)

The frequent itemset (FIS) mining algorithms *Apriori* and *Eclat* both explore the same prefix tree

breadth-first and depth-first. Eclat can be implemented by storing the transactions as rows in a sparse bitmatrix and by using the columns to compute the intersections.

Simple algorithms for frequent itemset mining
C. Borgelt (2010)

The split-and-merge algorithm for frequent itemset mining preprocesses the data:

- Compute the item frequencies;
- Remove the items below the desired threshold;
- Sort the items in each transaction by increasing frequency;
- Aggregate identical transactions (keep track of their count).

The dataset is then processed recursively (divide and conquer):

- Take the least frequent item;
- Recursively process the itemsets that do not contain it, by removing it from the transactions and reaggregating them (some may become equal);
- Recursively process the transactions that contain it: discard the other transactions, and remove the item from the remaining transactions.

A comprehensive assessment of methods for de novo reverse engineering of genome-scale regulatory networks
V. Nerendra et al. (2010)

Algorithms to identify (undirected) causal relations include:

- Relevance networks: add an edge between variables with a significant mutual information

$$MI(x, y) = \iint p(x, y) \log \frac{p(x, y)}{p(x)p(y)} dx dy$$

(use a kernel estimator for the densities, and change the order of the nested loops to avoid recomputing the 1-dimensional densities $p(x)$, $p(y)$ each time);

- Add an edge between variables with a mutual information above some threshold;
- Prune an MI-derived graph by removing the edge with the lowest mutual information in each triangle (Arcane);
- Methods based on higher order mutual information

$$H(X) = \int -p(x) \log p(x) dx$$

$$H(X, Y) = \iint -p(x, y) \log p(x, y) dx dy$$

$$H(X, Y, Z) = \iiint -p(x, y, z) \log p(x, y, z) dx dy dz$$

$$H(X; Y, Z) = H(X) + H(Y, Z) - H(X, Y, Z)$$

to test if $Y \rightarrow X \leftarrow Z$;

- Add an edge between variables with a significant correlation;
- Add an edge between variables with a significant partial correlation; the partial correlations can be computed from the concentration matrix (the inverse of the variance);
- The graphical lasso, *i.e.*, and L^1 -penalized estimator of the concentration matrix;

- Limited partial correlation (*qp*-graphs);
- Hierarchical clustering;
- Local methods.

Fast calculation of pairwise mutual information for gene regulatory network reconstruction
P. Qiu et al.

To compute the mutual information matrix

$$MI_{k\ell} = \iint p_{k\ell}(x, y) \log \frac{p_{k\ell}(x, y)}{p_k(x)p_\ell(y)} dx dy$$

one often uses a kernel estimator of the probability densities, which gives something like $MI_{k\ell} = \sum_i \log \sum_j f_{ijk\ell}$. This is often implemented with nested loops (for $k \dots$ for $l \dots$ for $i \dots$ for $j \dots$), but one can change the order of the loops (to i, j, k, ℓ) and factor out some of the computations (bits of the kernel estimators of $p_k(x)$, $p_\ell(x)$, which were recomputed each time).

A robust procedure for Gaussian graphical model search from microarray data with p larger than n
R. Castelo and A. Roverato (2006)

Relevance networks infer the structure of a graphical model by testing if $\text{Cor}(X_i, X_j) = 0$, but this ignores confounders, *e.g.*, if $B \leftarrow A \rightarrow C$, then $\text{Cor}(B, C) \neq 0$. Instead, one can look at the conditional independences, which can be tested with partial correlations

$$\text{Cor}(X_i, X_j \mid X_k, k \neq i, j)$$

or, equivalently, the zero pattern of the concentration matrix (the inverse of the variance). When it cannot be estimated, *e.g.*, if $p \gg n$, one can use the *limited partial order correlations* instead,

$$\text{Cor}(X_i, X_j \mid X_{k_1}, \dots, X_{k_q}).$$

The *non-rejection rate* is the proportion of subsets $\{k_1, \dots, k_q\}$ such that

$$H_0 : \text{Cor}(X_i, X_j \mid X_{k_1}, \dots, X_{k_q}) = 0$$

is not rejected (using the T test for zero regression coefficients) – if q is large, use a random subset of the $\binom{p}{q+2}$ subsets. The *qp-procedure* produces the graph whose edges have a non-rejection rate below some threshold. To choose q and assess its adequateness, look at the histogram of the non-rejection rate and the *qp-clique-plot*:

```
plot( max_clique_size ~ threshold | q,
      cex = number_of_edges )
abline( h = min(p,n) )
```

(you want enough edges to capture all the information, but a small maximum clique size).

**Local causal and Markov blanket induction
for causal discovery
and feature selection for classification**
C.F. Aliferis et al. (2010)

Review of a few algorithms to infer *local causality* in a graphical model, viz computing the parents and children (PC) of a node $X \in \mathbf{V}$ and its *Markov blanket* (MB) – a minimal element of

$$\{\mathbf{A} \subset \mathbf{V} \setminus \{X\} : \forall Y \in \mathbf{A} \setminus \{x\} \quad X \perp\!\!\!\perp Y \mid \mathbf{A}\}.$$

For a *faithful graph* (all dependence and independence relations come from the graph),

$$\text{PC}(X) = \{Y \in \mathbf{V} : \forall \mathbf{Z} \subset \mathbf{V} \setminus \{X, Y\} \quad X \not\perp\!\!\!\perp Y \mid \mathbf{Z}\}$$

and $\text{MB}(X)$ is uniquely defined and contains parents, children and childrens' parents (spouses) of X .

By stitching the $\text{PC}(X)$ for all X , one can estimate the whole (global) graphical model.

Local causality learning can also be used for *feature selection*.

Hash kernels for structured data
Q. Shi et al. (2009)

The idea behing the count-min sketch (use a hash table, with several hash functions, and ignore collisions) can be used to approximate scalar products in high-dimensional spaces (e.g., after the “kernel trick”) or to compress sparse feature vectors (in text processing)

$$k(x, y) = \langle \phi(x), \phi(y) \rangle \approx \langle \bar{\phi}(x), \bar{\phi}(y) \rangle$$

$$\bar{\phi}_j(x) = \sum_{i : h(i)=j} \phi_i(x).$$

If the features are duplicated, the drop in performance is not that bad. Hashing can be combined with random sampling – for instance, if the features are the number of subgraphs of size k in each isomorphism class. This idea is implemented in Vowpal Wabbit.

**New methods for separating causes
from effects in genomics data**
A. Statnikov et al. (2012)

Finding the direction of a causal link from observational data alone (no intervention analysis) looks hopeless: in terms of graphical models, $A \rightarrow B$ and $A \leftarrow B$ are in the same Markov equivalence class. However, comparing the complexities of both models, *i.e.*, of the decompositions of $P(A, B)$ into $P(A)P(B|A)$ or $P(B)P(A|B)$, or checking if the conditional distribution is constant, *i.e.*, $B|A \perp\!\!\!\perp A$, can sometimes give the answer – many algorithms have been proposed.

Also check the “Cause-effects pairs” Kaggle competition.

**A linear non-Gaussian acyclic model
for causal discovery**
S. Shimizu et al. (2006)

Variables x_1, \dots, x_n , related by cause/consequence relations described by a directed acyclic graph (DAG), and observed with a non-Gaussian, additive noise ε , can be modeled as $x = Bx + \varepsilon$, where B is strict lower triangular. But since $x = (I - B)^{-1}\varepsilon$, independent component analysis (ICA) can recover $B = I - \text{ICA}(x)$, up to a permutation of the rows and columns. The resulting DAG can be pruned with statistical tests for the strength of the causal relations.

**Distinguishing causes from effects using
non-linear acyclic causal models**
K. Zhang and A. Hyvärinen (2007)

The LiNGAM algorithm (ICA-based causality discovery) can be extended to allow for non-linearities

$$x_{k+1} = f_{k+1}(g_{k+1}(x_1, \dots, x_k) + \varepsilon_{k+1}),$$

which can be reformulated as

$$x = f(Bs)$$

with B strict lower triangular. In the case of two variables, one can find g_1 and g_2 so that x_1 be as independent as possible from $g_2(x_2) - g_1(x_1)$, e.g., by minimizing their mutual information with a multilayer perceptron (MLP) and using a statistical test to check the independence.

**Nonlinear causal discovery
with additive noise models**
P.O. Hoyer et al.

Given a non-linear noise with *additive* non-Gaussian noise $y = f(x) + \varepsilon$, plot the density of $y|x$ for several values of x : it should be the same curve, up to translations. This property is unlikely to hold for $x|y$ and strengthens the belief that $x \rightarrow y$.

The actual test checks that $x \not\perp\!\!\!\perp y$ and $\text{res}(y \sim f(x)) \perp\!\!\!\perp y$, where $y \sim f(x)$ is a non-linear regression and $\text{res}(\cdot)$ its residuals.

Inferring deterministic causal relations
P. Daniušis et al. (2012)

Causal inference often relies on the assumption that the noise is additive and non-Gaussian. This breaks down in the case of a deterministic relation $Y = f(X)$, especially if f is invertible. However, one can expect $X \perp\!\!\!\perp f$ and $Y \not\perp\!\!\!\perp f$, where $\perp\!\!\!\perp$ denotes *algorithmic independence* – the shortest description of $p(x, y)$ is a separate description of $p(x)$ and f .

Given a family of distributions \mathcal{E} well-suited to model a probability density p , one can measure the complexity of p as

$$D(p|\mathcal{E}) = \min_{q \in \mathcal{E}} D(p||q),$$

where

$$D(p||q) = \int p(x) \log \frac{p(x)}{q(x)} dx$$

is the Kullback-Leibler divergence. The information-geometric causal inference (IGCI) method computes

$$C_{X \rightarrow Y} = D(p_X || \mathcal{E}_X) - D(p_Y || \mathcal{E}_Y)$$

and concludes that $X \rightarrow Y$ if $C_{X \rightarrow Y} < 0$. If $\mathcal{E}_X = \mathcal{E}_Y$ only contains the uniform distribution $U(0, 1)$,

$$\begin{aligned} C_{X \rightarrow Y} &= \int_0^1 \log |f'(x)| p(x) dx \\ &\approx \frac{1}{m-1} \sum_{i=1}^{m-1} \log \left| \frac{y_{i+1} - y_i}{x_{i+1} - x_i} \right|, \end{aligned}$$

where $x_1 \leq \dots \leq x_m$.

The architecture of SciDB
M. Stonebraker (2011)

SciDB is a database for scientific data, not unlike a column store, but with arrays instead of columns. It can be queried with a SQL-like language (AQL) or a more procedural one (AFL). In addition to relational operators (join, etc.), it provides scientific operations (matrix multiplication, singular value decomposition (SVD), regression, machine learning). Data is stored in *overlapping* chunks, because many operations (on time series, images, geographical data, etc.) require neighbouring values. It also supports versioning (the data is never deleted, but stored to optimize queries with current data).

Latent Dirichlet allocation: towards a deeper understanding
C. Reed (2012)

A *topic* is a probability distribution on a collection of words. Latent Dirichlet allocation (LDA) is similar to k -means, but with bags of words instead of vectors in \mathbf{R}^n : it models a “mixture” of topics, one step of the algorithm assigning each text to the nearest topic, the next refining the topics by “averaging” the texts associated with it.

The R package metaLik for likelihood inference in meta-analysis
A. Guolo and C. Varin (2012)

Meta-analysis (combining the result of many studies, without access to the raw data of each), boils down to a seemingly simple random-effects model: estimate β in

$$\begin{aligned} Y_i &= \beta_i + e_i \\ \beta_i &= \beta + \varepsilon_i \\ e_i &\sim N(0, \sigma_i^2) \quad \text{precision of study } i \\ \varepsilon_i &\sim N(0, \tau^2) \quad \text{heterogeneity of the studies.} \end{aligned}$$

Unfortunately, most statistical procedures (tests, confidence intervals, etc.) rely on asymptotic results: the small size of the sample (the number of studies aggregated) makes them invalid. In this context, higher-order expansions (of the log-likelihood) are preferable.

Non-parametric kernel distribution function estimation with kerdie: an R package for bandwidth choice and applications
A. Quintela-del-Río and G. Estévez-Pérez (2012)

If you are more interested in the cumulative distribution function (cdf) than the probability distribution function (pdf), e.g., probability of exceedance, mean return period, quantiles, etc., the optimal bandwidth for kernel density estimation is different.

Spherical k-means clustering
K. Hornik et al. (2012)

Spherical k -means, often used in text clustering, refers to k -means for the cosine dissimilarity, *i.e.*, after projecting the data on the sphere, $\min_{p,c} \sum_i 1 - \cos(x_i, p_{c(i)})$, *i.e.*,

$$\min_{M,p} \sum_{ij} \mu_{ij} (1 - \cos(x_i, p_j)),$$

with $\mu_{ij} \in \{0, 1\}$ and $M\mathbf{1} = \mathbf{1}$. In the fixed point algorithm, local improvements are possible (change the membership of a single observation; this also changes the prototypes p). Extended spherical k -means minimize

$$\sum_{ij} w_{ij} \mu_{ij}^m (1 - \cos(x_i, p_j)),$$

with $\mu_{ij} \in [0, 1]$ and $M\mathbf{1} = \mathbf{1}$ (m and w are given).

ClustOfVar:
an R package for clustering of variables
M. Chavent et al. (2012)

PCAMIX is a generalization of principal component analysis (PCA) that allows both quantitative and qualitative variables. The first component is

$$\operatorname{Argmax}_{\mathbf{u} \in \mathbf{R}^n} \sum_{j \text{ quantitative variable}} \operatorname{Cor}^2(\mathbf{u}, \mathbf{x}_j) + \sum_{j \text{ qualitative variable}} \operatorname{Corr}^2(\mathbf{u}, \mathbf{y}_j)$$

where $\operatorname{Corr}(\mathbf{u}, \mathbf{y})$ is the *correlation ratio*, i.e., the proportion of the variance of \mathbf{u} explained by \mathbf{y} . It can be computed from the singular value decomposition (SVD). It can also be used to cluster the variables, by considering

$$\operatorname{Argmax}_{\substack{\mathbf{u}_1, \dots, \mathbf{u}_k \in \mathbf{R}^n \\ \mathcal{C}_1, \dots, \mathcal{C}_k \text{ partition} \\ \text{of the variables}}} \sum_{\ell=1}^k \sum_{j \in \mathcal{C}_\ell \cap \text{Quant}} \operatorname{Cor}(\mathbf{u}, \mathbf{x}_j) + \sum_{j \in \mathcal{C}_\ell \cap \text{Qual}} \operatorname{Cor}(\mathbf{u}, \mathbf{y}_j).$$

This can be approximated by hierarchical clustering of the variables, or a k -means-like algorithm.

The devil is in the tails: actuarial mathematics and the subprime mortgage crisis
C. Donnelly and P. Embrechts (2010)

The default times, needed to price CDOs, are often modeled with a 1-parameter Gaussian copula and (say) exponential margins. This is inadequate: it implies asymptotic independence – one should use another copula or, at least, stress the model with other copulas.

R and data mining: examples and case studies
Y. Zhao (2013)

Examples (working code with little or no explanations of what is computed) of data mining algorithms in R. The paper version also contains case studies. The topics include:

- Decision trees: `party::ctree`, `rpart`, `randomForest`;
- Regression: `lm`, `glm`, `nls`;
- Clustering: `kmeans`; `cluster::pam`, `cluster::clara`, `fpc::pamk`; `hclust`; `fpc::dbscan`;
- Outlier detection: `boxplot.stats`; `DMwR::lofactor`, `Rlof::lof`; `dbscan`, `kmeans`, time series models, `extremevalues`, `mvoutlier`, `outliers`;
- Time series: `decompose`, `stl`, `timsac::decomp`, `ast::tsr`; `arima`; `dwt`; clustering with `dwt::dwtDist`; classification after transforming the time series into features, e.g., with `dwt`, or with k -nearest-neighbours (`RANN::nn`);
- Association rules: `arules::apriori`, `arules::eclat`, `arulesViz`;
- Text mining: `twitterR::userTimeline`; `tm::vectorSource`, `Corpus`, `tm_map`, `getTransformations`, `TermDocumentMatrix`, `find*`; `wordcloud`; `textcat` (n -grams), `lda`, `topicmodels`;
- Social network analysis: `igraph`, `sna`

There is no mention of the forecast and caret packages.

An efficient algorithm for automatic peak detection in noisy periodic and quasi-periodic signals
F. Scholkmann et al. (2012)

The *local maxima scalogram* (LMS)

$$m_{k,i} = \mathbf{1}_{x_i < x_{i-k}, x_i > x_{i+k}}$$

may help detect peaks in a signal.

Graph databases
I. Robinson et al. (2013)

Relational databases are cumbersome and inefficient when dealing with graphs (self-joins, recursive joins), and nullable columns complicate queries even further. NoSQL databases can fake foreign keys, but all the work has to be done by the application. Graph databases use index-free adjacency (the relations are not stored in a global, separate index, but locally, bidirectionally, at each node), often separate graph structure from property data (not unlike column stores), and provide efficient graph-theoretic operations (depth-first search, breadth-first search, shortest path (Dijkstra), A^* , etc.). They can be used for predictive modeling, e.g., identify missing links (*triadic closure*: if $A-B$ and $A-C$, then $B-C$ is likely) or important links (a *local bridge* is a relation that leads to a different part of the network).

Applications include social data (find colleagues with similar interests, colleagues of colleagues interested in a given topic, etc.), email forensics, recommendations, geographical data (parcel delivery and shortest path queries, R-trees), master data management, network and data center management (machines, applications, etc.), access control (dealing with complex organization structures and product hierarchies requires recursive joins in SQL), bioinformatics (protein networks).

Data modeling is very similar to entity-relation (ER) modeling: use a node for each entity (and for most relations: only encode simple relations as relationships), avoid attributes on relationships (prefer fine-grained relationships). Time can be stored in linked lists (previous/next) or date nodes (or, even, a timeline tree:

each day points to its month, each month points to its year). Optimizing a graph database just means adding direct links for relations that would otherwise require several links.

Neo4j provides several APIs: a core API (in Java, with `Node` and `Relationship` objects), a traversal API (more declarative), and Cypher (a SQL-like language – the book has a lot of examples); SPARQL (for RDF) and Gremlin are other query languages. It can be embedded (either persisted on disk, or in-memory), used as a server (REST, JSON – the server can be extended: use JAX-RS annotations to indicate to which URIs a class/method responds), supports transactions, recovery, master-slave replication.

Data-intensive text processing with MapReduce

J. Lin and C. Dyer (2010)

1. With the help of infrastructures such as MapReduce, the “unreasonable effectiveness of data” has made data-intensive scientific discovery the “fourth paradigm of science” (after theory, experiment and simulations).

Contrary to most books on MapReduce or its implementation Hadoop, which hide actual contents (if any) under complicated installation instructions (this is Java) and boilerplate code (this is Java), this one focuses on MapReduce *algorithm* design – no actual code, just clear Python-like pseudo-code.

2. MapReduce assumes that failures are common, moves processing closer to the data and processes data sequentially (no random access). It can be seen as a cloud analogue of the map and fold primitives of functional programming.

$$\begin{aligned}\text{map: } (k_1, v_1) &\longrightarrow [(k_2, v_2)] \\ \text{reduce: } (k_2, [v_2]) &\longrightarrow [(k_3, v_3)]\end{aligned}$$

The Hadoop infrastructure works as follows:

- The input data is stored in a distributed file system (HDFS), often serialized (ProtocolBuffers, Avro, Thrift); the files are stored on *data nodes* (each file is replicated three times); the metadata is on the *name node*.
- The *mapper* receives the data, as key-value pairs, and emits more key-value pairs.
- The *combinator* (optional) pre-aggregates the data: for instance, when counting words, emitting pairs $(w, 1)$ is inefficient

```
def mapper(id, terms):
    for term in terms:
        emit term, 1
def reducer(term, counts):
    emit term, sum(counts)
```

 and the counts can be pre-aggregated.
- The *partitionner* (optional) groups the data, usually by key but, for some applications, you may want to use only part of the key.

- The framework shuffles and sorts the data (transparently);
- The *reducer* receives (key,list) pairs and emits more key-value pairs.
- The *jobtracker* oversees the MapReduce jobs (on the job submission node), the *tasktrackers*, on each data node, run the code.

3. Here are a few MapReduce design patterns:

- *In-mapper recombiner*: while it is possible to pre-aggregate the data in a combiner, it is often more efficient to do it in the mapper – not in its `map` method (called for each key-value pair), but in its `close` method (called when the node has finished processing all the data). You may need to flush the accumulator if it gets too large. For some operations, e.g., the mean, the combiner and the reducer do different things.

```
def mapper(t,x):
    emit t, (x,1)
def combiner(t, xcs):
    xs, cs = zip(*xcs) # unzip
    emit t, (sum(xs), sum(cs))
def reducer(t, xcs):
    xs, cs = zip(*xcs) # unzip
    emit t, sum(xs)/sum(cs)
```
- *Pairs*: to compute co-occurrences, use pairs of words as keys.
- *Stripes*: to compute co-occurrences, use one word as key, and a hash table as value.
- *Order inversion*: if you need the result of the aggregation before it is ready, e.g., to compute relative frequencies, duplicate the data (e.g., one copy for the word count, another for the word pair count), make sure the intermediate result (word count) is computed first (set the sort order), and partition the data accordingly.

```
emit (w1,*):1
emit (w1,w2):1
emit (w1,w3):1
partition on w1
```
- *Value-to-key conversion*: when the reducer must produce sorted data, ask the framework to sort it before, by putting the value to sort in the key.
- *Reduce-side join*: for a 1-to-1 join of \mathcal{T} and \mathcal{S} , emit $k : (t, T)$ and $k : (s, S)$ (where s and t are the primary keys of \mathcal{S} and \mathcal{T} , k the column to join on, and T, S the other columns), for a 1-to-many join, emit $(k, s) : S$ and $(k, t) : T$, define a custom partitioner, ensure that the values of the small table come first and cache them.
- *Map-side join*: if the data has already been partitioned on disk, e.g., as a result of a previous MapReduce process, map over the larger set after reading the corresponding chunk of the smaller one in the mapper – no reducer is needed.
- *Memory-backed join*: put the smaller dataset into memory (or some distributed key-value store: Memcached, etc.) in every mapper – if it does not fit into memory, partition it into n pieces and perform n in-memory joins.

4. An *inverted index* maps words to sorted lists of document ids (there may be some data (“payload”) with the id: term frequency, position, style (title or not), HTML link, linguistic function (POS, type of entity: place, person), etc.). For efficient set operations (intersection, union), the list should be sorted: do not emit `term:(id,freq)`, but `(term,id):freq` to have the framework sort the ids (you need a custom partitioner to ensure that all the messages for a given term are sent to the same reducer).

The volume of data is huge: the process can benefit from compression.

- Only store the differences (*d*-gaps) between document ids – since they are sorted, the numbers are smaller.
- Variable length *integer coding*: set the 8th bit to zero as long as the number is not finished.
- Group varInt: group the numbers by 4 and prefix each group with a byte indicating (on 2 bits) the length of each number.
- Simple-9: in each 32-bit word, use 4 bits to indicate how the remaining 28 bits are split into equal-sized parts.
- Unary code: encode n as $n - 1$ 1s and one 0.
- γ -code: encode n as $\lfloor \log_2 n \rfloor$ 1s, a 0, and the binary encoding of the number, without the leading 1.
- δ -code: similar to the γ code, but the first part is not unary-encoded but γ -encoded.
- Golomb code: choose b , encode $q = \lfloor (n - 1)/b \rfloor$ in unary, encode the remainder $r = n - 1 - qb$ in truncated binary (the smaller numbers are encoded on k bits, the others on $k + 1$ – unassigned k -bit codes followed by 0 or 1).

MapReduce is a poor solution for document retrieval, but you could partition the documents, and cache the most-requested results.

5. Many sequential graph algorithms rely on some global data structure (e.g., a priority queue): they are not straightforward to implement in MapReduce. For instance, breadth-first search (Dijkstra’s algorithm) can be implemented as a sequence of MapReduce iterations: store the estimated distance from the source in each node, process each node in each iteration, stop when the distances no longer change – there are as many iterations as the longest shortest path (you also need to keep track of the adjacency list, e.g., by emitting it as well).

```
def mapper(id,d):
    for a in neigh(id):
        emit a, d+w
def reducer(id,ds):
    emit id, min(ds)
```

PageRank (a random walk on the graph, with teleportation, computing a score (equilibrium probability) for each node), HITS (random walk on a bipartite graph of hubs and authorities, computing two scores for each node on the initial graph – the graph is usually

query-dependent: pages containing the search terms and their neighbours), SALSA (idem) can be computed in the same way, each iteration spreading the probability mass (but pay attention to dangling nodes). Combiners can improve performance, if you partition the data with some heuristic (sort by zipcode, school, language, domain name, etc.). To avoid underflow, use log-probabilities: they can be added as

$$a \oplus b = \begin{cases} b + \log 1p(e^{a-b}) & \text{if } a < b \\ a + \log 1p(e^{b-a}) & \text{if } a \geq b. \end{cases}$$

6. If a statistical model contains parameters θ (unobserved, to be estimated), hidden variables y (unobserved, but we do not care much about their values), and data x (observed), maximum likelihood estimators

$$(\hat{\theta}, \hat{y}) = \underset{(\theta, y)}{\operatorname{Argmax}} P(X = \mathbf{x}, Y = \mathbf{y}; \theta)$$

give a very noisy estimator of θ : prefer the *marginal likelihood* estimator (i.e., integrate y out):

$$\begin{aligned} \hat{\theta} &= \underset{\theta}{\operatorname{Argmax}} P(X = \mathbf{x}; \theta) \\ &= \underset{\theta}{\operatorname{Argmax}} \prod_i \sum_y P(X = x_i, Y = y_i; \theta). \end{aligned}$$

The *expectation-maximization* (EM) algorithm is a hill-climbing algorithm that attempts to maximize the marginal log-likelihood:

$$\theta_{n+1} \leftarrow \underset{\theta}{\operatorname{Argmax}} \sum_{x,y} P(x, y; \theta_n) \log P(x, y; \theta).$$

This single formula is often, confusingly, presented as two steps:

- Estimation of the probability distribution $X, Y \mid \theta = \theta_n$ in the E step (it is a probability distribution: in the discrete case, it is a set of probabilities);
- Computation of the expected log-probability

$$\sum_{x,y} P(x, y; \theta_n) \log P(x, y; \theta)$$

(it is a function of θ : if it is explicitly computed, it is also part of the E step);

- Maximization, in the M step.

Given a hidden Markov Model (HMM), the problems of computing the probability that the model generated the data (used for clustering or outlier detection) and computing the most probable sequence of hidden states that could generate the observed data can be solved with dynamic programming (the forward algorithm computes the probability that the process is in state q at time t ; the Viterbi algorithm computes the probability of the most probable sequence of states leading to state q at time t): they can be implemented with MapReduce, by processing one column of the dynamic programming table (one time t) in each iteration; each mapper receives a small part of the data; each reducer computes a cell in the dynamic programming table. Similarly, estimating the parameters of a HMM (forward-backward algorithm) can be implemented with EM.

HMM can be used, for instance, to align texts in different languages:

$$\begin{aligned} P(\text{target, alignment} \mid \text{source}) \\ &= \prod P(t_{i+1} \mid t_i) \times \prod P(t_i \mid s_{a_i}) \\ &= \text{language model} \times \text{translation model}. \end{aligned}$$

MapReduce can also be used for parallel but non-data-intensive tasks.

The book also mentioned, with few details, other technologies in the MapReduce/Hadoop ecosystem: Mahout (machine learning), HBase (tables in HDFS), Cassandra (key-value store), Giraph (bulk-synchronous parallel (BSP) framework), GPU programming (e.g., for streaming data), Pig, Hive, Hadoop (data processing).

Financial risk modelling and portfolio optimization with R **B. Pfaff (2013)**

Each chapter is structured in the same way: terse presentation of a few mathematical notions (consider it as a mere check-list), list of relevant R packages (not unlike the CRAN task views), and (more interesting) examples.

The topics covered are

- Risk measures: VaR, ES, mVaR, mES, coherent measures;
- Efficient frontier;
- Distributions to model returns: generalized lambda distribution (GLD), GHD (ghyp, lmomco::pargld, fBasics::gldFit);
- Extreme value theory: block maxima, peaks over thresholds, exceedance declustering (evir::gev, esmev::gev.fit, fExtremes::gevFit, ismev::rlarg.fit, fExtremes::mrlPlot, gpdFit, deCluster);
- Volatility: GARCH models (fGarch::garchFit, rugarch);
- Dependence: correlation, rank correlation, Kendall's τ , lower tail dependence, copula GARCH model (fit a GARCH model to individual time series, and then a copula to the (joint) residuals), mixture of copulas (QRM::fit.tcopula, QRM::rcopula.t, copula::dcopula);
- Robust estimation: M-estimator, MM-estimator, MVE, MCD, S-estimator, SDE, OGK estimator (rrcov::Cov*);
- Robust optimization: scenario-based, box or elliptic uncertainty set (FRAPO::Socp, Rsocp);
- Diversification: risk contribution, diversification ratio, defined with the volatility or some downside risk measure such as the tail dependence coefficient (FRAPO::P*, FRAPO::dr, FRAPO::cr, Portfolio::Analytics::optimize.portfolio);
- Portfolio optimization with VaR, ES or drawdown in the objective or the constraints (fPortfolio::minRiskPortfolio, FRAPO::P*);

- Time series models: ARMA, VAR, VECM, SVAR, SVEC (urca, vars);
- Tactical asset allocation: Black-Litterman, copula opinion pollomg, entropy polling (TTR, fTrading, BLCOP).

Lectures on modern convex optimization **A. Ben-Tal and A. Nemirovski (2012)**

Convex programming is too general to be amenable to practical, efficient methods, but many special cases are – linear, conic quadratic, semi-definite programming are all examples of *conic programming*.

1. To find a lower bound of

$$x^* = \underset{x}{\text{Min}} \{f(x) : \forall i \, g_i(x) \geq b_i\},$$

consider a linear combination of the constraints

$$\sum_i y_i g_i(x) \geq \sum_i y_i b_i$$

(with $y \geq 0$). If $f(x) \geq \sum_i y_i g_i(x)$, then $\sum y_i b_i$ is a lower bound. The best such lower bound is

$$\underset{y \geq 0}{\text{Max}} \left\{ \sum_i y_i b_i : \forall x \, f(x) \geq \sum_i y_i g_i(x) \right\}.$$

This is the *dual problem*; its optimal value is less than that of the primal (weak duality). If f and g are linear, set x to $+1$ and -1 : the inequalities become equalities, and the dual of

$$\underset{x}{\text{Min}} \{c'x : Ax \geq b\}$$

is

$$\underset{y}{\text{Max}} \{b'y : y \geq 0, A'y = c\}.$$

For linear problems, there is a *strong duality*: the primal has an optimal solution iff the dual has, and the optimal values are the same – but there are two ways in which a problem can fail to have a solution: it can be infeasible, or unbounded; if the primal is unbounded, then the dual is infeasible, but the converse is false: both can be infeasible.

Applications of linear programming include compressed sensing (ℓ^1 penalty as an approximation of a (non-convex) ℓ^0 one), support vector machines (SVM), discrete-time linear dynamic systems.

Replacing the linear objective function by an arbitrary (convex) function is not the only way of generalizing linear programming into non-linear programming – one can keep the objective function linear but replace the constraints $Ax - b \geq 0$ with $Ax - b \succ_K 0$, where \succ_K denotes the partial order induced by a closed, pointed convex cone with non-empty interior K . In the dual problem, $y \geq 0$ gets replaced by $y \succ_{K^*} 0$, i.e., $y \in K^*$, the dual cone. This is **conic programming**.

To formulate the dual of

$$\underset{x}{\text{Min}} \{c'x : Ax \succ_K b\},$$

we are looking for a lower bound on the objective

$$c'x \geq \langle \lambda, Ax \rangle \geq \langle \lambda, b \rangle$$

for some λ . But an arbitrary λ does not preserve inequalities: the dual of K is the set of λ that always do:

$$K^* = \{\lambda : \forall x \succ_K 0 \langle \lambda, x \rangle \geq 0\}.$$

For the dual, consider

$$\text{Max}_{\lambda} \{\langle \lambda, b \rangle : \lambda \succ_{K^*} 0, \forall x \langle c, x \rangle \geq \langle \lambda, Ax \rangle\}.$$

The last condition can be written as

$$\forall x \langle c, x \rangle \geq \langle A^* \lambda, x \rangle.$$

By setting x to a basis vector and its opposite, we see that this is equivalent to $c = A^* \lambda$. The dual is therefore:

$$\text{Max}_{\lambda} \{\langle \lambda, b \rangle : \lambda \succ_{K^*} 0, A^* \lambda = c\}.$$

The primal can be formulated in the same way (intersection of a cone and an affine subspace) by adding a variable $y = Ax - b$. More compactly:

$$\text{primal} : \text{Min}_{\lambda} \{\langle d, y \rangle : y \in \mathcal{L} - b, y \succ_K 0\}$$

$$\text{dual} : \text{Max}_{\lambda} \{\langle b, \lambda \rangle : \lambda \in \mathcal{L}^\perp + d, \lambda \succ_{K^*} 0\}.$$

Strong duality holds if the primal is strictly feasible, *i.e.*, $\exists x \ Ax - b \succ_K 0$ (strict inequality), *i.e.*, $\overset{\circ}{K} \cap (\mathcal{L} - b) \neq \emptyset$. (Without strict feasibility, anything can happen: primal solvable but dual infeasible, etc.)

2. The Lorentz cone

$$L^m = \left\{ x \in \mathbf{R}^m : x_m \geq \sqrt{x_1^2 + \dots + x_{m-1}^2} \right\};$$

is self-dual. A **second order cone program** (SOCP) is

$$\text{Min}_x \{c'x : Ax - b \in L^{m_1} \times \dots \times L^{m_k}\}.$$

The condition $Ax - b \in L^m$ can be written,

$$\begin{pmatrix} Dx \\ p'x \end{pmatrix} - \begin{pmatrix} d \\ q \end{pmatrix} \in L^m,$$

where

$$\begin{pmatrix} D & d \\ p' & q \end{pmatrix} = \begin{pmatrix} A & b \end{pmatrix},$$

i.e., $p'x - q \geq \|Dx - d\|_2$.

The dual of

$$\text{Min}_x \{c'x : \forall i \ \|D_i x - d_i\|_2 \leq p'_i q - q_i\}$$

is

$$\begin{aligned} &\text{Find} \\ &\text{To maximize} \quad \sum_i^{\mu, \nu} \mu'_i d_i + \nu_i q_i \\ &\text{Such that} \quad \sum_i D'_i \mu_i + \nu_i p_i = c \\ &\quad \forall i \ \|\mu_i\|_2 \leq \nu_i. \end{aligned}$$

Optimization problems rarely arise in this form: they have to be somehow transformed. For the objective, replace “minimize $f(x)$ ” with “minimize t such that $t \geq f(x)$ ”. For the constraints, there is a very, very long list of functions or constructions that can be used in SOCPs; here are a few of them.

– The Euclidian norm: $\|x\|_2 \leq t$;

– Its square:

$$\begin{aligned} \|x\|_2^2 \leq t &\iff x'x + \frac{1}{4}(t+1)^2 \leq \frac{1}{4}(t-1)^2 \\ &\iff \left\| \begin{pmatrix} x \\ \frac{1}{2}(t-1) \end{pmatrix} \right\|_2 \leq \frac{t+1}{2} \end{aligned}$$

– Convex quadratic forms (*i.e.*, quadratic programming):

$$\begin{aligned} x' C' C x + q' x + r &\leq t \\ \iff \left\| \begin{pmatrix} Cx \\ \frac{1}{2}(t + q'x - r) \end{pmatrix} \right\|_2 &\leq \frac{1}{2}(t - q'x - r); \end{aligned}$$

– Many (rational) powers;

– The L^p norm;

– etc.

Robustifying a linear program with elliptic (or, more generally, conic-quadratic representable) constraints gives a SOCP. For instance, the robustification of the constraint $ax - b \geq 0$ is

$$\text{Min}_{a^*, b^*} \left\{ a^* x - b^* : \left\| \begin{pmatrix} a^* - a \\ b^* - b \end{pmatrix} \right\|_2 \leq \varepsilon \right\} \geq 0$$

i.e.,

$$ax - b + \text{Min}_{u, v} \left\{ \begin{pmatrix} x \\ -1 \end{pmatrix}' \begin{pmatrix} u \\ v \end{pmatrix} : \left\| \begin{pmatrix} u \\ v \end{pmatrix} \right\|_2 \leq \varepsilon \right\} \geq 0$$

i.e.,

$$ax - b - \varepsilon \left\| \begin{pmatrix} x \\ -1 \end{pmatrix} \right\|_2 \geq 1.$$

(To robustify the objective $c'x$, replace it with a new variable t , add the constraint $c'x \leq t$, and robustify it.) The robustified problem can be used to assess the stability of the objective, the solution, the feasibility status of a linear problem.

3. Semi-definite programming (SDP) is another special case of cone programming, where the (self-dual) cone is that of positive semi-definite symmetric matrices. One can assume there is only one inequality – otherwise, put them in a single block-diagonal matrix. It is a generalization of conic quadratic programming:

$$\begin{pmatrix} x \\ t \end{pmatrix} \in L^k \iff \begin{pmatrix} t I_{k-1} & x \\ x' & t \end{pmatrix} \succ 0.$$

In addition, SDP can use the largest eigenvalue (or singular value), the sum of the k largest eigenvalues (or singular values), the spectral norm, (some rational powers of) the determinant, non-negative polynomials, trigonometric polynomials, etc. Applications include the stability of dynamical systems (eigenvalues) and robust cone programming.

Semi-definite programming provides *relaxations* of combinatorial problems, finer than LP relaxations, as follows. Formulate the problem as a quadratic program

with quadratic constraints (e.g., $x \in \{0,1\}$ is equivalent to $x^2 - x = 0$ or, since we prefer inequalities, $x^2 - x \leq 0$, $x - x^2 \leq 0$).

$$x^* = \underset{x}{\operatorname{Argmin}}\{f(x) : g(x) \leq 0\}$$

Consider the dual problem, *i.e.*, transform the constraints to penalties, with coefficients to be determined,

$$f_\lambda(x) = f(x) + \lambda g(x), \lambda \geq 0;$$

this provides a lower bound on $f(x^*)$

$$\zeta^* = \inf_x f_\lambda(x) \leq f(x^*).$$

But, since $f_\lambda(x)$ is a quadratic form, $\forall x \zeta \leq f_\lambda(x)$ means that $f_\lambda(\cdot) - \zeta \geq 0$. Finding the best bound is therefore a semi-definite program:

$$(\zeta^*, \lambda^*) = \underset{\zeta, \lambda}{\operatorname{Argmax}}\{\zeta : f_\lambda(\cdot) - \zeta \geq 0, \lambda \geq 0\}.$$

The SDP relaxation of a quadratically-constrained quadratic program can also be formulated as follows: replace inhomogeneous quadratic forms

$$g(x) = x'Ax + 2b'x + c$$

with homogeneous ones

$$G(x, t) = x'Ax + 2tb'x + ct^2 = \begin{pmatrix} t \\ x \end{pmatrix}' \begin{pmatrix} c & b' \\ b & A \end{pmatrix} \begin{pmatrix} t \\ x \end{pmatrix},$$

then, replace the quadratic forms $x'Gx$ with $\operatorname{tr}(GX)$. The relaxation corresponds to the embedding

$$\begin{cases} \mathbf{R}^n \rightarrow S_+^{n+1} \\ x \mapsto \begin{pmatrix} 1 \\ x \end{pmatrix} \begin{pmatrix} 1 \\ x \end{pmatrix}' \end{cases}.$$

Applications of SDP relaxation include graph problems (Shannon capacity, maxcut), other combinatorial problems, chance constraints.

Finding the best inner ellipsoidal approximation of a polytope defined by inequalities (or, more generally, of an intersection of ellipsoids) is a SDP.

Finding the best outer ellipsoidal approximation of a polytope defined as the convex hull of its vertices (or, more generally, of a union of ellipsoids) is a SDP.

4. Convex programming is a polynomial problem: the *ellipsoid method* needs $O(n^2 \log \varepsilon^{-1})$ steps (and each steps needs $O(n^2)$ operations) and goes as follows. Start with an ellipsoid containing the optimal set. If its center is not feasible, there exists a separating hyperplane between the center and the (convex) feasible set: use it to cut the ellipsoid. If it is feasible, the (sub) gradient of the objective defines a hyperplane, on one side of which the optimal set lies: use it to cut the ellipsoid. In both cases, take an outer approximation of the cut ellipsoid and iterate.

Interior point methods are interior penalty methods, *i.e.*, to solve

$$\underset{x}{\operatorname{Min}}\{c'x : x \in \mathcal{X}\},$$

they solve a sequence of unconstrained problems

$$x_*(t) = \underset{x}{\operatorname{Argmin}} tc'x + K(x)$$

where K is a *barrier function* (if $x_n \rightarrow x$ and $x \in \partial\mathcal{X}$, then $K(x_n) \rightarrow +\infty$) and t increases, $(x_*(t))_{t \geq 0}$ traces the *central path* (each is solved with the Newton method, which converges quadratically if sufficiently close to the solution).

With conic programming, a clever choice of the barrier function

$$\begin{aligned} x \geq 0 &\rightsquigarrow -\log x \\ X \succ 0 &\rightsquigarrow -\log \det X \\ x \in L^k &\rightsquigarrow -\log(x_k^2 - x_1^2 - \dots - x_{k-1}^2) \end{aligned}$$

and $t_{n+1} = 1.1t_n$, a single Newton step suffices for each value of t and the algorithm converges in $O(\log \varepsilon^{-1})$ steps. It is easier to monitor convergence and stay close to the central path if one traces both the primal and dual central paths; they are related by the augmented *complementary slackness* relation

$$\begin{aligned} x^*(t) &= -t^{-1} \nabla K(s^*(t)) \\ s^*(t) &= -t^{-1} \nabla K(x^*(t)) \end{aligned}$$

(since the cone is self-dual, the barrier is the same for both problems).

5. Interior point methods are polynomial, but for *large-scale problems* $O(n^3)$ or $O(n^2)$ will not do: if we want the algorithm to terminate in a reasonable amount of time, we can afford to evaluate the objective, its gradient, but nothing fancier.

There are information-theoretic bounds on the number of steps needed to achieve a given precision ε , e.g., $O(\log n / \varepsilon^2)$ as $n \rightarrow \infty$ for ball constraints (and much worse for box constraints) – it is almost independent of the dimension.

Mirror descent is a generalization of the projected gradient

$$x_{n+1} \leftarrow \operatorname{Prox}_{x_n}(\gamma_t f'(x_t)),$$

where one replaces the norm, distance and gradient to better suit the problem. For instance,

- Over an L^2 ball, $\|\cdot\|_2$, $\omega(x) = \frac{1}{2}x'x$ and the proxy mapping

$$\begin{aligned} \operatorname{prox}_x \xi &= \underset{y \in X}{\operatorname{Argmin}} \omega(y) + \langle \xi - \omega'(x), y \rangle \\ &= \underset{y \in X}{\operatorname{Argmin}} \|x - \xi - y\|_2 \end{aligned}$$

is the projection of $x - \xi$ on X ;

- Over the simplex Δ_n , use $\|\cdot\|_1$ and $\omega(x) = \sum x_i \log x_i$;
- Over the *spectahedron* $\{x \in S^n : x \geq 0, \operatorname{tr} x \leq 1\}$, use $\|\lambda(x)\|_1$ and $\omega(x) = \sum_i \lambda_i(x) \log \lambda_i(x)$.

A convex-concave saddle point problem (e.g., equilibrium, in a zero-sum game)

$$\text{Min}_{x \in X} \text{Max}_{y \in Y} \phi(x, y),$$

where ϕ is convex in x , concave in y , can be solved with mirror descent by considering the vector field (ϕ_x, ϕ_y) instead of the gradient.

There are a few variants: stochastic mirror descent if the gradient is noisy (the expected error converges in the same way), bundle mirror descent (momentum, to address plateau problems), etc.

Most non-smooth optimization problems are of the form

$$\text{Min}_{x \in X} \text{Max}_{y \in Y} \phi(x, y)$$

and can be smoothed as (Nesterov smoothing)

$$\text{Min}_{x \in X} \text{Max}_{y \in Y} \phi(x, y) + d(y).$$

The *mirror prox* algorithm (a variant of saddle point mirror descent) can be used to solve those problems. Convergence, for a non-smooth optimization problem, using only first-order information, is at best $O(1/\sqrt{rt})$, but it can be brought to $O(1/t)$ after such a transformation. Examples of non-smooth functions that can be used in this way include:

- The L^p norm, $\|x\|_p = \text{Max}_{\|y\|_q \leq 1} \langle y, x \rangle$.
- The L^p norm of the singular vectors of a matrix;
- The L^p -norm of the positive part,

$$\|x^+\|_p = \text{Max}_{\substack{\|y\|_q \leq 1 \\ y \geq 0}} \langle y, x \rangle$$

- The maximum entry of a vector, or the sum of the k largest entries

$$s_k(x) = \text{Max}_{y \in \Delta_{n,k}} \langle y, x \rangle$$

where $\Delta_{n,k} = [\mathbf{1}'y = k, y \geq 0]$;

- The sum of the k largest eigenvalues

$$S_k(x) = \text{Max}_{\substack{y \geq 0 \\ \text{tr } y = k}} \text{tr}(yx).$$

Maximum likelihood estimation of a multi-dimensional log-concave density M. Cule et al. (2010)

The log-concave maximum likelihood density estimator is well-defined, and asymptotically finds the log-concave density that minimizes the Kullback-Leibler divergence with the true density. Its support is the convex hull of the sample data (log-concave distributions have thin tails).

The estimator can be used for data visualization (e.g., checking for the presence of elliptic contours), classification (estimate the density of each class), clustering (fit a mixture of log-concave distributions with the EM algorithm, as you would a mixture of Gaussians), monte Carlo estimation of functionals of the

density (probabilities, moments, expectations, entropy, etc.), mixing detection (compare the log-concave estimator with a mixture of log-concave densities, or with $f(x) \propto \exp(\phi(x)_c \|x\|^2)$, with ϕ concave and fixes values $c > 0$ (this also accounts for fat tails), or with a permutation test comparing the data with samples from the estimated distribution).

Contrary to kernel-based estimators, this does not require the choice of a bandwidth matrix (problematic in high dimensions).

The density is found by minimizing

$$\sigma(y_1, \dots, y_n) = -\frac{1}{n} \sum y_i + \int_C \exp h_y(x) dx$$

where $y_i = \log \hat{f}(x_i)$ are the log-densities evaluated at the data points x_i , h_y is the smallest concave function with $\forall i \ h_y(x_i) \geq y_i$, the first term is the (negated) log-likelihood, the second term can be thought of as a Lagrangian term (we want the density to integrate to 1), C is the convex hull of the points (the support of the density). Since the concave function h_y is affine on each triangle of a triangulation of the points (obtained as a side result of the QuickHull algorithm), the integral is easy to compute. The objective function is convex, but non-differentiable: one could use Newton's algorithm with a subgradient, but convergence would be slow (linear or worse, versus quadratic for differentiable functions), or *Shor's r algorithm* (space dilation in the direction of the difference of two consecutive gradients – empirically faster)

There is an R implementation in the `LogConcDEAD` package (in dimension 1, also check `logconden`).

Efficient rank reduction of correlation matrices

I. Grubišić and R. Pietersz (2005)

A constrained optimization problem

$$\text{Max}_{x \in \mathbf{R}^n} \{f(x) : g(x) = 0\}$$

can be formulated and solved as an unconstrained one if the feasible set $M = [g(x) = 0] \subset \mathbf{R}^n$ is a manifold M on which you can explicitly compute the gradient and (for the Newton and conjugate gradient methods) the hessian: the gradient comes from the isomorphism between $T_y M$ and $T_y^* M$ induced by the Riemannian structure,

$$F_y(u) = \langle (\text{grad } F)_y, u \rangle_{T_y M},$$

the hessian from the Levi-Civita connection and the updates to the solution (“moving in some direction”) are given by parallel transport along geodesics.

In the case of rank-constrained correlation matrices, the feasible set is not a manifold (it is a stratified manifold, each stratum corresponding to a value for the rank), but it can be described as the quotient of a manifold (the “Cholesky manifold”) by the orthogonal

group. The resulting algorithm is equivalent to optimization using a parametrization with spherical coordinates.

Sparse inverse covariance selection via alternating linearization methods
K. Scheinberg et al. (2010)

There are many algorithms for sparse inverse covariance selection (SICS), *i.e.*, sparse estimators of the inverse covariance matrix corresponding to sparse graphical models ($\Sigma_{ij}^{-1} = 0$ iff $X_i \perp\!\!\!\perp X_j | X_{k, k \neq i, j}$):

$$\operatorname{Max}_{X \succ 0} \log \det X - \langle X, \Sigma \rangle + \lambda \|X\|_1.$$

The alternating linearization method solves the optimization problem

$$\operatorname{Min}_x f(x) + g(x)$$

with f and g convex, by rewriting the problem as

$$\operatorname{Min}_{x, y} \{f(x) + g(y) : x = y\}$$

and separately updating x and y . It can be adapted to solve the SICS problem.

Model selection through sparse maximum likelihood estimation for multivariate gaussian or binary data
O. Banerjee et al. (2006)

The sparse inverse covariance matrix

$$\operatorname{Argmax}_{X \succ 0} \log \det X - \operatorname{tr} SX - \rho \|X\|_1,$$

where S is the sample variance matrix, can be estimated by solving the dual problem, which is of the form

$$\operatorname{Max}_W \{\log \det W : \|W - S\|_\infty \leq \lambda\}.$$

It can be estimated one coordinate at a time (block-coordinate descent)

$$w_{12} \leftarrow \operatorname{Argmin}_y \{y' W_{11}^{-1} y : \|y - s_{12}\|_\infty \leq \rho\}.$$

Sparse inverse covariance estimation with the graphical lasso
J. Friedman et al. (2007)

This problem can in turn be solved though its dual

$$\operatorname{Min}_\beta \frac{1}{2} \left\| W_{11}^{1/2} \beta - b \right\|^2 + \rho \|\beta\|_1,$$

which is a lasso problem. The **glasso** package provides an implementation.

Covariance selection and estimation via penalized normal likelihood
N. Liu et al.

The coefficients of the Cholesky matrix can be interpreted as regression coefficients – penalized (lasso, ridge) regression gives a penalized Cholesky matrix, and a penalized variance matrix.

Covariance selection for non-chordal graphs via chordal embedding
J. Dahl et al.

The sparsity pattern of a variance matrix forms a chordal graph. One can easily estimate the inverse covariance matrix under a chordal sparsity constraint and, with more work, an arbitrary sparsity constraint.

Sparse permutation invariant covariance estimation
A.J. Rothman et al. (2008)

The L^1 -penalized inverse-variance (concentration) estimator

$$\operatorname{Argmin}_{\Omega \succ 0} \operatorname{tr}(\Omega \hat{\Sigma}) - \log |\Omega| + \lambda \|\Omega^-\|_1$$

(where Ω^- are the off-diagonal elements of Ω) can be estimated by parametrizing Ω as $\Omega = T'T$, with T lower-triangular, to ensure positivity, and using a quadratic approximation of the absolute value:

$$|u_{n+1}| \approx \frac{1}{2} \frac{u_{n+1}^2}{|u_n|} + \frac{1}{2} |u_n| \quad \text{or} \quad \frac{1}{2} \frac{u_{n+1}^2}{|u_n| + \varepsilon} + \frac{1}{2} |u_n|.$$

Efficient estimation of covariance selection models
F. Wong et al. (2003)

Bayesian approach for covariance selection (sparse estimation of the inverse covariance), with a Γ prior on the diagonal elements, and a zero-inflated prior on the correlations, estimated with Gibbs sampling, updating one partial correlation at a time (to keep the matrix positive definite).

Shrinkage algorithms for MMSE covariance estimation
Y. Chen et al. (2009)

How to choose the shrinkage coefficient when estimating a covariance matrix (the optimal coefficient depends on the unknown variance matrix and cannot be used, the Ledoit-Wolf coefficient can be improved on).

Identifying small mean-reverting portfolios
A. d'Aspremont (2008)

When looking for cointegrated assets to form mean-reverting portfolios, sparse portfolio are more investable. For instance, one could look for a portfolio whose prices $P_t = S_t x$ maximize the Ornstein-Uhlenbeck mean reversion parameter λ

$$dP_t = \lambda(\bar{P} - P_t)dt + \sigma dZ_t.$$

As a proxy for the mean-reversion, one can use the Box-Tiao *predictability*

$$\nu = \frac{\text{Var}_{t-1}[P_{t-1}]}{\text{Var}_{t-1}[P_t]} = \frac{\text{Var}[P_{t-1}]}{\text{Var}[P_t|P_{t-1}]}$$

(maximizing mean-reversion corresponds to minimizing predictability, *i.e.*, momentum). If the asset prices follow a VAR(1) process $S_t = S_{t-1}A + Z_t$, then $P_t = S_t x = S_{t-1}Ax + Z_t x$ and

$$\nu(x) = \frac{x' A' \Gamma A x}{x' \Gamma x}$$

where $\Gamma = \text{Var } S_t$ – it is a generalized eigenvalue problem.

To estimate the matrices A and Γ , one can use penalized methods (covariance selection for Γ , lasso for A).

The sparse generalized eigenvalue problem

$$\text{Max}_x \left\{ \frac{x' Ax}{x' Bx}, \|x\|_0, \|x\| = 1 \right\}$$

can be approximately solved greedily (progressively increase the number of non-zero coefficients, assuming that those sets of indices are increasing) or by semi-definite relaxation.

An open-source implementation of the critical line algorithm for portfolio optimization
D.H. Bailey and M. López de Prado (2013)

When people compute the efficient frontier

$$\begin{array}{ll} \text{Find} & w \\ \text{To minimize} & w' \Sigma w \\ \text{and maximize} & w' \mu \\ \text{Such that} & w' \mathbf{1} = 1 \\ & l \leq w \leq u \end{array}$$

they often solve a series of optimization problems, each with a different target return, and interpolate. This is imprecise and computationally wasteful.

The *turning points* on the efficient frontier are efficient portfolios such that nearby efficient portfolios contain different assets – points, on the efficient frontier, at which an asset enters or leaves the portfolio. Between two turning points, the efficient portfolios are the solution of an unconstrained problem (only equality constraints: $w' \mu = \mu_{\text{target}}$ and $w' \mathbf{1} = 1$) on a subset of the assets, for which an analytic expression can be derived (via Lagrange multipliers); they are also convex

combinations of the turning points (2-fund theorem). The efficient frontier can be computed by starting with the maximum return portfolio and moving down, from turning point to turning point.

The authors provide an implementation in Python.

Loglog counting of large cardinalities
M. Durand and P. Flajolet (2003)

To approximately count the number of different elements in a stream of words (words in a text, IP addresses in an intrusion detection system, values in a column in a database for query optimization, etc.) one can:

- Distribute the hashed (randomized) values in N buckets, in a bitmap, and count the occupied buckets (there are adaptive and hierarchical variants);
- Keep a proportion $p \ll 1$ of the data (by looking at the first bits of the hashed value) and count it, exactly;
- Look at the maximum position $\rho(x)$ of the first non-zero bit in the hashed data: $\log_2 N \approx \text{Max } \rho(x)$.

The log-log algorithm uses this idea, after splitting the data into m buckets, and averages the estimates.

HyperLogLog: the analysis of a near-optimal cardinality estimation algorithm
P. Flajolet et al. (2007)

In the loglog counting algorithm, one can replace the arithmetic mean of the \hat{N}_i with the harmonic mean of the $2^{\hat{N}_i}$.

Firefly algorithm, stochastic test functions and design optimisation
X.S. Yang (2010)

The firefly algorithm is similar to particle swarm optimization (PSO), but each particle moves randomly (no momentum) and is more attracted by nearby fitter particles (it is not attracted by less fit particles at all). If the local minima are hardly distinguishable, the particles can end up in several of them.

Empirical mode decomposition of financial data
K. Drakakis (2008)

An intrinsic mode function (IMF) is a continuous function with positive maxima and negative minima, *i.e.*, a function that oscillates (e.g.,  or ). A function f can be decomposed into an IMF (empirical mode decomposition, EMD) as follows (sifting):

- Interpolate the local maxima (upper envelope) and local minima (lower envelope) of f ;
- Average them;
- Subtract this average from the function;
- Iterate until this difference is an IMF;
- Subtract the IMF from f and start again to decompose the residuals.

**Recent mathematical development
on empirical mode decomposition**
Y. Xu and H. Zhang

The first intrinsic model function (IMF) of the empirical mode decomposition (EMD) is intuitively similar to the Hilbert transform (HHT, Hilbert-Huang transform):

$$Hf(t) = \text{pv} \int_{\mathbf{R}} \frac{f(s)}{t-s} ds$$

$$Af = f + iHf$$

$$Af(t) = \rho(t)e^{i\theta(t)}$$

where $\rho(t)$ is the instantaneous amplitude, $\theta(t)$ the phase, $\theta'(t)$ the frequency.

This technical article tries to describe which functions can be obtained as IMF.

In R, check the EMD and hht packages.

MCMC Using Hamiltonian dynamics
R.M. Neal (2011)

To sample from a probability distribution $P(q) \propto \exp -U(q)$, the Hamiltonian Monte Carlo (HMC) method adds another variable p (momentum) and considers the Hamiltonian system $H(q, p) = U(q) + K(p)$, with $K(p) = \frac{1}{2}p'Mp$; its dynamics are

$$\frac{dq_i}{dt} = \frac{\partial H}{\partial p_i}$$

$$\frac{dp_i}{dt} = -\frac{\partial H}{\partial q_i}.$$

To be numerically stable, the discretization of this system should remain reversible, volume-preserving, symplectic. The Euler method does not, but the *leapfrog* method (start with a half-step for momentum, and then use full steps for both position and momentum so that the updates are staggered) does. The HMC algorithm goes as follows: start with a state (q, p) , sample p from $P(p) \propto \exp -K(p)$ (Gaussian), make L leapfrog steps of size ϵ , and use the new state as a Metropolis proposal. HMC avoids the random-walk-like behaviour of the Metropolis algorithm, especially when the dimension is high or the variables correlated; fine-tuning the mass matrix M can improve things even further. Choosing ϵ and L is difficult, though.

**The No-U-Turn Sampler:
Adaptively setting path lengths
in Hamiltonian Monte Carlo**
M.D. Hoffman and A. Gelman

The leapfrog simulation in HMC sampling is usually done a fixed number of times L . To avoid having to specify L , one can try to move in one direction, as long as $\|q_{\text{new}} - q_{\text{old}}\|$ increases, *i.e.*, as long as

$$\frac{1}{2} \frac{d}{dt} \|q_{\text{new}} - q_{\text{old}}\|^2 = (q_{\text{new}} - q_{\text{old}}) \cdot p_{\text{new}} \geq 0.$$

But this is not time-reversible: we would not be sampling from the right distribution. The NUTS algorithm fixes that problem by moving $s_n 2^n$ steps ahead, for increasing values of n , with s_n a random sign (the technical details are more complicated than that).

Stan modeling language
M.D. Hoffman and A. Gelman (2012)

Stan is a Bayesian sampler, not unlike Bugs or Jags, but it uses Hamiltonian Monte Carlo (HMC) sampling: when a Gibbs sampler converges slowly and generates correlated samples, HMC should perform better. The model is converted into heavily-templated C++ (formal differentiation of the log-likelihood) and compiled (this can take time). Stan can automatically select the tuning parameters: the mass matrix is set to the identity; the number of steps can be chosen with the NUTS algorithm; the step size can be estimated during warm-up. Instead of a sampling statement

```
y[i] ~ normal(mu, sigma)
```

one can explicitly increment the log-probability

```
log__ <- log__ + normal_log(y[i], mu, sigma)
```

This is useful to integrate out discrete parameters.

**PyMC: Bayesian stochastic modeling
in Python**
A. Patil et al. (JSS 2010)

PyMC is a Bayesian sampler, not unlike Bugs or Jags, using Python instead of a more limited DSL (domain-specific language).

```
import numpy as np
from pymc import *
n = 5 * np.ones(4, dtype=int)
x = np.array([-0.86, -0.3, -0.05, 0.73])
alpha = Normal('alpha', mu=0, tau=.01)
beta = Normal('beta', mu=0, tau=.01)
@deterministic
def theta(a=alpha, b=beta):
    return invlogit(a+b*x)
d = Binomial('d', n=n, p=theta,
    value=np.array([0,1,3,5]), observed=True)
M = MCMC(d)
M.isample(iter=10000, burn=1000, thin=10)
M.trace('alpha')[:]
plot(M); M.stats()
g = geweke(M); geweke_plot(g)
raftery_lewis(M)
Matplot.autocorrelation(M)
```

It can also deal with “factor potentials”, *i.e.*, the unnormalized probabilities that appear in undirected graphical models.

Convergence can be assessed with the Geweke test,

$$z = \frac{\hat{\theta}_{\text{begin}} - \hat{\theta}_{\text{end}}}{\sqrt{\text{Var } \theta_{\text{begin}} + \text{Var } \theta_{\text{end}}}},$$

comparing the beginning (say, the n th decile) and the end (say, the last half) of the chain, or the Raftery

and Lewis procedure, that estimates the required burn-in, sequence length and thinning to have a $q = 97.5\%$ quantile, precise at $r = .5\%$, with probability $s = 95\%$,

$$P[|\hat{q} - q| \leq r] \geq s.$$

Goodness of fit can be estimated by sampling from the fitted model and comparing with the real data, e.g., by comparing the discrepancy $\langle (x - \hat{x})^2 \rangle$ (where \hat{x} is the (fitted) expected value of x) of the two datasets.

Five balltree construction algorithms **S.M. Omohundro (1989)**

Balltrees are an alternative to k-d-trees (which split the space in two at each node, orthogonally to one axis) and octrees (which split the space into 2^d quadrants at each node): a binary tree of balls, not necessarily disjoint, with the children included in the parents. They are used with two types of queries: pruning (e.g., find all leaves containing a given query node) and branch&bound (e.g., finding the nearest neighbours).

There are a few algorithms to build them:

- k-d algorithm: choose the axis along which the range of the data is larger, split the balls along the median of their centers;
- Top-down: idem, but choose the dimension and split point to minimize the total volume of the bounding balls;
- Insertion: add a new observation as a sibling of an existing leaf, in the position that increases the volume the least;
- Bottom-up: find the two balls whose bounding ball has the lowest volume, merge them, iterate;
- Improved bottom-up: idem, but each node keeps track (e.g., with another balltree implementation) of the best ball to merge it with, and the resulting volume; the balls are in a priority queue and only need to be updated when they are removed from the queue.

The bottom-up construction gives better results (smaller volume) for continuous distributions, manifolds and hierarchical clusters (e.g., the Cantor set).

An unscented Kalman smoother for volatility extraction: evidence from stock prices and options **J. Li (2011)**

To estimate the volatility from a stochastic volatility model: discretize it, linearize it, and apply a Kalman smoother. The unscented Kalman smoother does not explicitly linearize the model, but uses several points around the current state ($2d + 1$ of them: one in each axis direction) to estimate the mean and variance needed by the Kalman filter.

A short introduction to learning to rank **H. Li (2011)**

In information retrieval (IR, e.g., web search), the computer returns the top 100 answers and somehow ranks

them. Those two steps are often separate (the relevance function used to extract the top 100 is not used to sort the results): one can use machine learning to learn that sorting function.

To evaluate the ranking, use a penalty for misranked results, (logarithmically) higher if the difference is large, (exponentially) smaller if the element is far from the top.

Pointwise methods use standard classification methods (ordinal regression). Pairwise methods learn the function $(x, y) \mapsto x \leq y$ or $(x, y) \mapsto \text{rank } x - \text{rank } y$. Listwise methods learn an \mathbf{R} -valued score function (not uniquely defined) that induces the desired order.

Most of the examples presented are variants of support vector machines (SVM).

What HMMs can do **J. Bilmes (2002)**

Hidden Markov models (HMM) are graphical models, *i.e.*, they can be defined by a set of conditional independence relations between the state S and the emitted message M :

$$\{S_{[t,T]}, M_{[t,T]}\} \perp\!\!\!\perp \{S_{[1,t-2]}, M_{[1,t-2]}\} \mid S_{t-1} \\ M_t \perp\!\!\!\perp \{S_{-t}, M_{-t}\} \mid S_t.$$

In other words:

- Future $\perp\!\!\!\perp$ past \mid present;
- Given the current state, the message is independent of all the other variables.

Gaussian processes in machine learning **C.E. Rasmussen**

A Gaussian process is an infinite family of random variables $(X_t)_{t \in \mathbf{R}}$; the mean and covariance functions

$$m(t) = E[X_t], \quad k(s, t) = \text{Cov}(X_s, X_t)$$

suffice to define it. The joint distribution of X_{t_1}, \dots, X_{t_n} is Gaussian, and the conditional distribution $X_{s_1}, \dots, X_{s_m} \mid X_{t_1}, \dots, X_{t_n}$, obtained in the usual way (Shur complement) is the posterior distribution.

To train a Gaussian process, one can use a hierarchical prior, *i.e.*, posit a parametrization of the mean and covariance functions, e.g.,

$$m(t) = at^2 + bt + c \\ k(s, t) = \sigma_1^2 \exp\left(-\frac{(s-t)^2}{\ell^2}\right) + \sigma_2^2 \delta_{ij}$$

(the $\sigma_2^2 \delta_{ij}$ term accounts for noisy observations) and select the hyperparameters via log-marginal likelihood.

***A dynamic programming
segmentation procedure
for hydrological and environmental time series***
A. Kehagias et al. (2005)

The empirical quality of a time series segmentation can be measured by the squared error of a constant, linear of AR(1) model estimated on each segment; the optimal segmentation with a given number of segments can be efficiently computed ($O(n^2)$) via dynamic programming. The number of segments can be estimated with the Bayesian information criterion (BIC).

If the true segmentation is known, the quality of the result can be assessed by looking at the number of misclassified pairs (i, j) with $|i - j| < N/2$.

***Löwdin orthogonalization
A natural supplement to Gram-Schmidt***
S. Beaver

Contrary to Gram-Schmidt orthogonalization, Löwdin orthogonalization

$$\operatorname{Argmin}_{Q \in O(n)} \|A - Q\|_F$$

is symmetric. It can be computed from the singular value decomposition (SVD) $A = U\Sigma V'$ as $Q = UV'$.

***Statistical outliers and dragon-kings
as Bose-condensed droplets***
V.I. Yukalov and D. Sornette (2012)

Model for power law distribution with endogenous outliers ("dragon-kings", as opposed to exogenous outliers or "black swans"): let $\varepsilon(n)$ be the number of cities with n inhabitants or more, *i.e.*, the rank of a city with n inhabitants; $w(\varepsilon) = ne^{-\beta\varepsilon}$ the attraction of a city with rank ε ; $P[\varepsilon(n) \leq \varepsilon] = aw(\varepsilon)^n$; and a boundary condition $\varepsilon(m) = \text{number of cities (i.e., all cities have } m \text{ or more inhabitants)}$ – the outliers come from this boundary condition.

***Linking agent-based models and stochastic
models of financial markets***
L. Feng et al. (2012)

Evidence from agent-based-models that fat tails and long memory come from herding among technical traders.

***Advances in cointegration and subset
correlation hedging methods***
**M.M. López de Prado and D. Leinweber
(2012)**

Hedging a portfolio P_1 with assets P_2, \dots, P_n means finding w so that the spread

$$S_t = P_{1,t} + \sum_{k \geq 2} w_k P_{k,t}$$

be "small", in the sense that $S_T = 0$, or $S_{T+h} - S_T = 0$, or S_T small, or $S_{T+h} - S_T$ small, or $\text{Var } S_T$ small, or S stationary, etc.

Here are a few heging algorithms:

- Regression (only valid if the intercept is not significant);
- Minimum variance (equivalent to no-intercept regression), or minimum risk, for your preferred measure of risk (VaR, CVaR, etc.);
- Principal components: let V be the first $n - 1$ principal components of $\text{Var } \Delta P$, and choose w so that $V'w = 0$, $w_1 = 1$;
- Find w to minimize the Dickey-Fuller statistic (or the statistic of some other unit root test);
- Maximize the diversification ratio $\frac{\sum w_k \sigma_k}{\sigma_{\Delta S}}$
- Minimize the maximum subset correlation.

The *predictability* of an AR(1) process $P_t = \beta P_{t-1} + \varepsilon_t$ is

$$\lambda_t = \frac{E_{t-1}[P_t^2]}{E[P_t^2]} = 1 - \frac{E[\varepsilon_t^2]}{E[P_t^2]}.$$

If the asset prices P_{it} follow a VAR(1) model, the predictability of a linear combination $w'P_{\cdot,t}$ is defined similarly (after simplification, it is a generalized eigenvalue). The *Box-Tiao method* minimized the predictability of the spread.

***Economic scenarios for an asset and liability
management study of a pension fund***
C.C. Slagmolen

VAR models are often used to generate scenarios for ALM computations; the state variables could be 1-month interest rate, 10-year interest rate, inflation, equity returns and dividend yield; one can impose that some of the coefficients of the model be zero to account for causal relations.

$$z_{t+1} = \nu + Bz_t + \Sigma\xi_{t+1}$$

Those state variables can be used to estimate the value of the assets of a pension fund, but cannot be used, directly, to discount future liabilities: the term structure generated by a VAR model can present arbitrage opportunities. To estimate the term structure, one can first model the deflator (sometimes called stochastic discount factor or pricing kernel) M_{t+1} on $[t, t + 1]$

$$\begin{aligned} -\log M_{t+1} &= \delta_0 + \delta_1 z_t + \frac{1}{2} \lambda_t' \lambda_t + \lambda_t' \xi_{t+1} \\ \lambda_t &= \lambda_0 + \Lambda z_t \end{aligned}$$

(where $\delta_0 + \delta_1 z_t$ is the short rate and λ_t the market price of risk) and assume that the term structure is affine, *i.e.*, that the price, at time t , of a zero-coupon bond maturing at time $t + n$, is $P_t^{(n)} = \exp(A_n + C_n z_t)$. But the stochastic discount factor also gives a price, $P_t^{(n+1)} = E_t[M_{t+1} P_{t+1}^n]$, allowing us to compute A_n and C_n .

The model is very sensitive to the starting state (e.g., low interest rates) and the estimation periods (e.g., presence of a crisis).

***Optimal versus naive diversification:
how inefficient is the 1/N portfolio strategy?***
V. DeMiguel et al. (2007)

Comparison of the 1/N portfolio strategy with alternatives (minimum variance or tangent portfolio from sample variance, bayesian estimators, shrinkage estimators, prior from a CAPM or Fama-French pricing model, etc.): it is not significantly worse. Those alternatives have an edge when there is a lot of data, when the correlation is not invariant under the action of \mathfrak{S}_n , when there are few assets, and/or when the optimal Sharpe ratio is significantly higher than the 1/N one.

In defence of optimization: the fallacy of 1/N
M. Kritzman et al. (2010)

If you have enough data (5 to 50 years) or use reasonable expected returns, optimal portfolios significantly outperform 1/N portfolios.

***Why does an equal-weighted portfolio
outperform value- and
price-weighted portfolios?***
Y. Plyakha et al. (2012)

The equal-weighted portfolio outperforms the value-weighted portfolio, not only because of a different risk exposure (more small caps), but also because of frequent rebalancing.

Adaptive asset allocation
Macquarie Private Wealth

Amateurish (plots with no axes, confusion between correlation and volatility, plots that seem to omit the quantities of interest (performance, etc.) as if there was something to hide, ridiculous numeric precision, etc.) advocacy for risk parity portfolios (keep the contribution to risk constant, lower the leverage when the risk is too high) that ends with a minimum variance portfolio on high-momentum stocks.

Performance attribution for equity portfolios
Y. Lu and D. Kane

The Brinson method decomposes the performance of a portfolio as follows. Let W_j^B (resp. W_j^P) be the weight of sector j in the benchmark (portfolio), R_j^B (resp. R_j^P) the returns sector j in the benchmark (portfolio).

Active return

$$\begin{aligned} &= \text{Portfolio returns} - \text{Benchmark returns} \\ &= W^P R^P - W^B R^B \\ &= (W^P - W^B) R^B + W^B (R^P - R^B) \\ &\quad + (W^P - W^B) (R^P - R^B) \end{aligned}$$

The three terms are called “allocation”, “selection” and “interaction”. This can be generalized to several groupings (e.g., sectors and countries), but the number of interaction terms increases exponentially.

With several periods, you can neither add the returns (the aggregated returns would be wrong) nor compound them (the returns are correct, but the contributions no longer add up to them). Instead, one can use *optimal linking*: write the returns as

$$R_{[0,T]}^P - R_{[0,T]}^B = \sum_t \beta_t (R_t^P - R_t^B)$$

for some judiciously-chosen “linking coefficients” β :

$$\begin{aligned} \beta_t &= A + \alpha_t \\ A &= \frac{(R_{[0,T]}^P - R_{[0,T]}^B)/T}{(1 + R_{[0,T]}^P)^{1/T} - (1 + R_{[0,T]}^B)^{1/T}} \\ \alpha_t &= C(R_t^P - R_t^B) \\ C &= \frac{R_{[0,T]}^P - R_{[0,T]}^B - A \sum_t (R_t^P - R_t^B)}{\sum_t (R_t^P - R_t^B)^2}. \end{aligned}$$

Regression-based analysis can more easily accomodate several groupings or factors (Brinson analysis can be seen as a no-intercept regression), but time-aggregation poses the same problems.

In R, this is implemented in the pa package.

Equity performance attribution methodology
Morningstar (2008)

Since the interaction term, in the Brinson method, is difficult to interpret, it can be incorporated into the last decision: in the (preferred) top-down approach, the contributions are allocation and selection+interaction, in the bottom-up approach, they are selection and allocation+interaction.

For multi-period attribution, one can use a geometric approach:

$$\begin{aligned} \log(1 + R^P) - \log(1 + R^B) &= \\ \log(1 + R_{\text{allocation}}) + \log(1 + R_{\text{selection}}) & \end{aligned}$$

where $R_{\text{allocation}}$ and $R_{\text{selection}}$ are decomposed into sums of contributions.

Long and short positions should be analyzed separately. One can add a “return gap” term, for unexplained returns (intra-period trades, corporate actions, etc.)

***How news affect the trading behaviour
of different categories of investors
in a financial market***
F. Lillo et al. (2012)

Endogenous information (returns, volatility), exogenous information (news – they use the (non-free) General Enquirer; check C. Potts’s lexicons web page for more lists of words) and investor behaviour.

Comparing the performance of FA, DFA and DMA using different synthetic long-range correlated time series
Y.H. Shao et al. (2012)

Empirical comparison of various long-range correlation estimators (Hurst index):

- R/S (rescaled range) analysis;
- FA (fluctuation analysis): $\langle (y_{t+s} - y_t)^2 \rangle^{1/2} \sim s^{-\alpha}$;
- DFA (detrended FA): $\langle (y_{t+s} - g_t)^2 \rangle^{1/2} \sim s^{-\alpha}$, where g_t is a polynomial approximation of y_t on non-overlapping boxes of size s ;
- DMA: idem, with a moving average with window size s .

DFA is good enough.

Numerical evaluation of a generalized Cauchy principal value
A. Nyíri and L. Baranyi (1999)

The Cauchy principal value

$$\text{pv} \int_{x_0-\Delta}^{x_0+\Delta} \frac{f(x)}{h(x) - h(x_0)} dx$$

can be evaluated numerically as $\int_0^\Delta g$, where

$$g(u) = \frac{f(x_0 + u)}{h(x_0 + u) - h(x_0)} + \frac{f(x_0 - u)}{h(x_0 - u) - h(x_0)}$$

$$g(0) = \frac{f'_+ + f'_-}{h'} - f \frac{h''_+ + h''_-}{2h'}.$$

Principal-value integrals by a simple and accurate finite-interval method
W.J. Thompson (1997)

The Cauchy principal value can be approximated numerically, if the interval around the singularity is small, by using the Taylor expansion (only the odd derivatives remain).

$$\text{pv} \int_{x_0-\Delta}^{x_0+\Delta} \frac{f(x)}{x - x_0} dx = 2 \sum_{n \geq 0} \frac{f^{(2n+1)}(x_0) \Delta^{2n+1}}{(2n+1)!(2n+1)}$$

This can be generalized to $\text{pv} \int_{x_0-\Delta}^{x_0+\Delta} \frac{f(x)}{(x - x_0)^p} dx$.

Isoelastic agents and wealth updates in machine learning markets
A.J. Storkey et al. (2012)

A machine learning market is a way of combining several estimators of the distribution of a random variable X : the possible outcomes, $1, 2, \dots, n$ correspond to Arrow-Debreu securities, the estimators are investors, each endowed with an initial wealth (confidence in the model) and trying to maximize their expected utility. The equilibrium can be estimated by tatonnement; for some utilities, it can be derived in closed form.

Image processing
G. Sapiro (Coursera, 2013)

1. The JPEG compression algorithm works as follows: convert the RGB image to YCbCr (the channels are more independent – this is just a linear transformation), cut the image into 8×8 blocks, apply a discrete cosine transform (DCT) to each of them, quantize the resulting coefficients (you can use more bits for the most important ones – the number of bits is specified by the “quantization matrix”; rescaling it changes the size and quality of the result), use Huffman encoding on the resulting stream of bits. (The DCT is actually the empirical Kahunen-Loève transform (KLT) from stochastic calculus, in the special case of Markovian images.)

Predictive encoding uses some algorithm to predict the $(n+1)$ st pixel from the previous ones and encodes the error. It can be used for lossless compression (JPEG-LS) or lossy video compression (MPEG)

2. Some image enhancement algorithms are straightforward to implement: curves (e.g., gamma correction), histogram equalization, histogram matching, local averaging (local mean, local median). *Non-local means* denoising finds and averages similar neighbourhoods (e.g., all the windows, all the gargoyles, etc.), in different parts of the picture.

Different noise removing filters are adapted to different types of noise: median filter for salt-and-pepper noise, the gaussian blur for gaussian noise, etc. To infer the type of noise, you can pick a small region of the image and assume that it was initially uniform; the noise may not be the same on the whole image.

Image degradation can be modeled as

$$g = f * h + \text{noise}$$

where f is the initial image, h the degradation and $*$ denotes convolution. If the noise is negligible, the Fourier transform gives $G = FH$, therefore $F = G/H$. To estimate h , calibrate the camera on a known, simple image f , e.g., a single dot. The *Wiener filter* takes the noise into account: $\hat{F} = H^*/(H^2 + S_{\text{noise}}/S_{\text{signal}})G$ where S is the power spectrum and $*$ the complex conjugate (it minimizes the expected square error). Since $S_{\text{noise}}/S_{\text{signal}}$ is usually not known, it is often replaced with a constant K (the gain): just multiply by $H^*/(H^2 + K)$.

3. The *Hough transform* detects lines (or other parametric shapes). Let X be the set of the pixels in the image and Y the set of the shapes we want to detect, e.g., the set of straight lines in X , discretized (and parametrized in some way, e.g., $\rho = x \cos \theta + y \sin \theta$). For each pixel in X , increase the intensity of the corresponding pixels in Y . The most prominent shapes are the pixels in Y with the highest intensity. To find segments, rather than (infinite) lines, check back on the image where there are pixels on the line

Otsu's image segmentation algorithm is simplistic: look at the histogram of the image and try to see two modes,

e.g., find the threshold that minimizes the within variance. Since the total variance is the within variance plus the between variance, you can instead maximize the between variance; as you move the threshold, it is easy to update. If the background is not uniform, it may not work: try to apply the algorithm on a moving window instead.

The *Mumford-Shah* image segmentation algorithm solves an optimization problem: find a new image, locally smooth, with a penalty for the difference with the initial image (MSE), and another penalty for the presence of a lot of edges. More precisely, find a new image J and the edge locations B to minimize

$$\alpha \int_D \|I - J\|^2 d\Omega + \beta \int_{D \setminus B} \|\nabla J\|^2 d\Omega + \gamma \int B d\Omega.$$

Image segmentation is often interactive: the application asks the user to indicate what is the foreground and what is the background, by a few strokes inside those regions. We can adapt Otsu's algorithm: look at the distribution of the colour of the pixels along those strokes, and assign each new pixel to the region whose distribution is closest. The *weighted distance transform* also uses geometric information: for each pixel, compute the weighted geodesic distance to the foreground (using Dijkstra's algorithm, in linear time) and the background scribble, and assign the pixel to the closest scribble; as weight, use the change in the foreground probability along the direction of the path, $|\nabla p_{\text{Foreground}} \cdot ds|$. You can refine the result by adding new scribbles, automatically, inside the detected foreground, and inside the detected background.

Segmentation can also be formulated as a graph-theoretic problem: consider the graph whose vertices are the pixels, plus one vertex for the background, and one for the foreground. The edges correspond to neighbouring pixels, with also one edge from the background to each pixel, and the same for the foreground. The graph is weighted: between pixels, use the absolute value of the difference between a pixel and its neighbours; between the foreground and a pixel, use the probability that a pixel belongs to the foreground, e.g., from the scribbles given by the user in interactive segmentation. This is a *min-cut* problem.

Those algorithms can be generalized to process video (e.g., Roto-brush video segmentation in Adobe After Effects): do not consider the image as a whole, but smaller windows covering it; take motion into account (the same window on the next frame is not exactly at the same place); use mixed models for the distribution of the colours of the background and foreground; use a shape prior and a colour prior to find the new segmentation, with more weight on the shape prior if the colours are not distinct enough.

4. Let C be a planar curve, s its arclength parametrization, C_s its first derivative (of length 1), C_{ss} its second derivative, orthogonal, of length κ (the curvature). Cartan's theorem states that, up to Euclidian transformation, a curve is entirely determined by its curva-

ture $(s, \kappa(s))$, seen as a function of the arc length. It can be generalized to equi-affine transformations, *i.e.*, affine transformations preserving areas (their determinant is 1): an equi-affine parametrization v is such that $\det(C_v, C_{vv}) = 1$; the equi-affine curvature μ is defined by $C_{vvv} = \mu C_v$; up to equi-affine transformation, a curve is entirely determined by its equi-affine curvature $(v, \mu(v))$, seen as a function of the equi-affine arclength v .

The evolution of a planar curve can be described by a partial differential equation (PDE),

$$\frac{\partial \text{Curve}}{\partial t} = V(p, t),$$

such as the curvature flow $C_t = \kappa n$ (or heat flow, $C_t = C_{ss}$, a simple curve becomes convex and turns into a circular point), the affine affine heat flow $C_t = \kappa^{1/3} n$ (elliptic points), the constant flow $C_t = n$. (The tangential components do not affect the geometry of an evolving curve – they just change the parametrization.) Geodesic *active contours* use $C_t = g\kappa n$, with $g = 1/\|\nabla I\|$. Curves can also be represented by a level set, $f(x, y) = 0$: the normal is $n = -\nabla f / \|\nabla f\|$, the curvature $\kappa = \text{div}(\nabla f / \|\nabla f\|)$ and the curve evolution $C_t = Vn$ becomes $f_t = V \|\nabla f\|$.

Calculus of variation refers to infinite-dimensional optimization problems: finding a function (e.g., a curve) that minimizes some quantity. For instance, if we want to find the function u (subject to some boundary conditions) to minimize $\phi(u) = \int F(x, u, u_x) dx$, the first order conditions are given by the *Euler-Lagrange equation*, $\phi'(u) = 0$, where ϕ' is the functional derivative, *i.e.*,

$$\frac{\partial F}{\partial u} - \frac{d}{dx} \frac{\partial F}{\partial u_x} = 0.$$

Solving the variational problem with the steepest descent method $u_{t+1} - u_t - \alpha \phi'(u)$ is tantamount to adding a time parameter t and solving the PDE $u_t = -\alpha \phi'(u)$. For instance, minimizing $\int \rho(\|\nabla I\|) d\Omega$ with $\rho(a) = a^2$ gives isotropic diffusion (gaussian smoothing, the heat equation) $I_t = \Delta I = \text{div}(\nabla I)$, and $\rho(a) = a$ gives anisotropic diffusion $I_t = \text{div}(\nabla I / \|\nabla I\|)$ – there is less diffusion when the gradient is high, *i.e.*, near the edges, which are preserved.

For instance, $\phi(u) = \int \|\nabla I\|^2 d\Omega$ gives $\phi'(u) = -2 \text{div} \nabla I = -2\Delta I$ – the corresponding diffusion (isotropic diffusion) is the heat equation, *i.e.*, Gaussian smoothing.

More generally, one can consider $\phi(I) = \int \rho(\|\nabla I\|) d\Omega$. In particular, $\phi(I) = \int \|\nabla I\| d\Omega = \iint \sqrt{I_x^2 + I_y^2} dx dy$ gives $\phi'(u) = -\text{div}(\nabla I / \|\nabla I\|)$: this anisotropic diffusion is similar to Gaussian diffusion, but with less diffusion near the edges (where the denominator $\|\nabla I\|$ is large).

The gradient ∇I gives some edge information, but only locally. To have global edges, start with some local

edge detection, e.g.,

$$g(x, y) = \frac{1}{1 + \|\nabla(G * I)\|^2}$$

($G * I$ is the smoothed image, G can be chosen to detect some specific shapes, and since the gradient is in the denominator, edge pixels have a low value) and find a curve C that minimizes $\int_C g(x, y) ds$; the resulting diffusion gives *active contours*. You need a starting curve to deform: take segments regularly placed on the image, or a closed curve around the boundary of the image.

Histogram equalization (contrast enhancement) can also be formulated as a diffusion:

$$\frac{dI(x, y)}{dt} = I(x, y) - \text{number of pixels of value} \geq I(x, y).$$

It minimizes

$$\frac{1}{2} \int (I - \frac{1}{2})^2 dx - \frac{1}{4} \iint (I(x) - I(y)) dx dy.$$

You can change the objective function, e.g., by giving more/less weight to some region.

Inpainting fills in the missing parts of an image (e.g., because they contained undesirable elements, or they were damaged or lost). This can be done with PDEs: assume that the laplacian ΔI does not change as we move along the edges, i.e., in a direction $\nabla^\perp I$ orthogonal to the gradient ∇I ; propagate according to

$$I_t = \nabla \Delta I \cdot \nabla^\perp I$$

(only the missing parts of I change).

Inpainting can also be done with calculus of variations: if we know the normalized gradient $\theta = \nabla I / \|\nabla I\|$, then $\theta \cdot \nabla I = \|\nabla I\|$. We can look for θ and I to minimize (on the region to fill in)

$$\int (\|\nabla I\| - \theta \cdot \nabla I) d\Omega;$$

the corresponding Euler-Lagrange equations are

$$\frac{dI}{dt} = \text{div} \frac{\nabla I}{\|\nabla I\|} - \text{div} \theta.$$

(In practice, one would add a regularizing term, e.g.,

$$\int (\text{div} \theta)^p (a + b \|\nabla(G * I)\|) d\Omega,$$

to the function to minimize.)

To preserve texture, while inpainting, decompose the image into a smooth (say, locally constant) component and a texture component, and inpaint both separately. To inpaint the texture, use smart cut-and-paste: find a similar region, elsewhere in the image (like non-local means), allowing for some deformation; do this for a covering by small regions, but require that the translation vector changes smoothly from one region to a

neighbouring one. This can be formulated in a variational way.

5. Noise can be removed from an image y by finding the image x that minimizes

$$f(x) = \|x - y\|^2 + \lambda G(x).$$

There are many popular choices for the penalty term (Bayesian prior) $G(x)$: $\|x\|^2$, $\|\Delta x\|^2$ (smoothing), $\rho(\Delta x)$ (robust statistics), $\|\nabla x\|$ (total variation), etc.

Sparse modeling tries to express an image as a linear combination of images (“atoms”) from a set of reference images (“dictionary” – it could be a basis, but it will usually be larger), with as few atoms as possible, i.e., with an L^0 penalty. Often, one can replace the L^0 pseudo-norm with the L^1 norm: the optimal solution is the same; the relaxed problem is convex (and a greedy algorithm, adding one element at a time, gives reasonably good results). The *k-SVD* algorithm learns the weights and the dictionary for a given set of images (usually, small overlapping patches in the same image) at the same time: start with a random dictionary (or, say, the DCT one used by JPEG), compute the weights, update the reference images, iterate. This can be used for denoising, inpainting, video inpainting, zooming, demosaicing (for camera sensors: for each pixel, only one of the three colours is present), etc.

Compressed sensing is another form of sparse modeling: it models each 8×8 patch as a mixture of (say) 10 Gaussians (these are 64-dimensional Gaussians: use low-rank variance matrices), alternates between the estimation of the Gaussians and the estimation of the weights of the patches (MAP-EM) and only uses one of the Gaussians for each patch.

Sparse modeling can also be used for classification – concatenate dictionaries adapted to the different types of scenes to recognize, and look at which atoms were used.

Artificial Intelligence Planning **G. Wickler and A. Tate (Coursera, 2013)**

1. A planning problem is described by a set of states, a set of actions, acting on the set of states, an initial state, and a goal state.

There are more parsimonious descriptions, with symbols (e.g., `robot1`, `box1`, `locationA`), predicates (e.g., `location(what, where)`), and parametrized actions (e.g., `move(who, what, from, to)`); each action has a set of (positive and negative) preconditions, and a set of (positive and negative effects). This can be extended with disjunctions and quantifiers in the preconditions. Those problems can be represented in a Lisp-like (PDDL) or Prolog-like (STRIPS) syntax.

Examples include puzzles (canibals and missionaries, 8-puzzle, 8-queen problem, etc.), autonomous systems (elevators, space probes, unmanned vehicles) and business process management.

There are many algorithms to solve those (NP-

complete) problems: state-space search (A* and variants, with a heuristic function), plan-space search, graphplan, reduction to other problems (SAT, ASP (answer set programming), integer programming).

2. State-space search algorithms rely on some graph search algorithm, often based on a heuristic (an approximation of the distance between a state and the goal), such as best-first-search (explore the node whose estimated distance to the goal is shortest) or A* (also include the distance from the initial state), in their tree-search or graph-search variants (if you assume that the graph is a tree, you do not have to check if a node has already been visited; if it is not, you should check, and the technical condition on the heuristic is slightly different).

There are memory-efficient variants of A*, such as iterative deepening A* (depth-first search with a bound on the cost, restart many times as you progressively increase the bound – since most of the work is done in the last iteration, it is not that slow).

Instead of *forward search* (going from the initial state to the goal), you can try *backward search* (going from the goal to the initial state), but in both cases, the branching of the tree can be too high. To reduce it, you can consider partially instantiated actions ($a(s, -)$, where “-” is left unspecified until needed).

But in the case of n independent actions that can be executed in any order, there are still $n!$ different paths...

3. *Plan space* search is another form of backward search, in which we progressively build the plan, by adding actions, but without imposing any order until absolutely necessary. More precisely, start with the goal, look at its preconditions, find one that is not satisfied, find an action that enforces it (you will need to backtrack on that choice) and add it as a causal link (“action a establishes precondition p of action b ”). Unsatisfied preconditions are only one of the two types of “flaws” a partial plan can have: there is a “threat” when the effect of an action contradicts a causal link – this can be remedied by imposing an order relation, putting the action before or after the causal link. (In addition, the actions added can be partially instantiated, e.g., `move(who, what=apple, from=tree, to=bag)`, and one progressively adds constraints ($=, \neq$) on unbound variables.) This is no longer a search in the state graph, but in the graph whose nodes are partial (and partially ordered) plans, and whose edges are partial plan refinements.

4. *GraphPlan* addresses the branching factor problem by considering an (easy-to-solve) relaxed problem and searching among the solutions of the relaxed problem.

The planning graph is a layered, directed graph:

- The first proposition layer P_0 contains the propositions valid in the initial state (we assume that there are no negative conditions);
- The action layer A_i contains all actions whose pre-

conditions form a subset of the previous proposition layer P_{i-1} ; also add no-op actions for each proposition in layer P_{i-1} ;

- The proposition layer P_i contains all the propositions in P_{i+1} plus all the positive effects (not the negative ones) of the actions on A_i (P_0 corresponds to a state, but later proposition layers no longer do: they usually contain incompatible propositions);
- Edges from the preconditions of an action (in the previous layer) to this action;
- Edges from an action to its positive and negative effects in the next layer (use two edge types).

This already gives a necessary condition for reachability. We can also add edges inside layers to indicate incompatibilities (*mutex*). Two propositions are non-mutex if they are produced by independent (non-mutex) actions (or by a single action) (you need to distinguish between positive and negative effects). Two actions are mutex if they are dependent, or if some of their preconditions are mutex. The layers are increasing in size, and the sets of mutexes are decreasing, so that the layers stop changing at some point.

5. To build a *heuristic* for the A* algorithm, you can try to simplify the problem in some way, by removing some of the information or constraints. For instance, for the 15 puzzle, you can ignore the labels on cells 8–15, and store the number of (marked) tiles to move in a *pattern database*. Even better, you can do this for cells 1-7 and 8-15 (disjoint pattern databases), and add the corresponding heuristics. (In general, to find disjoint pattern databases, try to find mutually exclusive sets of proposition symbols – e.g., 2 sets – if there are too many, the problems are trivial and not informative.

The traveling salesman problem (TSP) gives another example: when moving the truck, do not remove it from its old position (*ignore deletes*), so that it is in several positions at the same time (the relaxed problem reduces to the minimum spanning tree (MST) problem, which also gives a heuristic solution).

Heuristic search often wins the International Planning Competition.

The *FF planner*, and most state-of-the-art planners, use the planning graph on a relaxed problem (no deletes) to find a heuristic: it is not admissible, but it is usually good.

6. *Hierarchical task networks* (HTN) rely on more domain knowledge to group actions into higher level tasks: the problem is then to find a decomposition of a goal into tasks.

7. Planning problems can be augmented with resources, time (time points, or interval algebra), uncertainty (replace “state” with “sets of states”), probability (partially observable markov decision process (MDP)), interacting agents. Real-world planners need to monitor the plan execution and modify the plan if something unexpected happens.

When run on similar problems, the planner can learn

macro operations (the tasks in a HTN) and refine its heuristic function (to help choose between nodes with the same heuristic).

Private equity as an asset class
F. Fraser-Sampson (2010)

Private equity (PE) refers to equity (shares in a company) not listed on a stock exchange. A *GP* is a manager of a PE fund, an *LP* is an investor in a PE fund.

When investing in a PE fund, you pledge that you will invest a certain amount (the *committed capital*), in the coming years, when required (when the money is *called* or *drawn down* – you do not know the dates in advance). The *invested capital* will be lower – when you start to invest in PE, it will remain very low, for several years. The committed capital is usually 1.6 to 2 times the *allocated capital* (the proportion of your wealth you wish to eventually invest in PE).

Since the cash flows are random, and mostly negative, there is no good definition of annual returns. One can look at the *J-curve*, *i.e.*, the running internal rate of return (IRR), $IRR_{[0,t]} \sim t$, or various multiples:

$$\begin{aligned} \text{DPI} &= \frac{\text{Distributed}}{\text{Paid in}} \\ \text{DCC} &= \frac{\text{Distributed}}{\text{Committed capital}} \\ \text{PICC} &= \frac{\text{Paid in}}{\text{Committed}} \\ \text{RVPI} &= \frac{\text{Remaining value}}{\text{Paid in}} \\ \text{TVPI} &= \frac{\text{Distributed} + \text{Remaining}}{\text{Paid in}} \end{aligned}$$

Look at their distribution for a given sector, fund size, region, industry, vintage year (starting date of the fund), time since inception.

There is no useable notion of “risk” either.

[Apparently, no one tries to model the randomness of those cash flows – lack of data?]

A **buyout** fund takes a majority part in a company, using a lot of debt: since steady cash flows are needed to service the debt, the target is a mature company, with good cash flows and too little debt. Buyout returns are driven by earnings (strictly speaking, the cash flows, but the EBITDA is often used instead: it is available, does not include interest payments (they will change), taxes (they will change: debt is more tax-efficient), depreciation and amortization (mere accounting cookery, not real cash)), earnings growth, “multiple” (P/E, *i.e.*, price/earnings ratio, influenced by the market), leverage. In the valuation, do not forget to take inflation into account (or use a real currency).

When investing in a buyout fund, decompose the performance into the contribution of leverage, market and earnings growth as follows (with $\{i, j\} = \{1, 2\}$), and

compare with peers.

$$\begin{aligned} \text{Enterprise value} &= \text{Debt} + \text{Price} \\ &= \text{Debt} + \text{Earnings} \times \text{Multiple} \\ \Delta \text{EV} &= \Delta \text{Debt} \\ &\quad + \text{Earnings}_i \times \Delta \text{Multiple} \\ &\quad + \text{Multiple}_j \times \Delta \text{Earnings}. \end{aligned}$$

When choosing a buyout, check the accounting data and projections, the supply and distribution channels, the anti-trust legislation, the pension scheme (often in deficit).

Venture refers to a majority share in young companies, developing new applications of extant technologies (rather than new, unproven technologies: that would be too risky), usually in the IT or biotech industries. Most companies (95%) in which a venture fund invests fail – the performance of the fund is often due to a single company succeeding (its value increases 25-fold) – a *home-run*. Valuing those companies is problematic: data is scarce, accounting rules are murky (Europe) or just advisory (US). Each financing round changes the valuation and increases the dilution. When investing in a venture fund, look at its multiple and the proportion of home-runs; compare with the industry. When choosing a venture company, check the technical soundness of the project, the potential key customers, the key personnel, and intellectual property ownership.

Development capital refers to a minority investment in an established company, with steady cash flows and a decent market share; the money is needed for a specific goal (e.g., to develop a new product) or because one of the current shareholders is leaving (retiring).

Growth capital is similar, but the goal is to grow the market share further, or maintain it in a growing market: since this requires extra marketing and product development, the profits will drop – but the sales and the company value will increase.

Both development capital and growth capital are short-term (3 years) minority investments: minority protection (e.g., negative control, *i.e.*, veto right) and exit protection are necessary.

Graphical Markov models
with mixed graphs in R
K. Sadeghi and G.M. Marchetti
(R Journal, 2012)

Directed acyclic graphs (DAG) describe conditional independence relations in an imperfect way. In particular, they are not stable under marginalization and conditioning. They can be generalized by adding *arcs* between response variables (when a common cause has been marginalized)

and *lines* between explanatory variables (when a common consequence has been conditioned on)

Ribbonless graphs are the smallest class of mixed graphs, containing DAGs, and stable by marginalization and conditioning. The notion of d -separation (to read independence relations off the graph) can be generalized to m -separation.

The **ggm** package can manipulate those graphs (**gRain** dealt with DAGs and d -separation, **graph**, **igraph**, **gRbase** are more general-purpose).

Rfit: rank-based estimation for linear models
J.D. Kloeke and J.W. McKean
(R Journal, 2012)

Rank regression estimators are

$$\hat{\beta}_\phi = \underset{\beta}{\operatorname{Argmin}} \|y - X\beta\|_\phi$$

where

$$\|\varepsilon\|_\phi = \sum_{i=1}^n \phi \left(\frac{\operatorname{Rank} \varepsilon_i}{n+1} \right).$$

The crs package: nonparametric regression splines for continuous and categorical predictors
Z. Nie and J.S. Racine (R Journal, 2012)

There are many types of splines: *smoothing splines* (penalized splines) use observations as potential knots; *regression splines* use equidistant or equiquantile knots. Discrete predictors can be accommodated with **kernel weighting**: replace the indicator functions $\mathbf{1}_{X=x}$ (which take two values, 0 and 1) with $\lambda^{\mathbf{1}_{X=x}}$ (which take two values, 1 and λ) – for ordered categorical variables, use $\lambda^{|X-x|}$ instead.

The splines come from GSL (GNU scientific library) and the metaparameters are estimated by cross-validation with the NOMAD black box optimizer (mesh adaptive direct search, MADS).

influence.ME: tools for detecting influential data in mixed effects models
R. Nieuwenhuis et al. (R Journal, 2012)

This package computes the influence (DF betas, Cook's distance, percentile change $(\hat{\beta} - \hat{\beta}_{-j})/\hat{\beta}$, change in significance) of observations, or groups of observations, in mixed effects models (**lme4**).

Strategic risk management and risk monitoring for pension funds
S. van Hoogdaem et al.

Asset liability management (ALM) should use the same tools as traditional (1-period) portfolio management:

performance attribution, risk decomposition, stress tests, etc.

Balanced baskets: a new approach to trading and hedging risks
D.H. Bailey and M.L. de Prado (2012)

The many variants of the minimum variance portfolio can be used to hedge a position (by fixing one of the weights, say, w_1).

- Minimum variance: $\operatorname{Argmin}_w w'Vw$, i.e.,

$$\operatorname{Argmin}_w \operatorname{Var} \left[\sum_i w_i X_i \right]$$

- Maximum diversity:

$$\operatorname{Argmax}_w \frac{\sum_i w_i \operatorname{Sd} X_i}{\operatorname{Sd} \sum_i w_i X_i}$$

- Equal risk:

$$\forall i, j \quad w_i \frac{\partial \operatorname{Risk}}{\partial w_i} = w_j \frac{\partial \operatorname{Risk}}{\partial w_j},$$

where $\operatorname{Risk} = \sum_i w_i \frac{\partial \operatorname{Risk}}{\partial w_i}$ by Euler's formula.

There is a variant of the equal risk portfolio, the *diversified risk portfolio*, which asks for an equal contribution of each principal component (or each risk factor, if you have a risk model) – since the largest components correspond to the main sources of risk, you probably do not want them in a hedging basket – but it makes sense for a trading basket.

- Equal correlation:

$$\forall j, k \quad \operatorname{Cor} \left(\sum_i w_i X_i, X_j \right) = \operatorname{Cor} \left(\sum_i w_i X_i, X_k \right)$$

- Minimax subset correlation:

$$\operatorname{Argmin}_w \max_{\substack{I \subseteq [1, n] \\ I \neq \emptyset}} \left| \operatorname{Cor} \left(\sum_j w_j X_j, \sum_{i \in I} w_i X_i \right) \right|$$

Some of those approaches can also be used to build trading (rather than hedging) portfolios, e.g., the maximin subset correlation portfolio,

$$\operatorname{Argmax}_w \min_{\substack{I \subseteq [1, n] \\ I \neq \emptyset}} \left| \operatorname{Cor} \left(\sum_j w_j X_j, \sum_{i \in I} w_i X_i \right) \right|.$$

The article also provides Python implementations.

Beware of the DAG!
A.P. Dawid (2009)

One could be tempted to interpret directed acyclic graphs (DAGs) representing graphical models as describing causal relations: they only describe a set of conditional independence relations (or, alternatively, a factorization of the joint probability distribution), and the direction of the edges is not that meaningful.

Causal independence $X \perp\!\!\!\perp Y$ implies conditional independence $X \perp\!\!\!\perp Y \mid Z$, but the converse does not hold: some causes could cancel out, or there may be confounding (overlooked) causes.

To have a causal interpretation of a DAG, one can add two types of nodes: intervention nodes (whose value can be chosen – passively observing the system is not sufficient for causal discovery: this is the difference between observational and experimental sciences) and confounding nodes (for each set S of nodes on the original graph, add a node with edges towards each node in S – that is a lot of nodes, but for a given analysis, only a handful is usually needed).

The best you can do with a DAG with no observational nodes is apply Occam’s razor: the conditional independence relations are consistent with many causal interpretations; choose the most parsimonious, e.g., to choose between

$$p(x, y) = p(x)p(y|x)$$

and $p(x, y) = p(y)p(x|y),$

pick the relation with the lowest algorithmic complexity.

The big data bootstrap
A. Kleiner et al.

The *bootstrap* (resampling with replacement) is expensive for large datasets (you have to build new datasets of size n): to *subsampling* (resample $m \ll n$ observations without replacement) or *m out of n bootstrap* (resample $m \ll n$ observations with replacement), prefer the *bag of little bootstraps* (take s subsamples of size $m \ll n$, e.g., $m = n^{0.6}$, resample them r times with replacement to form datasets of size n , not m – since there are many duplicates, you just need to keep track of the number of occurrences of each observation): it is more robust and has better theoretical properties.

A scalable bootstrap for massive data
A. Kleiner et al. (2012)

More details, on the choice of the hyperparameters (e.g., stop using a subsample when the corresponding estimate ceases to change), with applications to time series (e.g., the stationary bootstrap: take a block of length $m \ll n$, take a point at random, with probability $1 - p$ take the next point, with probability p take another point at random, iterate with more points, repeat with more blocks).

Improving GARCH volatility forecasts with regime-switching GARCH
F. Klaassen (2001)

GARCH forecasts are too high in volatile periods; they can be improved by using a regime-switching GARCH model (with two regimes). The straightforward model,

$$\sigma_{1,t}^2 = \omega_1 + \alpha_1 \varepsilon_{t-1}^2 + \beta_1 \sigma_{1,t-1}^2$$

$$\sigma_{2,t}^2 = \omega_2 + \alpha_2 \varepsilon_{t-1}^2 + \beta_2 \sigma_{2,t-1}^2,$$

is difficult to estimate. Instead, one can replace $\sigma_{i,t-1}^2$ in the right handside with

$$E_{t-1}[\sigma_{i,t-1}^2] = p\sigma_{i,t+1}^2 + (1 - p)\sigma_{2,t-1}^2$$

or, better, $E[\sigma_t^2 | r_t = i]$.

A review of backtesting and backtesting procedures
S.D. Campbell (2005)

Regulators check the validity of a VaR (value-at-risk) model by counting the number of exceedances (violations) in the past year (and they increase the market risk capital accordingly). The violations should be Bernoulli, independent: one can check if they have the correct distribution (`prop.test`, `binom.test`), or if they are independent (independence χ^2 on the contingency table of consecutive observations, runs test – but this only tests for very short term independence), or both (χ^2 test on the same table).

One could also convert the observations to p -values for the VaR model and check if they are uniform $U(0, 1)$ and independent. Since we are only interested in the tail, we could bin those values (say, $[0, 1\%]$, $[1\%, 2\%]$, $[2\%, 5\%]$, $[5\%, 100\%]$) and perform a χ^2 test (we expect $(\beta - \alpha)N$ observations in $[\text{VaR}_\alpha, \text{VaR}_\beta]$).

Those tests may have low power and may fail to identify underreporting.

One could also use a loss function, e.g., that defining the expected shortfall – but it will just tell you that VaR estimators are bad CVaR estimators. (But it makes sense for the regulators to do that: this is how they use the VaR – to compute the risk capital.)

Extended analysis of backtesting frameworks for value at risk
G.J. van Roekel (2008)

To test your value at risk (VaR) model, use the following tests, after checking their power, *i.e.*, the proportion of type I and type II errors, for different null ($p = 1\%$, $p < 1\%$) and alternative ($p \neq 1\%$, $p > 1\%$) hypotheses.

- Test the number of exceedances, with an exact test or a likelihood ratio (LR) test, test the time to the next one.
- Test their independence, with an LR test, using indicator functions “exceedance in $[t - k, t + k]$ ” rather than “exceedance at t ”; test the distribution of the

time between two exceedances: it should be geometric, *i.e.*, easy to approximate with an exponential distribution (for instance, you could test the null that the distribution is exponential vs the alternative that it is Weibull but not exponential). Tests for discrete distributions have more power.

- Compare the regulatory capital (derived from the VaR) with the average expected shortfall (CVaR).

A guide to modelling counterparty credit risk **M. Pykhtin and S. Zhu (2007)**

The *counterparty exposure* of an asset of value v is v_T (its value when the counterparty defaults, at some time T in the future). Using simplified pricing models, you can simulate possible evolutions of v_t and compute its expectation and quantiles (for instance, for bonds or swaps, it progressively increases, because of uncertainty, with a drop at each cash flow, because the remaining cash flows are decreasing). The *credit value adjustment* (CVA) is the risk-neutral expectation of the loss.

Algorithms, design and analysis II **T. Roughgarden (Coursera, 2012)**

The second part of the course covered greedy algorithms, dynamic programming and NP-completeness.

Greedy algorithms never come back on a decision they made, and therefore run in linear time: e.g., optimal caching (remove from the cache elements you will not need any time soon), scheduling (each job has a weight and a duration, sort them by weight/duration). If they happen to be correct (rarely), this can often be proved by induction or with an *exchange argument* (start with an optimal solution and transform it into the output of the algorithm, without ever making it worse).

For the minimum spanning tree (MST) problem, Prim's algorithm grows a connected tree (and can be efficiently implemented with a heap), while Kruskal's algorithm grows a forest by adding the cheapest edges as long as they do not introduce a cycle (and can be implemented with a *union-find* data structure). They are correct and fast, but there are faster algorithms. Kruskal's MST algorithm can be used to find the k -clustering of a set of points that maximizes spacing (the spacing is $\min d(a, b)$ where a and b are in different clusters) *i.e.*, the distance between the most alarmingly close points that are not in the same cluster.

Huffman codes (binary prefix-free codes; they can be represented as binary trees) are also built greedily, bottom-up: start with each symbol in a 1-element tree, merge the two least frequent elements, iterate.

Dynamic programming solves a problem by considering sub-problems, with an order relation (often inclusion), from whose solutions it is possible to solve the original problem. Contrary to divide-and-conquer, the sub-problems are overlapping, and it is necessary to cache (memoize) the intermediate results. Here are a few examples.

- Independent set (a set of vertices, no two of which are adjacent) of maximum weight in a path-graph (a graph that is also a path, *i.e.*, a tree of arity 1) [hint: either the last element is in the set or not];
- Knapsack with integral sizes [same hint];
- Sequence alignment;
- Optimal binary search tree (minimum average search time, when the frequency of each term is known);
- For the single-source shortest path problem, use Dijkstra's algorithm, if there are no negative edges, or Bellman-Ford's algorithm (slower): look at shortest paths from s with at most k edges (you can save on space by keeping a pointer to the previous vertex in the shortest path) – a distributed version is used for internet routing;
- For the all-pairs shortest paths problem (APSP), the Floyd-Warshall algorithm computes the length of the shortest path from i to j passing through (at most) $1, 2, \dots, k$; Johnson's algorithm modifies the weights, by adding them $p_i - p_j$, where p_i is the length of the minimum path from a new vertex to i : this makes them nonnegative, so we can use Dijkstra's algorithm.

A problem A reduces to a problem B , denoted $A \preceq B$, if a polynomial algorithm for B gives a polynomial algorithm for A . If \mathcal{C} is a class of problems, a problem $A \in \mathcal{C}$ is \mathcal{C} -complete if all problems in \mathcal{C} reduce to A , *i.e.*, A is the most intractable problem in \mathcal{C} (but there can be many problems as difficult as A). Let P denote the class of problems solvable in polynomial time. Let NP be the class of problems for which it is possible to verify a solution in polynomial time, and whose solutions have polynomial lengths; intuitively, these are the problems solvable by brute-force search. It is conjectured, but not proved, that $P \neq NP$.

There are many NP-complete problems: TSP, 3SAT, etc.

To solve an NP-complete problem, you can:

- Focus on solvable special cases, e.g., the 2-SAT problem: when solving a 3-SAT problem, you may be able to isolate 10 or 20 variables so that, when you fix them, the problems becomes a 2-SAT problem: you can then combine brute force search on those variables and a polynomial 2-SAT algorithm;
- Use heuristics: for the knapsack problem, there are greedy (sort the items by decreasing value/weight – to prove that the the solution is at least 50% of the value of the optimal solution, consider a “fractional solution”, in which you can cut the objects) and dynamic-programming-based (rounding) heuristics;
- Find an exact algorithm, exponential-time but faster than brute-force search: for instance, dynamic programming for the knapsack problem, dynamic programming for the traveling salesman problem (2^n instead of $n!$: consider $L(S, j)$, the minimum length of a path from 1 to j that passes exactly once through each vertex in S , for all S containing 1 and j), etc.

In the vertex cover problem, you are asked to find a minimum set of vertices so that each edge has at least

one extremity in it. It can be solved in special cases, e.g., trees (dynamic programming) or bipartite graphs (maximum flow problem); for small graphs, use the fact that G has a vertex cover of size k iff G_u or G_v has a vertex cover of size $k-1$, where G_u is G without vertex u , and $u-v$ is an edge.

The maximum cut problem (finding the cut with the largest number of edges) is NP-complete. It is tractable in special cases: for instance, in bipartite graphs, there is a cut with all edges, and it can be found by breadth-first search in linear time. In general, you can use a *local search* heuristic: let $c(v)$ (resp. $d(v)$) be the number of edges from vertex v that cross (resp. do not cross) the cut, start with an arbitrary cut, move v if $d > c$. Use multiple random restarts to help improve the solution.

The 2-SAT problem (find an assignment of boolean variables so that some statement of the form $\bigwedge_k \varepsilon_k a_{i_k} \vee \eta_k a_{j_k}$, where ε_k, η_k are the identity or the negation) can be solved in polynomial time (only the 3-SAT problem is NP-complete):

- By considering the graph whose vertices are the variables and their negations, with an edge for each implication implied by the clauses (each is equivalent to two implications), the problem reduces to finding the strongly connected components;
- Backtracking (each clause forbids one assignment of the variables);
- Randomized local search (find an arbitrary unsatisfied clause and flip one of the variables, at most $2n^2$ times, and use $\log_2 n$ random restarts: the probability of finding an assignment if there is one is at least $1 - 1/n$ – this estimate is very conservative, but the algorithm is quadratic).

The following topics were not covered: maximum flow, linear programming, computational geometry, parallel or distributed algorithms, algorithms that run forever, streaming algorithms (when the data is too large to be kept in memory), etc.

Heterogeneous computing W.-M. W. Hwu (Coursera, 2012)

GPU programming is getting more popular, and the main API is currently CUDA, targeted at NVidia chips.

A CUDA program is just a C program, with a few more keywords. The memory can be allocated either on the host (CPU, `malloc`, `free`) or the device (GPU, `cudaMalloc`, `cudaFree`), can be copied between them (`cudaMemcpy`). Functions can be declared as callable and/or runnable from/on the host and/or the device: kernel functions, prefixed with `__global__`, are called from the host as

```
vecAddKernel<<<blocks,threads>>>(x,y,z, n);
```

and run on the device, in parallel (`blocks` \times `threads` threads); they do not return any value, but can change

the data in the arrays pointed to by their pointer arguments; they can retrieve the thread block and thread number through implicitly-defined variables `threadIdx.x`, `blockDim.x`, `blockIdx.x`.

Threads and blocks are arranged in 1-, 2- or 3-dimensional arrays. Threads in the same block can share memory: declare it as `__shared__` in the kernel function. Threads in a block can wait for other threads in the same block to reach the same point, by calling `__syncthreads()`. Shared memory and thread blocks can reduce the amount of data transferred between the host and the device, and greatly increase the program speed – the typical example is *tiling matrix multiplication*, i.e., multiplying block matrices. Convolution (or solving PDEs, e.g., wave propagation) requires *halo* data: data from neighbouring nodes, close to the boundary – you may want to process it in priority to avoid delaying the neighbouring nodes.

Many linear algorithms, such as the sum or the cumulated sum of a vector, can be executed in log-linear time (*parallel prefix sum*, or scan), by arranging the computations in a tree (dividing the number of threads by 2 at each iteration).

There are other “parallel design patterns” such as compaction (the use of sparse matrices), binning (the Barnes-Hut algorithm, for the N -body problem), scatter-to-gather conversion (map/reduce), etc.

Streams allow you to transfer data and compute at the same time. Manually managing them can be tricky.

MPI is a framework for distributed programming, where processes (possibly running on different machines) send and receive messages. The nodes can use CUDA.

OpenCL is similar to CUDA, but not limited to a single vendor, and a bit clunkier (the device code is compiled at runtime and has to be put in a string (sic); it cannot be called as a normal function: its arguments have to be pushed on a stack one by one; etc.).

OpenACC just adds a few `#pragmas` to a sequential C program:

```
#pragma acc parallel loop copyin(M[0:m*n])
                    copyin(N[0:n*p]) copyout(P[0:m*p])
for(int i=0; i<m; i++){
    #pragma acc loop
    for(int j=0; j<p; j++){ ... }
}
```

It is possible to fine-tune the number of workers (threads) and gangs (thread blocks).

C++Amp is a Microsoft-specific extension to C++ providing a `parallel_for_each` loop, synchronization, and implicit data transfer between host and device.

OpenMP and Thrust were not covered.

Software testing (Udacity, 2012)

Review of:

- The various types of tests: assertions, black box, white box, unit, integration, validation, differential, stress, random;
- Coverage metrics: lines of code; statements; loop (each loop is executed 0 times, once, several times); paths; modified condition/decision coverage (MC/DC): each condition in a decision is shown to independently affect the outcome of the decision; boundary value; synchronization (each lock does something); interleaving;
- Oracles (*i.e.*, ways of checking the output): weak oracles check for crashes, exceptions, failures in a controlled environment (valgrind), assertions; a strong oracle compares the output with another implementation, or using an inverse function to recover the input, or changes the (random) input in a way that should not change the output (null-space transformation).

The emphasis was on random testing:

- Automated whitebox coverage testing: start with some input, check why the coverage is not 100% (modify the input to increase coverage (it is a constraint satisfaction problem), iterate);
- Fuzzing: throw random data (GUI events, network activity, file contents) and see if the application crashes, often to find exploitable security faults; to fuzz implicit inputs (e.g., timing), just overload the machine; for a multi-threaded program, you can also add a `sleep()` before/after each synchronized operation;
- Random testing: like fuzzing, after fine-tuning the probability of the random data to increase code coverage and make the input more realistic – otherwise, the program notices that the input is invalid and exits: most of the code is not run; the random input generation can often be described with a finite automaton.

Software debugging (Udacity, 2012)

The word “bug” is ambiguous: there is a difference between *defect* (the code does not do what it should), *infection* (the program state is wrong) and *failure* (this becomes visible to the user).

Debugging should be done explicitly, in a scientific way: if it takes more than 5 minutes, write down what you are doing, what you think the code is doing, test that it is indeed the case. This allows you to resume debugging should you be interrupted, and prevents you from running in circles.

It is very easy to write debugging tools in Python, with `sys.settrace`: running the code step by step, following the changes of a variable, etc.

Delta debugging is an automated way of simplifying a

failing test: split the input into n subsets, try to remove one or more of them, and check if the test still fails; repeat with other values of n if needed. You can use tokens instead of characters, to make the delta debugger more aware of the structure of the data. `git-bisect` does something similar on the code, rather than the input.

You should check the invariants of your data structure at the beginning of each public method. It is possible to automatically discover invariants: start with variable ranges, variables types, variable relations ($=$, \leq , between 2 variables – or more), etc. (cf. Daikon).

There are various types of bugs: Bohr bugs (repeatable), Heisenbugs (they disappear or change when you try to reproduce/probe/isolate them, e.g., the program fails in the field, but works in the debugger; they can be caused by malware, the many unspecified behaviours in the C/C++ standards, etc.), Mandelbugs (chaotic, very complex causes), Schrödingbugs (they do not manifest themselves until someone reads the code and realizes it should never have worked).

To find the cause of bug, you can reason from the failure to its cause, or from the inputs to the failure. (Part of this process can be automated: the computer can find the conditions under which some assertion fails.) A *backward slice* is everything a statement depends on (recursively), a *forward slice* contains all statements that depend on a specific statement; a *dynamic slice* is a slice of an execution (a trace), rather than of a program. Slices can be computed automatically and give a small subset of the program, with only the lines executed and influencing the output.

Reproducing failures, when the inputs are complicated, can be tricky: files, GUI interaction (have the widget record the events they receive), OS (record the output of the API calls and replay them), randomness (set the seed), scheduling (find a way to make thread scheduling deterministic), physics (e.g., the OS or processor can behave differently when running on battery). Look for correlations (the phi coefficient) between lines executed, functions called, return value (zero/non-zero, sign, etc.), etc. and the failure.

If the version control system and the bug database are linked, you can mine the data they contain, to identify the most bug-prone parts of the code.

Quantum computation U. Vazirani (Coursera, 2012)

Quantum computation is just linear algebra on a finite-dimensional complex vector space, with slightly unusual terminology and notation.

A quantum bit (*qubit*, quantum state) is an element of \mathbf{C}^2 of norm 1. The standard basis is noted $|0\rangle$, $|1\rangle$, instead of the more usual (e_1, e_2) or $((1, 0), (0, 1))$: these are the *classical states*. Similarly, a vector $u \in \mathbf{C}^2$ (more precisely, a state, *i.e.*, a unit vector, $u \in \mathbf{S}_{\mathbf{C}^2}$) will often be written $|u\rangle$ rather than \mathbf{u} or \vec{u} . The dual (complex conjugate) of $|u\rangle$ is written $\langle u|$. The projec-

tion on $\text{Span}|\psi\rangle$ is $p_\psi = |\psi\rangle\langle\psi|$. The scalar product of $|u\rangle$ and $|v\rangle$ is written $\langle u|v\rangle$. *Quantum superposition* refers to the fact that $|0\rangle$ and $|1\rangle$ are not the only possible states: any linear combination (of norm 1) is possible.

A *measurement* (in \mathbf{C}^2) is another orthonormal basis, $(|u\rangle, |u^\perp\rangle)$; after a measurement, the system that was in state $\psi \in \mathbf{C}^2$ is now in state u with probability $|\langle u|\psi\rangle|^2$ and in state u^\perp with probability $|\langle u^\perp|\psi\rangle|^2$. In particular, after the measurement, you can no longer recover any information about the previous state $|\psi\rangle$: a lot of information has been lost.

The *Hadamard basis* (or sign basis) is

$$\begin{aligned}|+\rangle &= \frac{1}{\sqrt{2}}|0\rangle + \frac{1}{\sqrt{2}}|1\rangle \\ |-\rangle &= \frac{1}{\sqrt{2}}|0\rangle - \frac{1}{\sqrt{2}}|1\rangle.\end{aligned}$$

If you measure $|+\rangle$ or $|-\rangle$ in the $(|0\rangle, |1\rangle)$ basis, you cannot distinguish the two states: the measurement is $|0\rangle$ or $|1\rangle$, each with probability $\frac{1}{2}$, in both cases.

The *uncertainty principle* says that you cannot know both the bit ($|0\rangle$ vs $|1\rangle$) and the sign ($|+\rangle$ vs $|-\rangle$) of a qubit with certainty.

The *evolution* of a quantum system is described by a unitary operator, such as

$$\begin{aligned}H &= \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} && \text{Hadamard gate} \\ U_\theta &= \begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix} && \text{Rotation gate} \\ \text{NOT} &= \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} && \text{NOT gate} \\ Z &= \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} && \text{Phase flip gate.}\end{aligned}$$

The NOT gate flips $|0\rangle$ and $|1\rangle$; the phase flip gate flips $|+\rangle$ and $|-\rangle$; the Hadamard gate flips the canonical and sign bases; one has $Z = HXH$.

Qubits do exist in the real world: polarization of a photon ($\cos(\theta)|0\rangle + \sin(\theta)|1\rangle$) corresponds to a polarization of angle θ ; spin; particle with two states (ground $|0\rangle$ and excited $|1\rangle$), etc.

Consider a photon, polarized as $|+\rangle$, passing through a $(|0\rangle, |1\rangle)$ polarizing filter: it is measured, giving $|0\rangle$ or $|1\rangle$, each with probability $1/2$, and discarded if $|0\rangle$ – it exits as $|1\rangle$ with probability $1/2$. Then, let it go through another filter, tilted at 45 degrees, *i.e.*, $(|+\rangle, |-\rangle)$: the probability that it exits is also $1/2$, and it will be in state $|+\rangle$. If you stack n such filters, the probability that the photon remains at the end is $1/2^n$ – classical physics suggests 0 if $n \geq 2$.

The states of a system of two quantum bits are unit vectors in the tensor product $\mathbf{C}^2 \otimes \mathbf{C}^2$. The standard basis is $(|00\rangle, |01\rangle, |10\rangle, |11\rangle)$. Elements of the form $|u\rangle \otimes |v\rangle$ are called *decomposable*, the others are *entangled* – giving the state of a system made of two qubits is

not the same as giving the state of two 1-qubit systems: $\mathbf{S}_{\mathbf{C}^2 \otimes \mathbf{C}^2} \neq \mathbf{S}_{\mathbf{C}^2} \times \mathbf{S}_{\mathbf{C}^2}$; in general, $\mathbf{S}_{(\mathbf{C}^2)^{\otimes n}} \neq (\mathbf{S}_{\mathbf{C}^2})^n$. The *Bell state* is one such state (the two particles are in the same state):

$$\frac{1}{\sqrt{2}}|00\rangle + \frac{1}{\sqrt{2}}|11\rangle = \frac{1}{\sqrt{2}}|uu\rangle + \frac{1}{\sqrt{2}}|u^\perp u^\perp\rangle.$$

Quantum computation is often said to be “exponentially powerful”: this power comes from the tensor product, $\dim(\mathbf{C}^2)^{\otimes n} = 2^n$, where classical systems have $\dim(\mathbf{C}^2)^n = 2n$. But once a measurement is made, the entanglement (and the exponential power) is destroyed.

The no-cloning theorem states that you cannot copy a qubit, *i.e.*, there is no unitary transformation U such that $U(|\psi\rangle \otimes |0\rangle) = |\psi\rangle \otimes |\psi\rangle$ for all states $|\psi\rangle$. But quantum teleportation is possible:

$$\exists U \quad \forall \psi \quad \exists u \quad U(|\psi\rangle \otimes |00\rangle) = |u\rangle \otimes |\psi\rangle;$$

to build this transformation, use the CNOT gate, which sends the canonical basis to a basis of Bell states.

We have only defined measurements in \mathbf{C}^2 , *i.e.*, for single qubits. In general, a *measurement* (or *observable*) is a hermitian operator A . From the spectral theorem, it can be written as

$$A = \sum_i \lambda_i |\phi_i\rangle\langle\phi_i|,$$

where the ϕ_i are a basis of eigenvectors with eigenvalues λ_i . The measurement of a quantum state $\psi = \sum_i \alpha_i |\phi_i\rangle$ is λ_i with probability $|\alpha_i|^2$.

The expectation and standard deviation of the measurement X of observable M on state $|\psi\rangle$ are

$$\begin{aligned}\mu &= \langle\psi|M|\psi\rangle \\ \sigma^2 &= E[X^2] - E[X]^2 \\ &= \langle\psi|M^2|\psi\rangle - \langle\psi|M|\psi\rangle^2.\end{aligned}$$

Those quantities can be interpreted as follows. Consider the distribution as a thick piece of wood (the area under the curve, thickened); the expected value is the point at which you can balance this piece of wood, as a see-saw; when you try to rotate this piece of wood (around a vertical axis, positionned on the mean), it offers some resistance (momentum of inertia), the same as that from two point masses, at $\mu + \sigma$ and $\mu - \sigma$. They also appear in the uncertainty principle:

$$\Delta A \Delta B \geq \frac{1}{2} |\langle\psi|[A, B]|\psi\rangle|$$

where

$$\begin{aligned}\Delta A &= \sqrt{\langle\psi|A^2|\psi\rangle - \langle\psi|A|\psi\rangle^2} \\ [A, B] &= AB - BA.\end{aligned}$$

The evolution of a quantum system is governed by Schrödinger's equation

$$i\hbar \frac{d|\psi(t)\rangle}{dt} = H|\psi(t)\rangle,$$

where H is an observable (a hermitian operator, also called “energy” – its eigenvalues are the energy levels); solving the equation gives

$$|\psi(t)\rangle = e^{-itH/\hbar} |\psi(0)\rangle$$

where $U = e^{-itH/\hbar}$ is a unitary operator (and \hbar is only here to keep the units consistent).

Here are a few building blocks to design quantum algorithms.

The Hadamard transform creates superpositions,

$$|0 \cdots 0\rangle \mapsto \frac{1}{2^{n/2}} \sum_{x \in \{0,1\}^n} |x\rangle,$$

on $(\mathbf{C}^2)^{\otimes n}$, and can be used to build other superpositions. For instance,

$$|\phi\rangle = \frac{1}{\sqrt{k}} \sum_{x \in f^{-1}(\{a\})} |x\rangle,$$

for $f : \{0,1\}^n \rightarrow \{0,1\}^n$ can be constructed as follows: start with $|0 \cdots 0\rangle |0 \cdots 0\rangle$, apply the Hadamard transform on the first half, to get $\frac{1}{2^{n/2}} \sum_x |x\rangle |0 \cdots 0\rangle$, apply f , to get $\frac{1}{2^{n/2}} \sum_x |x\rangle |f(x)\rangle$, and measure the second half; if the result is a (you do not get to choose a : it is random, in the image of f), the state becomes (proportional to)

$$\sum_{x \in f^{-1}(\{a\})} |x\rangle |f(x)\rangle.$$

The Hadamard transform is a special case of the *quantum Fourier transform* (QFT),

$$\sum_{k=0}^{n-1} \alpha_k |k\rangle \mapsto \sum_{\ell=0}^{n-1} \frac{1}{\sqrt{n}} \sum_{k=0}^{n-1} \alpha_k e^{i \frac{2\pi}{n} k \ell} |\ell\rangle$$

on \mathbf{C}^n , with basis $|0\rangle, |1\rangle, \dots, |n-1\rangle$. If you view $\sum_k \alpha_k |k\rangle$ as a function $k \mapsto \alpha_k$, it is the classical discrete Fourier transform.

To find the period r in a “periodic state”

$$\sqrt{\frac{r}{n}} \sum_{k=0}^{n/r-1} |kr + \ell\rangle,$$

take the QFT (the offset ℓ disappears, the phase changes, and the period becomes n/r), measure (you get a random multiple of n/r), repeat, and take the gcd of those measurements: with enough of them, you can recover n/r . If $r \nmid n$, it is trickier, but it is still possible to recover enough information.

Those ideas can be applied to factor a number n (Shor’s algorithm): pick $x \in \mathbf{Z}/n$ at random, consider

$$f : \begin{cases} \mathbf{Z}/m \longrightarrow \mathbf{Z}/n \\ a \longmapsto x^a, \end{cases}$$

with $m \gg n$, build the superposition

$$\sum_{a \in f^{-1}(\{y\})} |a\rangle = \sum_{a : x^a = y} |a\rangle,$$

it is periodic; find the period r ; use it to factor n , by letting $y = x^{r/2}$, so that $y^2 = 1$ (in \mathbf{Z}/n), i.e., $n|(y-1)(y+1)$ (if r is odd or $y = -1$, start again).

For another, readable presentation of those topics, check S. Aaronson’s *Quantum computing since Democritus*.

Visualizing data using *t-SNE*

L. van der Maaten and G. Hinton (2008)

Stochastic neighbour embedding (SNE) is a dimension reduction technique trying to make the low-dimension conditional probabilities

$$q(j|i) \propto e^{-\|y_i - y_j\|^2}$$

as close as possible from the high-dimensional ones

$$p(j|i) \propto e^{-\|x_i - x_j\|^2 / 2\sigma_i^2},$$

where the variance σ_i^2 at point i is chosen so that the entropy at each point

$$H_i = - \sum_j p_{j|i} \log_2 p_{j|i}$$

be the same (and equal to some user-specified value – the *perplexity*, or effective number of neighbours, is 2^{H_i}), for the Kullback-Leibler distance

$$\sum_{i \neq j} p_{j|i} \log \frac{p_{j|i}}{q_{j|i}}.$$

The Kullback-Leibler distance is asymmetric: there is a large cost for close points ending up distant, but a small cost for distant points ending up close. The gradient of the objective function is easy to compute, and the optimization can use momentum (to escape local extrema) and noise (of decreasing variance, as with simulated annealing).

The *t-distributed SNE* (*t-SNE*) algorithm uses the joint probabilities q_{ij} instead of the conditional ones $q_{j|i}$ (for the inputs, if i or j is an outlier, $p_{ij} \approx 0$, so one may prefer to cheat and use the symmetrized conditional probabilities

$$p_{ij} = \frac{p_{i|j} + p_{j|i}}{2}$$

instead), and replaces the Gaussian distribution e^{-d^2} with a Student (Cauchy) one $(1+d^2)^{-1}$. The optimization uses gradient descent, with momentum (small at the beginning), an L^2 penalty $\sum_i \|y_i\|^2$ and early exaggeration (multiply the p_{ij} by 4, and do not worry if they do not sum up to 1) to help separate the clusters.

If there are clusters in the data, they are much more clearly separated than with other methods such as *Isomap* (find the nearest neighbours of each point, build the corresponding neighbourhood graph, use the geodesic distance on the graph), *local linear embedding* (LLE) (express each node as a weighted average of its nearest neighbours, find points in a lower-dimensional

space with similar weights – it reduces to a linear algebra problem with sparse matrices), *maximum variance unfolding* (MVU) (build the neighbourhood graph, preserve the distances between neighbours and maximize the distances between non-neighbours – this reduces to a semi-definite optimization problem).

For large datasets, build the neighbourhood graph, pick landmarks (*i.e.*, a small number of points), and estimate the conditional probabilities $p_{j|i}$ using random walks (proportion of random walks starting at i and reaching landmark j before any other landmark).

Learning a parametric embedding by preserving local structure

L. van der Maaten

Non-parametric dimension reduction techniques (Isomap, local linear embedding (LLE), Sammon, maximum variance unfolding (MVU)) cannot easily be extended out-of-sample. t -SNE can, by parametrizing the mapping from the (high-dimensional) input space to the (low-dimensional) output space using a deep feed-forward neural net (with layer dimensions n , 500, 500, 2000, 2), trained as auto-encoders are: pre-train each pair of consecutive layers as a restricted Boltzmann machine (RBM), using contrastive divergence (*i.e.*, minimize the Kullback-Leibler distance between the data and its reconstruction after one Gibbs step, instead of an infinity of steps (thermal equilibrium)), starting with the input layer, each RBM using the output of the previous as input; use the resulting weights as initial weights and use back-propagation (mini-batch) to optimize the t -SNE objective function.

Neural networks

G. Hinton (Coursera, 2012)

Neural networks were popular until the 1990s but went out of favour; thanks to the advent of more powerful computers (GPUs), deep neural networks can now be trained and the field is progressively merging with that of graphical models.

The course is a motley collection of neural net architectures (perceptron, feed-forward net, convolutional net, recurrent net, Hopfield net, restricted Boltzmann machine, deep belief net, auto-encoders) and related algorithms (back-propagation, biased heuristics, penalization, constraints (shared weights), careful weight initialization (echo state net), generative pre-training, momentum, bayesian methods, Gaussian processes), presented in a seemingly random order, preserved below.

1. A *neural net* is a set of *idealized neurons* (“units”), somehow linked together, to perform some machine learning task (supervised learning (regression, classification), unsupervised learning (e.g., as a first step before supervised or reinforcement learning, for dimension reduction), reinforcement learning). Expect neural networks to be bad at things the human brain is bad at (e.g., arithmetics). There are many types of idealized neurons:

- Linear neuron: $y = b + \mathbf{w}'\mathbf{x}$;
- Binary threshold neuron: $y = \mathbf{1}_{b+\mathbf{w}'\mathbf{x} \geq 0}$;
- Rectified linear neuron: $y = (b + \mathbf{w}'\mathbf{x})_+$;
- Sigmoid neuron: $y = s(b + \mathbf{w}'\mathbf{x})$;
- Stochastic binary neuron: $y = 1$ with probability $s(b + \mathbf{w}'\mathbf{x})$, 0 otherwise.

In a *feed-forward neural network*, information always flows in the same direction, from the input layer, through the hidden layers, to the output layers (the neurons should be non-linear, otherwise it is equivalent to a net with no hidden layers).

Recurrent networks contain cycles; they are more powerful, but more difficult to train.

Input \longrightarrow Layer 1 \longleftrightarrow Layer 2 \longrightarrow Output

They are often unrolled and used to model sequences:

The weights do not depend on time; the hidden states can keep information for some time.

Symmetric neural networks are a special case of recurrent neural networks, where the weights are the same in each direction. They are more tractable. Teaching a symmetric net is equivalent to minimizing a simple function, called the “energy function”.

2. The most ancient neural net structure and learning algorithm is the **perceptron**.

The algorithm is straightforward: feed the data to the network; if the output is correct, do not change anything; if it outputs 0 instead of 1, add the input vector to the weights; if it outputs 1 instead of 0, subtract the output vector from the weights. If the data is linearly separable, it converges. But we need to find good features – ourselves.

3. Feed-forward neural networks with hidden units can discover relevant features themselves. They are usually trained with **back-propagation**, *i.e.*, by minimizing the quadratic error (the algorithm itself is just the chain rule for differentiation, expressed algorithmically: different types of neurons (transfer functions)

only change a multiplicative factor), with all the observations at a time (batch learning), or with one observation at a time (online learning) or, better, with groups of observations (mini-batch learning, to reduce zig-zags on the error landscape).

4. If the output is a non-binary discrete variable, you can use a *softmax*,

$$y_i = e^{z_i} / \sum_j e^{z_j}$$

(like a logistic function, but for more than two classes). For the cost function, you can use (minus) the logarithm of the probability of a correct answer or the cross-entropy, $-\sum \text{target}_i \times \log(\text{output}_i)$.

If this creates too many output neurons, you can add the discrete output variable to the inputs, and use a boolean output. (It is also possible to arrange the possible outputs in a binary tree, of which a single branch would be processed for each input.)

This can be used to model **relational data**, e.g., subject-verb-object triplets, using subject and verb as input, and the object as output: this can highlight regularities in a relational database, or find unlikely triplets (potential errors).

It also applies to language models: contrary to trigram models, which cannot understand similarities between words (e.g., dog/cat), the hidden layers (they can actually be learnt separately, and reused for other tasks) provide a representation of the context.

One can use dimension reduction, e.g., *t*-SNE (better than PCA or its non-linear analogues when there are clusters in the data) to represent the feature vectors in two dimensions.

5. In computer vision, to recognize objects, neural nets need to account for viewpoint invariance. This can be achieved by **convolutional neural nets**: each neuron in the hidden layer corresponds to (say) a 9×9 pixel area, but there are many similar neurons, constrained to have the same weights, to recognize the same feature in different positions. In the learning algorithm, the gradients are computed as usual, but modified to ensure that the constraints remain satisfied.

Good object recognition neural nets can have many (7) hidden layers, the firsts of which are convolutional.

6. **Learning** neural nets, especially deep ones, is tricky. The problems are often not caused by local minima, but by plateaus: for instance, if the learning rate is too high, the weights become so extreme that the output no longer depends on the inputs, and learning stalls. Classification problems also have a plateau on which the network only outputs the proportion of each class – learning useful features will take time, all the more so if the network is deep.

For small datasets (say 10,000 cases) standard optimization algorithms such as conjugate gradient (steepest descent in the direction of the gradient, then go in an "orthogonal" direction) or hessian-free methods (L-

BFGS uses a low-rank approximation of the hessian) are satisfactory. They can be combined with *stochastic gradient descent* (i.e., mini-batch learning).

Changing the *learning rate* may improve learning: if the error gets worse or oscillates, reduce it; if it decreases, slowly, increase it; at the end, turn down the learning rate, to smooth away the fluctuations due to the different samples. One can also use a separate learning rate for each parameter (e.g., a node-specific multiplicative gain, restricted to $[.1, 10]$ or $[.01, 100]$ applied to a global learning rate).

The *initial weights* are important: initialize them at random (otherwise, the units would all have the same weights: there would be no way to break the symmetry); and make their size proportional to the square root of their in-degree (otherwise, the output of neurons with a high in-degree has extreme values).

Preprocessing the input may also help learning: shift the inputs so that their average be zero, rescale them so that their variance be 1 (this makes the error surface more spherical); decorrelate the inputs, e.g., with principal component analysis (PCA).

Momentum can improve convergence and help escape local minima and plateaus: use the gradient to change the velocity, rather than the position; use a small momentum at the beginning (0.5), then raise to 0.9 or 0.99 – that is the most common method to learn large neural networks: mini-batches, stochastic gradient descent and momentum. While the usual momentum computes the gradient, then updates the direction, then jumps, one can first jump (in the previous direction), then compute the gradient, then update the direction and the position (Nesterov momentum).

Rprop only uses the direction of the gradient, not its amplitude, with a separate learning rate for each parameter. This only works with full batch learning: with mini-batches, use *rmsprop*, i.e., divide the gradient by a running average of the amplitude of the gradients.

7. Sequences are often modeled with autoregressive models, autoregressive models with hidden units (no memory), autoregressive models with hidden states and dynamics (linear dynamical system, aka Kalman filters, for continuous states, or hidden Markov models (HMM), for discrete states – but if there are n states, you can only store $\log n$ bits of information). **Recurrent neural networks** (RNN) are similar to HMM, but their hidden state is distributed, i.e., they have more memory, and they can describe non-linear dynamics.

For instance, adding two binary numbers of arbitrary length can be done with a 4-state finite automaton: it requires $\log_2 4$ bits of information, so we expect to find a RNN that solves this problem with fewer hidden neurons.

The most common task, predicting the next element of the sequence, blurs the difference between supervised and unsupervised learning.

After expanding a RNN over time, it is just a feed-forward network, with constraints on the weights: it can be trained by back-propagation through time.

8. Learning deep networks is problematic: the forward pass is fine, since the squashing (logistic) functions prevent the activities from exploding, but since the backward pass is linear (we replace the squashing functions with their derivative), it looks like A^n , where n is the number of layers – it will be either very large or very small. One can use an **echo state network** (ESN), *i.e.*, fix the input-hidden and hidden-hidden connections randomly (setting most of the weights to zero to have a sparse network, and rescaling them so that the amplitude of the activity vector remains the same), instead of learning them (it is a random equivalent of the kernel trick used by support vector machines (SVM)). This is sufficient for 1-dimensional time series, but for high-dimensional time series (video, sound), you can use the ESN as initial weights, and refine them with back-propagation (say, rmsprop with momentum).

One can also proceed as in electronics, and build RNN from modules, *e.g.*, “memory cells” able to remember things over a longer time.

9. The best cure against **overfitting** (learning the regularities specific to the training set – sampling error) is more data. If this is not possible, try a simpler model with few hidden layers.

Early stopping may help: start with small weights, and stop before overfitting (look at the performance on the validation dataset and stop when it gets worse) – the rationale is that a network with small weights is almost linear, therefore equivalent to a linear network with no hidden layers – the capacity will be sufficiently small.

You can limit the size of the weights, with an L^1 or L^2 *penalty*. With an L^2 penalty, if two weights play the same role, each will have half the weight (rather than, say, 1 and 0 or 101 and -100). With an L^1 penalty, you end up with many weights equal to 0; you can use other penalties, *e.g.*, $\text{Min}\{|x|, 1\}$, which penalizes small weights in the same way an L^1 penalty does (which leads to many zero weights), but does not penalize large weights. You can use weight constraints instead of weight penalties; you can put the constraint on a unit (say, L^2 norm of its weight vector), rather than on each individual weight.

Adding noise to the input of a linear net is equivalent to adding an L^2 penalty on the weights (adding an L^2 penalty is equivalent to adding a bayesian prior). You can add noise to the weights in recurrent nets. You can add noise to the activities, by using binary stochastic units in the forward pass, and logistic in the backward pass.

Averaging different models, either models with different forms, or models trained on different subsets of the data (bagging), improves performance. You could also consider a Bayesian approach: use a single neural net, but look at the posterior distribution of the weights, instead of just one set of values, and average

the predictions. For instance, the maximum a posteriori (MAP) estimator maximizes a penalized sum of squares, with the penalty being

$$\frac{\text{Var}(\text{noise})}{\text{Var}(\text{weights})} \times \sum \text{weight}_i^2.$$

You do not even have to assume the model is linear:

$$P[\text{Weights}|\text{Data}] = \frac{P[\text{Data}|\text{Weights}] \times P[\text{Weights}]}{P[\text{Data}]}$$

The first factor is unchanged, the second is the prior (the penalty), the last, a constant.

The *Empirical Bayes* cheats, and uses the data to decide on the prior: fit the model, look at the variance of the residuals and of the weights (*e.g.*, in each layer) use the ratio as the penalty coefficient, iterate.

Use cross-validation to choose the meta-parameters (or simply split the dataset in three: training data, validation data, test data).

10. There are many ways of **combining** multiple neural networks to improve generalization.

The error in a model can be decomposed into bias and variance. The bias is the inability of the model to learn the complexity of the phenomenon. The variance is the ability of the model to learn (undesired) sample-specific regularities. If you average the predictions of several models, the variance terms cancel out.

Bagging trains several models on different “subsets” of the data, obtained by sampling with replacement. For instance, bagging decision trees produces random forests (bagging neural networks would take a long time).

Boosting uses the same idea, but with weights instead of samples; the weights are not random, but focus on the misclassified cases: train a model on the data; then, train another model on the data, but give higher weights to test cases with a bad prediction; iterate.

Mixtures of experts combine several models, each trained on a part of the data (different regimes). A managing neural net looks at the input, infers the regime, and asks the corresponding expert. Since each expert only looks at a subset of the data, this requires a lot of data. This is not unlike boosting, but with boosting, the weights were only used in the training phase, not when using the network.

In the learning phase, one minimizes the squared distance between the target and the average (weighted) prediction (better, one could use the log-probability of the corresponding mixture of Gaussians), where the weights (competence of each expert for this problem) also have to be determined: each model tries to compensate the errors of the others, not to give a good prediction – this fosters cooperation.

Full bayesian learning does not output a single number, as the MAP estimator, but the full posterior distribution; you can use it to compute, say, the expectation of the forecasts. You can use complicated models with

little data – overfitting is the result of looking at a single number instead of the whole posterior distribution. The complexity of the model is a prior belief: it should not be influenced by the data... The posterior distribution can be estimated by putting a grid on the parameters and computing $p(W = w|\text{data})$ for all w on the grid.

To make full bayesian learning practical, you can use MCMC to sample from the posterior distribution, instead of a grid. Thanks to sampling noise, it works with mini-batches.

The *dropout* method is an approximation of the full bayesian approach, combining a very large number of networks, without having to train them all: for each test case, drop some of the units at random (with probability .5). Each model only has one test case, but the models share weights: this provides the needed regularization. This also prevents units from trying to fix the errors of other units instead of focusing on the task at hand. For prediction, use all the units, but halve their weights. For nets with one hidden layer, this gives the geometric mean of all the 2^H models. You can use the same idea on the input units, but with a high probability of keeping the units. Dropout reduces overfitting, better than early stopping.

11. A Hopfield net is a recurrent symmetric net with binary threshold units. Learning minimizes the “energy function”

$$\text{Energy} = - \sum_j s_i b_i - \sum_{ij} s_i s_j w_{ij}$$

where s_i is the state of unit i and w_{ij} the weight of edge $i-j$. Local minima of the energy function are memories; the network can store many memories, in a distributed way, and recover partial or corrupted memories. To increase the capacity of the network (the number of memories that can be stored – local minima close to one another tend to merge), *unlearn*: put the network in a random state, find the nearest local minimum, and learn its opposite – this is not unlike human sleep.

Hidden units in a Hopfield net encode an interpretation of the state of the visible units. For instance, in computer vision, visible units could be 2-dimensional lines on the sensor and hidden units 3-dimensional lines in space.

To escape from local minima, replace the binary threshold units with binary stochastic units,

$$p = \frac{1}{1 + e^{-\Delta E_i}}$$

or, even better,

$$p = \frac{1}{1 + e^{-\Delta E_i/T}}$$

i.e., simulated annealing. The network no longer converges to a single state, but to a probability distribution on the states, the “thermal equilibrium”, and the

probabilities are proportional to e^{-E} (Boltzman distribution); it can be sampled with Monte Carlo simulations.

A **Boltzman machine** is a stochastic Hopfield net with hidden units. They are good at modeling binary data, e.g., identifying the type of a text from a bag of words.

The Boltzmann learning algorithm maximizes the product of the probabilities of the vectors to learn. It turns out to be equivalent to:

$$\frac{d \log p(v)}{dw_{ij}} = \langle s_i, s_j \rangle_{\text{visible units clamped}} - \langle s_i, s_j \rangle_{\text{free}};$$

the two terms can be interpreted as learning and unlearning. To speed up the computation of those expectations (you have to wait until the machine settles in thermal equilibrium), start in the previous state, or “particle” (data-driven particles for the learning term, one for each data vector, fantasy particles for the unlearning term).

12. In a restricted Boltzman machine (RBM), there are no connections between hidden units or between visible units, *i.e.*, it is a bipartite network.

RBMs can be taught with *contrastive divergence*, alternating a learning and an unlearning phase (start with actual data, compute the hidden states, reconstruct the visible states (it looks like the initial data, with a few differences) and iterate many times, until thermal equilibrium: you end up with a completely distorted version of the initial states, which can be unlearned; this works well even if you do not wait until the thermal equilibrium: just take the first or second reconstruction (increase that number as the algorithm progresses)).

Collaborative filtering deals with a large matrix of ratings, with users in one dimension and items in the other, and most of the data is missing. Language models (modeling triples user-item-rating) convert each user into a feature vector, each item into a feature vector, and combines those vectors, e.g., with a scalar product, to produce a rating: this is actually a matrix *factorization model*, the most commonly used model for collaborative filtering. RBMs can tackle this problems: one visible unit per item, 100 hidden units, each training case corresponds to a user; to deal with missing values, discard the visible units with missing data: there are different networks, reasonably small, each with a single observation, but they share weights.

13. Back-propagation has a bad reputation: it does not work well with deep neural networks (those with many hidden layers, unless you impose a lot of constraints, as with convolutional nets), or with recurrent nets, and support vector machines (SVM) often perform better. The real problems are small datasets (neural networks need a lot of data), slow computers (to deal with the volume of data – GPUs are popular with neural network practitioners), simplistic networks (for simple models, low-dimensional datasets (up

to 100), or data plagued by noise rather than complex phenomena, statistics works best), and badly initialized weights.

A **belief net** (“Bayesian network”, in graphical model parlance) is a sparsely connected, directed acyclic graph, with stochastic variables. Contrary to Boltzmann machines (undirected graphical model, energy-based, “pairwise Markov networks” in graphical model parlance), belief nets are causal: they can easily be used to generate samples.

To initialize the weights carefully, to improve learning, one can use a generative model.

Learning sigmoid belief nets would be easy if we could sample from the posterior distribution of the hidden states. But, because of “explaining away”, it is difficult: if A and B are independent, improbable, and both imply C , they are negatively correlated given C – it is almost an exclusive or. MCMC can be used, but it is extremely slow: a Markov chain would get stuck on A or B and would never visit the other. *Variational methods* sample from an incorrect but simple approximation of the posterior.

The *wake-sleep* algorithm assumes that the posterior distribution (over the hidden configurations) factorizes into a product of distributions for each separate hidden unit, *i.e.*, that we can forget about explaining away. Consider two sets of weights: generative weights (the actual weights, from the hidden units to the observed ones) and recognition weights (in the other direction). In the wake phase, use the the data and the recognition weights, and sample the hidden units; given the state of those hidden units (considered as a sample from the posterior), train the generative weights. In the sleep phase, reverse the role of generative and recognition weights. The wake phase makes the recognition weights close to the (wrong) posterior; the sleep phase makes the wrong posterior close to the correct posterior.

14. RBMs are good at learning features, and those features can be reused as input of RBMs – and so on. Surprisingly, if you stack RBMs, the result looks like a sigmoid belief net – which suddenly becomes easy to learn.

Start by learning an RBM, with two layers, the data and a first hidden layer. Use this first hidden layer as input to another RBM: to learn it, you can initialize the second hidden layer with the data (the second RBM is just the first RBM upside down). You can then stack those two RBMs, to form a **deep belief net** (DBN) (it is a hybrid network, partly directed, partly undirected)

Hidden layer 2 \longleftrightarrow Hidden layer 1 \longrightarrow Data

The lower layers form a sigmoid belief net (perhaps with several hidden layers), the top two upper layers form an RBM. You may want to use different weights in the up and down phases.

To generate data, use Gibbs sampling on the top layers (RBM), until equilibrium; then propagate towards the

visible layer, using the generative weights.

Stacks of RBMs can be used to initialize the weights before back-propagation: this pre-training is unsupervised (the labels are not used).

RBMs can also model real-valued data: use visible linear units with Gaussian noise and hidden rectified linear units.

15. Principal component analysis (PCA) can be implemented with back-propagation:

Use back-propagation to make the output vector as close as the input vector. This can be generalized with non-linear layers:

The first part is an encoder, the last a decoder – the whole is an **auto-encoder**.

Since back-propagation does not work well with deep networks, you can use echo-state-net weight initialization or unsupervised pre-training (use a stack of RBMs to initialize the encoding weights, use the transpose to initialize the decoding weights) before fine-tuning with back-propagation.

Latent semantic analysis, *i.e.*, PCA of the vectors of word counts (or probability vectors) is often used for document retrieval. You can use deep auto-encoders instead of PCA, *e.g.*, start with 2000 words, encode them to 500 neurons, then 250, then 10, and then decode them in the same way. Even with 2 dimensions, the plot is much more informative (the clusters are much more separated) than with (linear) PCA.

The **semantic hashing** problem is that of finding a document (text, image) similar to a given document: use an auto-encoder with logistic units in the code layer, add noise to the inputs of the code layer (otherwise, the logistic units would be used in their middle range, sensitive to noise, but conveying more information – instead, you can use binary stochastic units), and threshold them to get a binary code. Similar documents are documents with the same (or similar) bi-

nary codes (for similar documents, flip a few bits, *i.e.*, perform an exhaustive search on the neighbourhood).

Semantic hashing also works for image retrieval: first, use a small (28-bit) binary code to build a (long) shortlist of candidates. Then, use a 256-bit binary code, and perform an exhaustive search on the shortlist; the layers could be 1024 pixels, 8192 units, 4096, 2048, 1024, 512, 256 (learning may take days, even on a GPU).

Since an RBM is like a shallow auto-encoder, you can pre-train with a stack of auto-encoders instead of RBMs – it works better with *denoising auto-encoders*, *i.e.*, by adding noise to the input vector by setting many of the components to zero (like dropout, but for the inputs), or *contractive auto-encoders*, which make the activity of the hidden units less sensitive to the inputs by penalizing the squared gradient of the hidden activities wrt the inputs.

16. Gaussian processes can be used to optimize the hyper-parameters, in a Bayesian way: they estimate a function

$$f : \text{hyperparameters} \mapsto \text{quality of the result}$$

by providing an estimate and an error, *i.e.*, $f(x) \sim N(\hat{f}(x), \sigma_x)$, and one can evaluate the function at the hyperparameters with the biggest expected improvement on the best values so far

$$E[\text{improvement} | \text{improvement} > 0].$$

Probabilistic graphical models D. Koller (Coursera, 2012)

1. Knowledge representation

1a. Modelling a set of discrete random variables seems easy: you just have to give the joint probability table. However, when there are many variables, there are too many parameters to estimate – perhaps even, too many to store in the memory of your computer. **Graphical models** provide a parsimonious description of discrete probability distributions – think of them as “factor models” for discrete variables (a factor model is a parsimonious description of a covariance matrix, $V = \text{eve}' + \Delta$, with v small, positive definite, e rectangular, Δ diagonal and V large square, often used in finance to describe stock returns).

With the Bayes formula, you can decompose the joint probability

$$\begin{aligned} P(A, B, C, D, E) &= \\ P(A|B, C, D, E)P(B, C, D, E) &= \\ P(A|B, C, D, E)P(B|C, D, E)P(C, D, E) &= \\ P(A|B, C, D, E)P(B|C, D, E)P(C|D, E)P(D, E) &= \\ P(A|B, C, D, E)P(B|C, D, E)P(C|D, E)P(D|E)P(E). \end{aligned}$$

If you choose the order wisely, some simplifications can occur: for instance, if A is independent of C , D and E , you can replace $P(A|B, C, D, E)$ with $P(A|B)$. For

instance, we could have

$$p = P(A|B)P(B|D, E)P(C|E)P(D)P(E).$$

The decomposition can be described by a **directed acyclic graph** (DAG), with an arrow from x to y if $P(y|\dots x \dots)$ appears in the decomposition.

Conversely, a DAG defines a decomposition of the joint probability (to find the order: start with a leaf, remove it, iterate): a **Bayesian network** is a DAG with a *conditional probability distribution* (CPD) $P(X_i|\text{Parents}(X_i))$ at each node X_i .

The **naive Bayes model**, popularized by spam detection (or, more generally, document classification),

$$\text{word}_i \perp\!\!\!\perp \text{word}_j \mid \text{Class}$$

$$P(\text{Class}, \text{word}_1, \dots, \text{word}_n) = P(\text{Class}) \prod_i P(\text{word}_i | \text{Class})$$

can be the first step before a better-informed Bayes model. Inference is straightforward.

From a developer’s point of view, bayesian networks are easy to maintain (the model is just data) and can lead to more flexible user interfaces (since they can easily deal with missing (unobserved, latent) values, the user can choose not to answer a question).

Many bayesian networks are built from simpler building blocks (“ground networks” or templates):

- Dynamic bayesian models (hidden Markov models (HMM), Kalman filters, , all the chain-like models in NLP), temporal models (with the Markov assumption and time invariance, they can model arbitrarily long trajectories);
- Grid models in image processing (similar model for each pixel or superpixel);
- Object-relational model (e.g., pedigree relations in genetics; student–course relations in a university; the BUGS-like plate models, when there are many repeated elements).

The distribution of $Y|X_1, \dots, X_n$ (say, when the X_i are binary) requires an exponential number of parameters: we often want a more concise description of those CPDs. **Tree-structured CPDs** encode context-specific independence

$$X \perp\!\!\!\perp_c Y | Z, C = c$$

(it just says that large parts of the table CPD are identical, and the decision tree is just a way of compressing it): the *multiplexer* CPD is one such tree

$$P(Y|K, X_1, \dots, X_n) = \mathbf{1}_{Y=X_K}.$$

In the **noisy OR**, each possible cause (say, diseases) triggers the consequence (a symptom) with some probability, and the consequence appears if any of the causes triggered it: this ignores dependence between causes.

Instead of OR, you could use AND, MAX, or a sum (sigmoid CPD, as in neural networks)

$$P(Y = 1|X_1, \dots, X_n) = \text{sigmoid} \left(w_0 + \sum_i w_i X_i \right).$$

1b. Markov networks are undirected graphical models. A **pairwise Markov network** decomposes the joint probability distribution as a product of “factors” (or “potentials”), one for each edge, e.g.,

$$P(A, B, C, D) \propto \phi_1(A, B)\phi_2(B, C)\phi_3(C, D)\phi_4(A, D);$$

for instance, the pixels (or superpixels) in an image form a lattice (an undirected graph). The factors do not have any direct interpretation. **Markov networks** (MN) (sometimes called **Markov random fields** (MRF) or general Gibbs distribution) do the same thing with hypergraphs.

$$P(X_1, \dots, X_n) \propto \prod_i \phi_i(D_i),$$

where the D_i are hyperedges. A Markov network can also be represented as a graph, with an edge between two vertices if they are in the same hyperedge. By replacing the hyperedges with their cliques, we lose some information.

1c. Conditional Random Fields (CRF) do not model $P(Y, X)$ but $P(Y|X)$: we can then ignore the distribution of X (the correlations do not matter – they could be difficult to model). Only the normalizing constant changes.

$$\begin{aligned} P(X, Y) &\propto \prod f_i(D_i) \\ Z(X) &= \sum_Y P(X, Y) \\ P(Y|X) &= P(X, Y)/Z(X). \end{aligned}$$

Log-linear models (feature-based models) are of the form

$$\begin{aligned} P &\propto \prod \phi_i(D_i) \\ \phi_i(D_i) &= \exp(w_i f_i(D_i)) \end{aligned}$$

where f_i is known (“feature”) and the w_i are parameters (there can be several factors with the same domain,

and you can impose that the weights be equal). Often, the features f_i are indicator functions, as in the Ising model. For metric MRF,

$$\begin{aligned} f_{ij}(X_i, X_j) &= \text{distance}(X_i, X_j) \\ \phi_{ij}(X_i, X_j) &= \exp(-w_{ij} f_{ij}(X_i, X_j)) \end{aligned}$$

where the distance can be a Kronecker delta, the absolute value of the difference, or some robust cost function such as $d(x, y) = \text{Min}(1, |x - y|)$.

BN are preferable when there is a natural direction (e.g., a causal network), MRF when there is none (e.g., adjacent pixels in an image), CRF when there are variables with a complicated dependency structure you do not want to model (e.g., complex features, in image analysis).

1d. The notions of **conditional independence**, causal reasoning (the path from evidence to conclusion follows the edge directions), evidential reasoning (opposite), intercausal reasoning (from one cause of an effect to another: $P(\text{Cause}_1|\text{Effect}, \text{Cause}_2)$, explaining away) and, more generally, inference flow can be expressed in graph-theoretic terms. Inference can flow from X to Y if they are linked by edges such as

$$\begin{aligned} X &\longrightarrow Y && \text{(causal relation)} \\ X &\longleftarrow Y && \text{(deduction)} \\ X &\longrightarrow W \longrightarrow Y \\ X &\longleftarrow W \longleftarrow Y \\ X &\longleftarrow W \longrightarrow Y && \text{(intercausal relation)} \end{aligned}$$

but inference does not flow through **v-structures**

$$X \longrightarrow Y \longleftarrow Z$$

for instance,

Trails with no v-structures, are called **active trails**.

Things are slightly more complicated with conditional inference: a trail $X_1 \longrightarrow \dots \longrightarrow X_n$ is active given Z if, for each v-structure $\longrightarrow X_i \longleftarrow$ it contains, X_i or one of its descendants is in Z , and no other X_i is in Z . It is simpler with undirected graphs: a trail $X_1 - \dots - X_n$ is active given Z if no X_i is in Z .

Bayesian networks can be interpreted as

- a factorization of the joint probability;
- a description of the dependencies among the variables;
- a description of the conditional independence relations between the variables.

The following properties are equivalent.

- $P \models (X \perp\!\!\!\perp Y|Z)$
- $P(X, Y|Z) = P(X|Z)P(Y|Z)$
- $P(X|Y, Z) = P(X|Z)$
- $P(Y|X, Z) = P(Y|Z)$

- $P(X, Y, Z) \propto \phi_1(X, Z)\phi_2(Y, Z)$ for some functions (“factors”) ϕ_1 and ϕ_2 .

If there is no active trail between X and Y given Z , then X and Z are said to be **d-separated** given Z and they are independent given Z . For instance, any node is d-separated from its non-descendants given its parents.

The **independence map** of a directed graph G is the set $I(G)$ of conditional independence relations coming from d-separation. A set of independence relations satisfied by a probability distribution P is said to be an **independence map** of P . One can show that a probability distribution P factorizes over a directed graph G iff $I(G)$ is an independence map of P .

For Markov networks as well, a probability distribution P factorizes over an undirected graph G iff G is an I-map for P (at least, if the distribution is positive, *i.e.*, never zero – in particular, there are no deterministic relations).

A graph is a minimal I-map if you cannot remove any edge – minimal I-maps exist, but need not be unique. A graph G is a perfect map if $I(G) = I(P)$ – perfect maps need not exist. Two graphs are I-equivalent if they encode the same independencies: there is an unidentifiability problem if you try to infer the structure of the graph.

It is possible to convert between BN and MN, but some independencies are lost: from BN to MN, we lose the independencies in the v-structures, from MN to BN, we must add triangulating edges to loops.

2. Inference

We have a network, some data (the evidence), and a question about it. Unfortunately, most inference problems on graphical networks are NP-hard.

A **conditional probability query** is the problem of computing $P(Y)$ (marginal probability) or, more generally, $P(Y|E = e)$ (*i.e.*, “reduce” the factors by the evidence). It is also called a **sum-product problem**: the aim is to compute an (exponentially large) sum of products. In the presence of evidence, or for undirected graphs, you also need to renormalize the result.

The algorithms include: variable elimination (exact), belief propagation (biased), variational approximation, MCMC (often with importance sampling).

The MAP (maximum a posteriori) inference problem is the problem of finding

$$\text{MAP}(Y|E = e) = \underset{y}{\text{Argmax}} P(Y = y|E = e)$$

where Y contains all the variables not in the evidence E . This is different from the maximum over the marginals. It is also called a **max-product problem**.

The algorithms include variable elimination, belief propagation, integer programming (efficient, popular), graph-cut methods (in some special cases), combinatorial search.

2a. Variable elimination (VE) integrates out one variable at a time from the sum-product; a judiciously-chosen elimination order can reduce the number of operations.

Variable elimination can be visualized as operations on a graph. First convert the graph to an undirected graph (you need to add edges for all v-structures, *i.e.*, create the cliques associated to the factors); then eliminate the nodes one by one (you need to add *fill edges* between the neighbours of the node you remove). We want an elimination order for which the induced graph (with all the fill edges added) has small cliques.

To find a good elimination order, one can use a greedy approach, *i.e.*, eliminate the node with the smallest cost, where the cost is one of

- the number of neighbours in the current graph;
- the number of values in the factor formed (if the factors are not all binary) (min-weight);
- the number of new fill edges (min-fill – it works much better);
- the total weight (number of values) of the new fill edges (weighted min-fill).

To find a good elimination order, one can look for a low-width (small cliques) triangulation (no loop of length greater than 3 without a “bridge”) of the initial graph (the induced graph is triangulated).

2b. Belief propagation (BP) considers a covering of the graph by subgraphs, which exchange information. A *cluster graph*, associated to a Markov network, is a graph whose vertices (clusters) are sets of variables, with edges labeled by sets of variables (sepsets) common to both clusters (not necessarily all the variables in the intersection), and each factor assigned to a cluster with all the required variables. The factor ψ of a cluster is the product of the (MN) factors ϕ associated to it. Clusters then exchange messages $\delta_{i \rightarrow j}$: initialize the messages to 1, multiply the messages you received with the information you have, and send it (suitably marginalized) to the other neighbours; when sending to a neighbour, do not use the information you directly received from it. After some time, compute the beliefs: $\beta = \delta\psi$. They often converge (but sometimes oscillate), and are biased (significantly, but for few variables – BP is useful when there are many variables). Convergence and accuracy are worse in presence of tight loops or potentials pulling in opposite directions.

Cluster graphs should satisfy the running intersection property: if two clusters have a variable in common, there is a unique path between them all of whose sepsets contain the variable. In other words, for any variable X , the clusters and sepsets containing it form a tree (connected, no loops).

The *Bethe cluster graph* is a bipartite cluster graph, with a cluster for each variable and for each factor, and edges between a variable and a factor if it is in its scope. It is a good first choice.

A cluster graph is said to be calibrated if clusters agree

on their sepsets.

Even if the beliefs are biased (as estimators of marginal probabilities), information is not lost: the unnormalized joint probability can be recovered as

$$\frac{\prod_i \beta_i}{\prod_{i,j} \mu_{i,j}}$$

where $\mu_{i,j} = \delta_{i \rightarrow j} \delta_{j \rightarrow i}$ are the sepset beliefs.

For *clique trees*, *i.e.*, cluster graphs that form a tree, and in which the sepsets are exactly cluster intersections, the belief propagation computations are equivalent to variable elimination and lead to correct marginals. Messages from a leaf are final: if you pass the messages from the leaves inwards (find a node that has received messages from all its neighbours except one), belief propagation converges immediately.

You can easily compute all marginals (with variable elimination, you had to redo everything for each marginal). To answer queries, you may need to recompute some messages, but not all: only those from the new evidence to the variable of interest.

Clique trees can have large clusters: each sepset separates the graph into two conditionally independent parts (this is a consequence of the running intersection property).

Do not use synchronous BP – asynchronous BP converges more often and faster. On an arbitrary cluster graph, propagation order matters:

- Tree reparametrization (TRP): choose a tree at random (it works better with larger trees, *e.g.*, spanning trees), calibrate it, and iterate with other trees (make sure you sample all edges);
- Residual belief propagation (RBP): pass messages between clusters whose belief over their common sepset disagree most (use a priority queue).

To limit oscillations, you can smooth (dampen) the messages (bias them towards their previous value).

Turbo codes (efficient error-correcting codes) were one of the flagship applications of loopy BP.

The MAP estimation problem is a Max-Sum problem, formally identical to the sum-product problem: it can be solved via variable elimination. Message passing can be used, but the beliefs at each clique are just max-marginals; however if the global MAP assignment is unique, it can be recovered from the max-marginals (if it is not, perturb the problem to make it unique, or build the assignment one variable at a time, backtracking if needed).

Some MAP problems are tractable (via ad hoc algorithms): matching (over a bipartite graph); associative potentials (when two binary variables are dependent, they tend to agree more often than not); metric MRF (a continuous analogue of associative potentials); cardinality factors ($\text{score}(X_1, \dots, X_n) = f(\sum X_i)$, where the X_i are binary); sparse pattern factors (the table CPD is sparse); convexity factors (contiguity in texts,

contiguous activities in temporal data, image segmentation), etc.

The **dual decomposition** uses optimization techniques to address the MAP problem: separate 1-variable factors from many-variable factors

$$\begin{aligned} \text{MAP}(\theta) &= \text{Max}_x \left(\sum_i \theta_i(x_i) + \sum_F \theta_F(x_F) \right) \\ &= \text{Max}_x \left(\sum_i \theta_i(x_i) + \sum_{F \ni i} \lambda_{Fi}(x_i) + \right. \\ &\quad \left. \sum_F \theta_F(x_F) - \sum_{i \in F} \lambda_{Fi}(x_i) \right) \\ &\leq \sum_i \text{Max}_x \left(\theta_i(x_i) + \sum_{F \ni i} \lambda_{Fi}(x_i) \right) + \\ &\quad \sum_F \text{Max}_x \left(\theta_F(x_F) - \sum_{i \in F} \lambda_{Fi}(x_i) \right) \end{aligned}$$

and solve those subproblems (or “slaves” – choose the decomposition so that they are tractable); when they disagree, *i.e.*, $x_{Fi}^* \neq x_i^*$, reduce the fitness on both sides

$$\begin{aligned} \lambda_{Fi}(x_i^*) &= \alpha \\ \lambda_{Fi}(x_{Fi}^*) &= \alpha; \end{aligned}$$

the algorithm converges if $\sum \alpha_t = \infty$ and $\sum \alpha_t^2 < \infty$. If the slaves agree, this is the MAP; if not, use heuristics (voting, decompositions into a spanning tree (it will be consistent), etc.) to “decode” them.

2d. Monte Carlo methods (Gibbs Sampling, Metropolis-Hastings) can also be used for inference.

2e. Graphical models are also used to support decision making: we do not only want to estimate a model, we want to find a decision rule that maximizes some expected utility (MEU). An *influence diagram* is a bayesian network with added “action” nodes and a “utility” node (if the utility function is separable *i.e.*, a sum of simpler functions, There can be several utility nodes).

This diagram can help decide which variable to measure, by computing the *value of perfect information*, the difference between the MEU of the influence diagram with an edge added (from the variable to measure to the action node) and the MEU of the initial influence diagram.

3. Learning. Given data and a partial description of the network (*e.g.*, the structure but not the parameters, or just the nodes, without the edges – in addition, some of the data can be missing, and some of the nodes may be unknown (latent variables)), we want a complete description of the graphical model (structure and parameters).

3a. Maximum likelihood estimation (MLE) is the most straightforward: the likelihood can be decomposed into a product of local likelihoods – but use cross-validation to prevent overfitting (in particular, the likelihood of a complete graph is always higher).

Learning is a special case of inference: parameters can be seen as random variables. *Bayesian learning* combines an imaginary Dirichlet sample (the Dirichlet prior generalizes the Beta prior, for the multinomial distribution instead of Bernoulli), with real data samples; it is asymptotically equivalent to the MLE (the relative size of the prior decreases as more data arrives), but converges faster.

One can also use maximum a posteriori (MAP) estimators.

3b. Structure learning is trickier. If an arc is missing, you cannot recover the true distribution, but the network may have good generalization properties. If there is an arc in excess, you can recover the true distribution, but the network may have poor generalization properties.

To learn the structure, one can define some score function (distance between model and data) and optimize it: consider all the possible graphs on the nodes you have, compute a score for each of them, and pick the graph with the highest score.

The *likelihood* is not a good scoring function: it is guaranteed to overfit – it prefers the fully-connected graph. You can add a constraint or, better, a penalty on the complexity of the graph, as in the *Bayesian information criterion* (BIC).

$$\text{log-likelihood} - \frac{\log(\text{number of instances})}{2 \times \text{number of independent parameters}}$$

(the opposite is sometimes called the MDL (minimum description length) criterion). It is asymptotically consistent.

The *bayesian score* is

$$P(\text{model}|\text{data}) \propto P(\text{data}|\text{model})P(\text{model});$$

it is dominated by the marginal likelihood $P(\text{data}|\text{model})$. This is not the likelihood but the marginal likelihood: the likelihood is evaluated at the best parameters, while the *marginal likelihood* is averaged over all possible parameters (for a given graph structure). The marginal likelihood can be easily computed for multinomial models: it is a sum, one term for each node, only involving information about its parents. For the structure prior, $P(\text{model})$, you can use a constant (uniform distribution on the space of graphs: the marginal likelihood is penalized enough), or a penalty for the number of edges or parameters. For the parameter priors (needed to compute the integral inside $P(\text{data}|\text{model})$), use a Dirichlet prior, *i.e.*, the parameters for a network with no edges, or the parameters from a simple network structure. Asymptotically, the Bayesian score is equivalent to the BIC score: in particular, it is consistent.

The scoring function is decomposable: it is a sum over the nodes (or “families”: each node and its parents). In the case of trees or forests, it can be transformed into a sum over the (undirected) edges, and finding

the optimal tree (or forest) is just a minimum spanning tree problem. For more general graphs, the problem can still be reduced to a graph-theoretic one, but it is NP-hard: we have to resort to some heuristic, such as greedy hill climbing or simulated annealing – to avoid local maxima and plateaux (equivalent networks are often neighbours), use random restarts and a tabu list, and make sure the neighbourhoods are sufficiently large (in particular, you do need edge reversals, otherwise there are many more local extrema).

The decomposability can help speed up the implementation: we only need the differences in scores, which only involve one or two nodes, and do not change unless we touch those nodes: just put the possible moves in a priority queue (heap) sorted by the score differences.

3c. Hidden variables can simplify the structure of the network, but make the optimization problem more complex: because of unidentifiability (e.g., values of a discrete hidden variable can be permuted), which leads to the multiplication of local extrema, and non-decomposability. Missing data pose the same problem. One could use gradient descent: there is a simple formula for the gradient, but it requires inference for each data instance. Expectation maximization (EM) is faster: it uses the fact that given complete data, parameter estimation (M step) is easy; and that given parameters, computing the distribution of missing data (inference, E step – it is a *soft completion* of the data: not a single value but a probability distribution) is easy (uses the same efficient statistics as complete data MLE). You should not only look at the likelihood, but also at the parameter values (they continue to fluctuate even though the likelihood seems to be stable); you should use cross-validation to know when to stop the optimization (the longer it runs, the higher the overfitting risk); you should use several restarts (random, or from prior knowledge, or from a simpler (clustering) algorithm).

Successful uses of probabilistic graphical models mix and match models (directed and undirected), inference algorithms (approximate (BP, MCMC) and exact on some subsets of variables), and learning algorithms (e.g., SVM for some potentials, CRF for others).

Market Risk Analysis IV Value-at-Risk Models C. Alexander (2008)

1. There are many measures of risk: standard deviation, semi-variance, lower partial moments, etc.. The **value at risk** (VaR) is a quantile of the distribution of discounted returns, for a given significance level α and horizon h . It is not a *coherent* risk measure, but once you have a VaR model, you can also compute the *expected shortfall* (ES). The VaR (or ES) can be measured absolutely or with respect to a benchmark.

The expected returns can be neglected in short-term VaR, but not in very long-term VaR. For long-term

VaR, the difference between *dynamic VaR* (continuously rebalance the portfolio to keep the risk exposures constant) and *static VaR* (do not touch the portfolio, let it drift) becomes more pronounced.

The greeks are sometimes incorrectly seen as risk measures: they are only *risk sensitivities* – the actual risk is the product with the risk factor returns.

2. Equity and cash flow portfolios are linear in their risk factors (strictly speaking, cash flow portfolios are linear in the discount factors, not the rates, but the linear approximation is very good). When there is a term structure of risk factors, principal component analysis (PCA) can reduce their number.

The **parametric linear VaR** model is not limited to Gaussian iid risk factor returns: it can be corrected for autocorrelation (AR(1)); it can be generalized to a Student distribution (with heavy tails) or a mixture distribution (to model different regimes).

To account for volatility clustering, one can estimate the variance matrix with an exponentially weighted moving average (EWMA) or, better, a GARCH model.

Model risk can be very high: try several models.

3. Historical simulation, *i.e.*, the use of historical returns (for the factors or for the portfolio), provides VaR estimates with no distributional assumptions. The returns should be adjusted so that the volatility be the same as the current volatility:

$$y_t = \frac{\hat{\sigma}_T}{\hat{\sigma}_t} x_t,$$

where $\hat{\sigma}$ comes from a GARCH (or asymmetric GARCH (A-GARCH), to account for the leverage effect) model. In a multivariate setup, divide and multiply by the Choleski matrices instead of the volatilities.

The square root rule, for *time scaling*, is only valid for Gaussian iid returns. For stable iid returns, there is a similar rule, with a different exponent (to be estimated). For non-iid returns, you can use an h -period ahead volatility forecast from a GARCH model.

To estimate extreme quantiles from historical data, you need to model the tail, *e.g.*, with kernel density estimators; extreme value theory (EVT) (but you have to choose a threshold); the Cornish-Fisher expansion (which tends to over-estimate the VaR); or (better) the Johnson SU distribution.

To decompose the VaR, decompose the returns

$$\text{return} = \sum_i \beta_i \times \text{return}_i + \varepsilon_i.$$

One can compute the VaR of each term (*standalone VaR*, not additive), the VaR from all the risk factors (*systematic VaR*) or from the residuals (*specific VaR*), or use Euler's identity and numeric differentiation to have an actual decomposition (*marginal VaR*, *incremental VaR*). For instance, for FX risk, you can use

$$\text{log-returns}_{\text{GBP}} = \text{log-returns}_{\text{USD}} + \text{FX log-returns}$$

(you may need to assume that log-returns and ratio-returns are the same, which may be fine for very short horizons).

4. Monte Carlo simulations are often preferable to linear VaR or historical VaR models: just sample from a statistical model for the risk factor returns.

GARCH (or, better, *Markov-switching GARCH*) models can account for volatility clustering. Principal component analysis (PCA) will reduce the number of factors and make them orthogonal. *Copulas* can model the dependence between risk factors: even elliptic copulas as useful, since they allow different marginal distributions (*e.g.*, Student with different degrees of freedom, or Gaussian mixtures).

Importance sampling can be used to improve the precision (reduce the *sampling error*) of the VaR – but it is a quantile, not an expectation: the details are different.

5. The main risk factors for **option portfolios** are price, squared price (to account for non-linearities) and implied volatility. The *value delta* (or dollar delta) is

$$\Delta_{\$} = \frac{\partial \text{Price}}{\partial \log S} = S \frac{\partial \text{Price}}{\partial S} = S \Delta.$$

It can be aggregated over different underlyers – it answers the question “how much would the value of the portfolio change if all prices simultaneously rose by 1%”. The other value greeks are defined similarly, and may be used to compute the Δ - Γ approximation

$$\text{P\&L} = \Delta'_{\$} R + \frac{1}{2} R' \Gamma_{\$} R,$$

where R is the vector of discounted returns for the underlyers.

The corresponding VaR can be computed analytically: one can compute the moments of the P&L distribution and either use the Cornish-Fisher expansion or (better) fit a Johnson SU distribution.

Time scaling may look straightforward if you only look at prices

$$\text{P\&L}_h = h^{1/2} \Delta'_{\$} R + \frac{1}{2} h R' \Gamma_{\$} R,$$

but it is not clear how to scale vega (the implied volatility is mean-reverting) – it is preferable to directly use h -day returns.

While the Δ - Γ -*vega approximation* (the other greeks do not add any significant information) is fast and often used for intraday (real-time) VaR, it is inadequate, especially for hedged portfolios: it is preferable to exactly reprice the options, using either historical data, or a dynamic model for the risk factors (volatility clustering, mean reversion for risk indices and implied volatility, etc.).

If there are too many risk factors (say, futures of different maturities on various underlyers; implied volatilities for many strikes, maturities and underlyers), you can use principal component analysis (PCA) to reduce their number and identify the “main” ones. PCA does not work well with implied volatilities: instead, you can

use “volatility beta mapping”, *i.e.*, choose a reference volatility (usually ATM).

As usual with options, one should not confuse the **P** and **Q** measures: the VaR is a quantile of the real-world (**P**) distribution of returns.

6. There are many sources of **model risk**:

- Volatility clustering, autocorrelation;
- Heavy-tailed return distributions;
- Choice of risk factors (e.g., vertex choice, for cash flow portfolios);
- Estimation procedures (e.g., the “ghost artefacts” in rolling unweighted OLS estimates: the estimators jump when an outlier enters and leaves the window);
- Inadequate scaling (the regulators encourage this: they ask banks to use a 10-day VaR to compute their capital requirement, but only mandate tests on the 1-day VaR, and allow the square root rule...).

You can compute confidence intervals for the VaR estimators (analytically, or via asymptotic results – bootstrap is not mentioned). Here are a few tests for the VaR, based on the number of *exceedances* n_1 and the number of consecutive exceedances n_{11} (the tests are only asymptotic, unlikely to be useful unless you really have a huge amount of data, and the independence test will overlook clustering unless the exceedances are exactly consecutive).

$$\begin{aligned} -2 \ln \frac{\alpha^{n_1} (1 - \alpha)^{n_0}}{\left(\frac{n_1}{n}\right)^{n_1} \left(\frac{n_0}{n}\right)^{n_0}} &\sim \chi^2_{\text{df}=1} \\ -2 \ln \frac{\left(\frac{n_1}{n}\right)^{n_1} \left(\frac{n_0}{n}\right)^{n_0}}{\left(\frac{n_{00}}{n_0}\right)^{n_{00}} \left(\frac{n_{01}}{n_0}\right)^{n_{01}} \left(\frac{n_{10}}{n_1}\right)^{n_{10}} \left(\frac{n_{11}}{n_1}\right)^{n_{11}}} &\sim \chi^2_{\text{df}=1} \\ -2 \ln \frac{\alpha^{n_1} (1 - \alpha)^{n_0}}{\left(\frac{n_{00}}{n_0}\right)^{n_{00}} \left(\frac{n_{01}}{n_0}\right)^{n_{01}} \left(\frac{n_{10}}{n_1}\right)^{n_{10}} \left(\frac{n_{11}}{n_1}\right)^{n_{11}}} &\sim \chi^2_{\text{df}=2} \end{aligned}$$

There are similar tests for the expected shortfall.

To check if the risk model uses all the information in the market, regress the exceedance indicator variable against the lagged risk factors (with several lags) and compare with the intercept-only model (the intercept is the significance level α).

If you are willing to assume Gaussian iid returns (test for autocorrelation, heteroskedasticity, normality), you could test the bias:

$$\text{sd} \left(\frac{Y_{t+1}}{\hat{\sigma}_{t+1}} \right) \sim N \left(1, \frac{1}{2T} \right).$$

Instead of looking at a single quantile, you could compare the whole forecasted distribution with the actual returns, e.g., with a likelihood ratio test (I would use a Kolmogorov-Smirnov test).

7. While VaR and ES look at extreme events in normal market conditions, **stress tests** (scenario analysis) look at abnormal market conditions.

Some *stress tests* are computed from the risk factors returns for a historical event (1987 crash, etc.).

Some rely on single-case scenarios, *i.e.*, a single vector of risk factor returns: for instance the *worst-case loss* stress tests look at the worst possible loss if the risk factors move by $\pm 6\sigma$ – but, since the portfolio may be hedged along those risk factors, it may be preferable to look at the losses for large changes in the principal components (especially if there is a term structure of risk factors) or if the risk factor returns are on the ellipse $x'\Omega^{-1}x = c$ (this uses the risk model Ω) – for non-linear portfolios, you should even look inside this ellipse (“trust region worst case loss”).

Other stress tests rely on distribution scenarios: for instance, the conditional distribution of the risk factor returns given that one of them jumped, $(f_j)_{j \neq i} | f_i > a$; or some subjective view; or a mixture distribution (the normal regime, from the risk model, and a “crash regime”, with some crash probability); or a bayesian blend of the two regimes (product of the probability distribution functions).

You can use data from a past crisis (sample covariance matrix, higher moments) to define the “crash regime” or correct the covariance matrix of (more recent) historical returns. If you manually tweak the correlation matrix, it can cease to be a valid correlation matrix, and you may need to correct it.

Exogenous *liquidity adjustment* of the VaR (by modeling the distribution of the bid-ask spread) has a negligible effect, but endogenous adjustment (linear or quadratic market impact, with some price drift if the liquidation is spread over several days, accounting for volatility clustering) may be necessary.

8. Regulatory capital is the capital that regulators ask banks to hold to ensure they remain solvent. It can be computed as $3\text{VaR}_{10\text{-day}}$ (either the average of the 10-day VaR over the past 60 days, or the latest 10-day VaR, whichever is higher) if the VaR model has been approved (*i.e.*, if it does not have too many exceedances). Alternatively, the regulators provide “standardized rules”: for equities, 8% of the value of the positions, plus a 4% to 8% charge for specific risk (insufficient diversification), and another one for credit risk – fixed income, commodities, currencies have similar rules.

Economic capital (EC) is similar, but used internally and presented to shareholders and rating agencies. It is often based on ES rather than VaR. *Risk budgeting* or *economic capital allocation* is the allocation of the economic capital to the various desks of the firm. Contrary to real capital (needed by funded activities, and whose financing cost should be included in the P&L), it is not additive, because of diversification. *Aggregation risk* (use of incorrect correlation when aggregating the VaR or ES of the various desks to compute the firm-wide economic capital, or when allocating the economic capital to the various desks – or incorrect use of correlations when they do not capture the dependences) is the

most important source of model risk. Risk budgeting is often done by looking at the efficient frontier in the $P\&L \times EC$ space, or by optimizing some risk-adjusted performance measure, such as

$$RORAC = \frac{E[P\&L]}{EC}$$

or

$$RAROC = \frac{E[P\&L] - kEC}{EC}$$

(they give the same point on the efficient frontier: the tangent allocation).

Social network analysis **L. Adamic (Coursera, 2012)**

1. Given a network, you can look at the following *descriptive statistics*.

- The degree of each node, the distribution of the degrees (distinguish in- and out-degrees for oriented graphs), the average degree, its standard deviation or the Gini coefficient (to measure how diverse the degrees are);
- The average shortest path;
- The size of the largest connected component (or strongly-connected, for oriented graphs).

To assess how central a node is, look at:

- Its degree;
- Its *betweenness centrality*, i.e., the proportion of pairs of nodes on whose shortest path the node is;
- Its *closeness centrality*, i.e., the average of the inverse of the distances from this node;
- Its *eigenvalue centrality*,

$$\text{centrality}_i = \sum_{j \text{ neighbour of } i} w_{ij} \text{centrality}_j,$$

which can be generalized to $C = (\alpha + \beta C)A$, where A is the adjacency matrix, β a parameter, and α a normalization constant. The analogue for directed networks, PageRank, is more complicated: it can be computed with a random walk on the directed graph, with some teleportation to avoid getting stuck in loops (it cannot happen with undirected networks: if you enter a loop, you can always leave it).

The strength of an edge A–B can be assessed with the *neighbourhood overlap*:

$$\frac{\text{number of neighbours of both A and B}}{\text{number of neighbours of either A or B}}.$$

The presence of communities can be assessed by the *clustering coefficient*:

$$\frac{\text{number of closed triangles}}{\text{number of connected triplets}}.$$

For a directed network, you can count all the 3-node patterns (“motifs”) and compare with the numbers for a random graph with the same average degree, or with the same degree distribution.

Identifying communities is trickier (most of those algorithms do not work on real-world networks, probably because communities overlap):

- Connected components, strongly-connected components;
- Cliques: they betray community structures, but they overlap, can be incomplete, are not robust; they only describe a “core” rather than the larger community;
- k -core: a subgraph in which every node is connected to at least k other nodes;
- Connected components of the graph with nodes the k -cliques and an edge if two k -cliques differ by only one node;
- Hierarchical clustering;
- Betweenness clustering: remove the edge with the highest betweenness, recompute, iterate until the betweenness of the remaining edges is sufficiently low; the connected components are the communities;
- Modularity: compare the presence of edges within and between communities with what you would expect if they were selected at random; start with random community assignments and change them to improve the modularity.

2. The simplest network model is the *Erdős-Rényi* random network: the edges are simply selected at random, independently. There is a giant component, there are no hubs, the degree distribution is binomial (asymptotically Poisson), the average shortest path is proportional to $\log n$.

Growth models, such as the *Barabasi-Albert preferential attachment model*, have hubs, and a more unequal degree distribution (power law).

Small world networks combine the short distances of ER random networks with a community structure. The *Watts-Strogatz model* starts with a lattice, starts to randomly rewire it, but stops before getting a random network. There are hierarchical (Watts-Dodds-Newman) and geographical (Kleinberg, the probability of an edge is proportional to some power of the distance). When rewiring, you can use simulated annealing to minimize

$$\lambda \times \text{average shortest path, in number of edges} + (1 - \lambda) \times \text{average shortest path, in kilometers}.$$

Changing the value of λ gives networks with hubs or with short edges

3. A *power law* (or Pareto distribution) is a probability distribution such that

$$P(X = x) \propto x^{-\alpha};$$

in the case of node degree, the variable is discrete. The *Zipf law* (the size of the r th largest event is proportional to $r^{-\beta}$) is the q-function of the Pareto distribution. Fitting a (discrete) power law distribution is tricky:

- When regressing the logarithm of the number of nodes with a given degree against the logarithm of

the degree, large numbers of observations are binned in a single point for low degrees, and there are many empty bins for high degrees – forgetting them gives a very biased estimator;

- Logarithmic binning is better, but discards information;
- Cumulative binning is preferable: the number of events in $[1, n]$ still follows a power law, with exponent $\alpha - 1$;
- The maximum likelihood estimator is (you need to choose where the power law starts, x_{\min})

$$\alpha = 1 + n \left(\sum \log(x_i/x_{\min}) \right)^{-1}$$

- The power law may not extend to the very end of the tail: you can try to add an exponential cut-off

$$p(x) \propto x^{-\alpha} e^{-x/k}.$$

4. One can study the influence of the network structure on various processes such as *contagion* (or information diffusion, opinion formation, coordination) or *resilience*. *Assortative* networks (hubs connect to hubs, as opposed to disassortative nets, such as the web, in which the hubs are on the periphery) are more resilient. You can also look at the correlation profile: compare the number of edges between nodes of degree k and l with that in a random network; look at the average degree of the neighbours, as a function of a node's degree; look at the correlation between the degree of two adjacent nodes.

5. From a software point of view, networks can be studied with Gephi (to look at the network), NetLogo (for experiments, and to explain things to others), iGraph, NetworkX (Python), sna (R).

Cryptography I

D. Boneh (Coursera 2012)

Many historical ciphers are generalizations of the Caesar cipher (rot-3): substitution cipher, Vigenere cipher (k rot- n ciphers), Hebern machine (k substitution ciphers, forming a “rotor”), Enigma machine (idem, with 3 to 5 rotors, rotating at different speeds).

Stream ciphers use a similar idea: in the one-time pad, the message is XORed with the key, which has to be as long as the message (the safety of this cipher relies on the fact that if X and Y are binary, independent, and X is uniformly distributed, then $X \text{ XOR } Y$ is uniformly distributed); most stream ciphers use a pseudo-random generator instead, e.g., Salsa20 (or the other eStream ciphers – do not use a linear congruential generator or `random` in `glibc`).

There are many notions of a “secure” cipher. A cipher is *semantically secure* if $E(m_1, k)$ and $E(m_2, k)$ are computationally undistinguishable (for cleartexts m_1, m_2 chosen by the attacker and a random key k). A cipher is *malleable* if you can change the ciphertext to generate predictable effects on the clear text (e.g., the one-time pad is malleable: if you know that

the message starts with `From: Bob`, you can XOR it with `From: Bob XOR From: Eve` to change the sender name). There are many more, each corresponding to a type of attack or information leakage we want to prevent. Not all attacks necessitate flaws in the algorithm: it is easier to attack the implementation, e.g., with side channel attacks (measure the time, the power consumption, the cache misses, etc.) or fault attacks (overclock the device so that it outputs a wrong result – this can give some information about the key).

A **block cipher** encrypts the message by blocks, somewhat hiding its exact length. Many are built from *Feistel networks*: cut the block in two (L, R) and consider $F_1 \circ \dots \circ F_n$, where $F_i(L, R) = (R, L \text{ XOR } f_i(R))$ – the F_i are invertible (*pseudo-random permutation*, PRP) for arbitrary f_i (*pseudo-random function*, PRF). DES and AES are block ciphers. (DES and double DES are broken; there is an attack on the triple DES, but it is not practical). AES is not a Feistel network: $c_i = \sigma(f_i(c_{i-1} \text{ XOR } k_i))$ (11 times, with a permutation σ and PRP f_i , starting with $c_0 = m$).

A pseudo-random generator (PRG) $G : K \rightarrow K \times K$ defines a block cipher: it is a 1-bit PRF, and by iterating it,

$$\begin{aligned} k &\mapsto (G(k)_1, G(k)_2) \\ &\mapsto (G(G(k)_1)_1, G(G(k)_1)_2, (G(G(k)_2)_1, G(G(k)_2)_2)) \end{aligned}$$

you get a 2-bit PRF (those 4 values correspond to the encoding of 00, 01, 10, 11), and eventually an n -bit PRF (you do not need to compute all 2^n values: since you only want one branch of the tree, there are only n values to compute). The PRF can then be turned into a PRP with the Ruby-Rackoff theorem (3-round Feistel). But it is much slower than heuristic block ciphers (or the stream cipher used).

The naive use of a block cipher, cutting the message into blocks and encrypting each block separately, with the same key (ECB, Electronic Code Book), is unsafe: two identical blocks give identical cipher texts, it is not safe against replay attacks – even worse, if you encrypt an image like that, its silhouette remains visible.

Cipher Block Chain (CBC) remedies this by XORing the cleartext with the ciphertext of the previous block before encryption:

$$\begin{aligned} c_0 &= \text{IV (Initialization Vector)} \\ c_i &= E(k, c_{i-1} \text{ XOR } m_i) \end{aligned}$$

To ensure that the initialization vector is not predictable, you can use a *nonce* (“number used once”), and encrypt it (with another key):

$$\begin{aligned} c_0 &= \text{nonce} \\ \text{IV} &= E(k_1, \text{nonce}) \\ c_1 &= E(k, \text{IV}) \text{ XOR } m_1 \\ c_i &= E(k, c_{i-1}) \text{ XOR } m_i \end{aligned}$$

Randomized counter mode (CTR) uses a similar idea, but is parallelizable: XOR the message with with

$F(k, IV)$, $F(k, IV + 1)$, etc., where F is a pseudo-random function.

The **integrity** of a message can be ensured with a *message authentication code* (MAC):

$$\begin{aligned} \text{tag} &= S(\text{message}, \text{key}) \\ V(\text{message}, \text{tag}, \text{key}) &= \text{"yes"} \end{aligned}$$

Contrary to checksums, MACs have to be robust to malicious errors, not just random ones. A PRF can be used as a MAC (it should be secure and sufficiently long – more than 80 bits), for small messages. For larger messages, you can chain the MAC computations, as in, encrypted CBC-MAC:

$$\begin{aligned} c_0 &= F(\text{key}, m_0) \\ c_1 &= F(\text{key}, m_1 \text{ XOR } c_0) \\ &\dots \\ \text{MAC} &= F(\text{other key}, c_n) \end{aligned}$$

or NMAC (nexted MAC):

$$\begin{aligned} c_0 &= F(\text{key}, m_0) \\ c_1 &= F(c_0, m_1) \\ &\dots \\ \text{MAC} &= F(\text{other key}, c_n \parallel \text{pad}) \end{aligned}$$

(without the last encryption, it is not secure: an attacker can append something to the message).

Padding the last block with zeroes is unsafe. Instead, you can add $100 \dots 00$, but you may need to add a dummy block. CMAC provides padding with no dummy block: replace the final encryption with

$$\begin{aligned} c_n &= F(\text{key}, (m_n \parallel 100 \dots 00) \text{ XOR } \text{key}_1) \\ c_n &= F(\text{key}, m_n \text{ XOR } \text{key}_2) \end{aligned}$$

depending on whether there is padding or not.

The MAC can be parallelized (PMAC):

$$\begin{aligned} c_1 &= F(\text{key}_1, m_1 \text{ XOR } P(\text{key}_0, 1)) \\ c_2 &= F(\text{key}_1, m_2 \text{ XOR } P(\text{key}_0, 2)) \\ \text{return } &F(\text{key}_1, c_1 \text{ XOR } \dots \text{ XOR } c_n) \end{aligned}$$

If F is invertible (a PRP rather than just a PRF), you can invert the last step, add some more data, or modify one of the blocks, and recompute the tag.

A one-time MAC can be computed from a large prime number q (e.g., $2^{128} + 51$), using two random numbers k , $a \in \llbracket 1, q \rrbracket$ as a key: if the message (m_1, m_2, \dots) is made of 128-bit integers, the tag is $\sum_i m_i k^i + a \pmod q$.

A one-time MAC can be transformed into a many-time MAC (Carter-Wegman MAC):

$$\text{tag} = (r, F(\text{key}_1, r) \text{ XOR } S(\text{key}_2, \text{message}))$$

where r is random, S is a 1-time MAC, F is a PRF. It is a random MAC: it is not deterministic.

From a collision-resistant compression function operating on small messages, you can build a collision-resistant function that operates on larger messages, by chaining the hash function: e.g., SHA-1 (almost broken), SHA-256, SHA-512, Whirlpool (slower) .

A collision-resistant function is not a secure MAC: use a Hash MAC (HMAC) instead (it is very similar to NMAC, which used two keys, and a PRF instead of a hash):

$$S(\text{key}, \text{message}) = \text{Hash}(\text{key} \parallel \text{outer pad}, \text{Hash}(\text{key} \parallel \text{inner pad}, \text{message})).$$

When checking if the MAC is correct, you need to compare several bytes: the compiler (lazy language, optimizing compiler, `||/∆∆` shortcut, etc.) may want to stop as soon as it knows the result, telling a potential attacker whether the first byte was incorrect. Before the comparison, you can encrypt the correct MAC and the MAC to test, and compare the encrypted values.

Encryption alone is not secure against tampering (it is safe against passive attacks only, not active attacks): always use **authenticated encryption** instead. We want a new notion of safety, *ciphertext integrity*: the recipient can reject messages if they are not valid; the attacker cannot create a valid ciphertext; the attacker chooses the ciphertext. This does not provide any safety against replay attacks

Encrypt-and-MAC (add the MAC of the plaintext and send it in clear) is not safe (it leaks information); MAC-then-encrypt (add the MAC of the plaintext and encrypt everything) is only safe in some special cases; encrypt-then MAC (add the MAC of the ciphertext, in clear) is safe.

There are many standards that combine a cipher and a MAC: TLS (to prevent replay attacks, the sender and the recipient keep track of a counter, incremented each time, used in the MAC computation, but never exchanged; suffers from padding attacks, timing attacks, information leakage (the reason why a message is rejected); renegotiates the key in case of a problem to avoid those attacks); 802.11b (MAC-then-encrypt (the reverse is safer), linear CRC (not a cryptographic MAC), repeated IV, related keys, etc.); SSH (the length of the message is not authenticated).

In many situations, you have one key, but the algorithm needs several: you can use a *key derivation function* (KDF). You could use a PRF, if the source key is uniform. Use a salt (non-secret, fixed, chosen at random) to extract a pseudo-random key from the source key, $K = \text{HMAC}(\text{salt}, \text{source key})$ and use HMAC as a PRF with key K . Do not use password-based KDFs: there is not enough entropy, and dictionary attacks work well – if you insist on using them, use a salt and a slow hash function, e.g., iterate $x \mapsto \text{hash}(x \parallel \text{salt})$ many (10^6) times.

Deterministic encryption (no nonce, the ciphertext is always the same) allows you to search in an encrypted database but is unsafe, if the messages are small or repeated (e.g., foreign keys).

Tweakable encryption, $E(\text{key}, \text{tweak}, \text{message})$, where each $E(k, t, \cdot)$ is a PRP, is often used in disk encryption (e.g., xts), with t the sector number and $E(k, t, x) = E(E(k, t), x)$.

Key exchange can be performed through a trusted third party (TTP), who shares a key with everyone: the TTP chooses a random key K_{AB} , encrypts it for A as $E(K_A, K_{AB})$, sends it to A , encrypts it for B as $E(K_B, K_{AB})$, and sends it to A (not B , A will forward to B). This is safe against eavesdropping, but not against active attacks or TTP corruption.

In the *Merkle puzzle* scheme, A sends n puzzles to B , each taking $O(n)$ time to solve. B chooses one, solves it, and the solution is of the form (id, key) (A had generated n different keys). B sends the id to A ; they both know the key. There is a gap between the work done by B and the attacker: $O(n^2)$; it is very inefficient.

Public-key encryption relies heavily on number theory:

- Euclid's theorem (there exists u and v so that $au + bv = \gcd(a, b)$) can be used to compute inverses in $\mathbf{Z}/n\mathbf{Z}$.
- Fermat's theorem ($x^{p-1} = 1 \pmod{p}$) can also be used to compute inverses ($x^{-1} = x^{p-2}$), but is less efficient ($(\log p)^3$ instead of $(\log p)^2$). It can also be used to select random prime numbers: pick p at random, until $2^{p-1} = 1 \pmod{p}$; You can be fairly confident ($P[\text{not prime}] < 2^{-60}$), but there are better, non-probabilistic, tests of primality.
- Euler: \mathbf{F}_p^\times is a cyclic group.
- Lagrange: $\text{ord}_p(g) | p-1$ (the order of an element of an abelian group divides the order of the group) can be used to prove Fermat's theorem.
- Fermat: $x^{p-1} = 1 \pmod{p}$.
- Fermat: $x^{\phi(n)} = 1 \pmod{n}$ if $x \in (\mathbf{Z}/n\mathbf{Z})^\times$ (a special case of Lagrange), where $\phi(n) = |(\mathbf{Z}/n\mathbf{Z})^\times|$ is Euler's totient function.

Many algorithms rely on the difficulty of the following problems:

- Computing a modular e -th root: the best known algorithms require a factorization of the modulus. In \mathbf{F}_p , $x > 0$ is a quadratic residue (i.e., a square) iff $x^{(p-1)/2} = 1 \pmod{p}$ (Legendre symbol); if $p = 3 \pmod{4}$ and c is a quadratic residue, then $\sqrt{c} = c^{(p+1)/4}$; if $p = 1 \pmod{4}$, the square root can be found in $O((\log g)^3)$, with a randomized algorithm; you can also solve quadratic equations with the high-school formula.
- Inverse in $\mathbf{Z}/n\mathbf{Z}$;
- Roots of a polynomial of arbitrary degree in \mathbf{F}_p ;
- Discrete logarithm mod p : find x so that $g^x = a \pmod{p}$ (believed to be hard for \mathbf{F}_p^\times (p large) and elliptic curves; can be computed with the GNFS algorithm for \mathbf{F}_p^\times); can be used to create a collision-

resistant hash: $H(x, y) = g^x h^y$ in $G = \mathbf{F}_p^\times$, with $g, h \in G$ (key) – finding a collision is equivalent to computing a discrete log;

- Factor a number into a product of two large primes (soon possible for 1024-bit numbers, hard for 2048-bit numbers)
- Find a root of a polynomial of degree $> 1 \pmod{n}$ (the best known algorithms factor n).

In the *Diffie-Hellman* scheme, choose a large prime p , and g a generator of the cyclic group $(\mathbf{Z}/p)^\times$. A chooses a in $\{1, \dots, p-1\}$, sends $g^a \pmod{p}$ to B ; B chooses b in $\{1, \dots, p-1\}$, sends $g^b \pmod{p}$ to A . They both compute g^{ab} and use it as a key. For a 256-bit key, you need a 16,000-bit prime. The same idea works with other cyclic groups, e.g., elliptic curves: a 512-bit curve suffices. It is insecure against man-in-the-middle attacks. It can work passively: everyone publishes g^a , and can read the g^b of everyone else. It only works to communicate between two parties; it can be generalized to 3 but, beyond that, the problem is still open.

Many public-key encryption schemes are based on trapdoor encryption: a pair of functions that can be generated randomly, one inverse of the other, but otherwise very difficult to invert. One is non-deterministic and used to encrypt messages (public key), the other is deterministic (private key, trapdoor).

The RSA functions are $x \mapsto x^d$ and x^e , where $N = pq$ is a product of two large prime numbers, $\phi(N) = (p-1)(q-1)$, x invertible mod N (most are), d is random and e is such that $de = 1 \pmod{\phi(N)}$; the functions are inverses because $x^{\phi(N)} = 1 \pmod{N}$. It can be used to exchange the key for a symmetric cipher (rather than encrypt messages, as some textbooks suggest: the functions are deterministic).

We do not know if RSA is safe: we do not know if computing e -th roots is as hard as factoring. Encryption is much faster than decryption (other public key encryption algorithms are more balanced: ElGamal). There are timing or power attacks: computing $c^d \pmod{N}$ can expose d ; there are fault attacks: a single error in the computation of $c^d \pmod{N}$ (check, by elevating to the e -th power: it should be 1) can leak the decomposition of N . There are key generation problem: p is generated before q , when there is not enough entropy: many routers/web servers have the same p (and different q): compute $\gcd(n_i, n_j)$ for all the pairs of routers/web servers you can find – if it is not 1, you have factored n_i (0.5% of web servers are affected).

PySP: Modeling and solving stochastic programs in Python
J.P. Watson et al. (2011)

Stochastic programs can be converted into deterministic programs (the objective function, an expectation, becomes a weighted sum; each decision variable is duplicated for each scenario; the constraints are likewise duplicated; you just have to add non-anticipatory constraints, that encode the structure of the scenario tree),

but the size of the resulting problem (most optimizers have a pre-solver, that identifies and removes redundant variables and constraints, but this only halves the size of the problem) makes it difficult to solve, unless you exploit the structure of the problem.

Vertical strategies, such as *Bender's decomposition* (*L*-shaped method, for 2-stage problems) or nested decomposition schemes decompose the problem by stages. Horizontal strategies, such as **progressive hedging** or the dual decomposition, decompose it by scenarios.

Progressive hedging suggests to:

- Solve the deterministic problems for all the scenarios;
- Average the solutions (the result does not satisfy the non-anticipatory constraints);
- To each sub-problem, add a penalty for the breached non-anticipatory constraints, re-solve the problems, and iterate.

The algorithm can be improved:

- The first iterations do not require a precise solution;
- Detect if a variable converges early; if so, fix its value;
- Detect cycles (tabu search, with a Bloom filter), which are common with integer variables;
- The sub-problems can be solved in parallel.

Pyomo: modeling and solving mathematical programs in Python
W.E. Hart et al. (2011)

The article stresses the need for more modularity in mathematical programming software: one should separate the structure of the problems (abstract model) from the data (concrete model) and the solver; use a high-level programming language (Python, as opposed to AMPL, AIMMS, GAMS), which makes it easy to enumerate sets of constraints and allows you to implement algorithms that require many optimizations (e.g., branch-and-cut; Bender's decomposition for stochastic programs; problems with an exponentially large number of constraints in which you can quickly identify the breached constraints, add them to the problem and iterate).

Coopr contains: Pyomo, to specify the problem; and interface to different solvers; a parallelization framework, build from pickle (serialization) and pyro (RPC), should you want to solve several subproblems in parallel.

The (only?) open-source solvers supported are CBC, GLPK, IPOPT, from the COIN-OR project.

Alternatives include:

- FlopC++: a problem is a C++ class, derived from `MP_Model`; thanks to operator overloading, the syntax looks readable – but I suspect the error messages are not;
- OptimJ, a Java extension – not a library, but an extension to the language, with its compiler, integrated with Eclipse, no longer commercially developed.

The Cornish-Fisher expansion in the context of delta-gamma-normal approximations
S.R. Jäschke (2001)

Proof of the Cornish-Fisher expansion: a series expansion of $F^{-1} \circ \Phi$, with F the cumulative distribution function (cdf) of interest and Φ a known cdf, typically Gaussian), often used to estimate the value at risk (VaR) of non-gaussian distributions. The error increases as you progress into the tail, and the approximated VaR need not even be monotonic. However, the errors from the Cornish-Fisher expansion are smaller than those coming from a quadratic approximation (Δ - Γ -normal): to be safe, compare with a Monte Carlo estimator. Using a reference distribution Φ with fatter tails may reduce those problems.

Asset liability management for individual households
M.A.H. Dempster and E.A. Medova (2010)

There are three ways of solving ALM problems: dynamic programming; stochastic programming (transform the stochastic program into a huge, sparse, deterministic, linear program); various heuristics. Dynamic programming suffers from the curse of dimension; so does stochastic programming, but to a lesser extent. The authors model 10 asset classes (monthly, but the investment and consumption decisions are annual) with geometric brownian motions (equities, bonds, commodities, alternative investments, real estate) or geometric Ornstein-Uhlenbeck processes (cash, inflation, treasury bill rate), with correlated noises, from market data (for some asset classes, you have to compute the total returns from the prices, by adding dividends or coupon payments), and use the corresponding scenarios in an ALM problem, looking for the optimal consumption and investment decisions, to maximize the expected utility of life-time consumption. The utility is piecewise linear and specified separately for each goal; it is penalized for bankruptcy (excess borrowing). The simulation also includes the death of the investor (variable investment horizon), and fixed, inflation-indexed or growing liabilities. Consumption is divided between equity-preserving goals (e.g., housing), often requiring a downpayment and subsequent mortgage payments (making the problem path-dependent), and non-capital goals.

Individual asset liability management
E.A. Medova et al. (2008)

Presentation of the corresponding GUI, to specify the ALM problem and analyze the results.

Discretionary Wealth Hypothesis and ALM
D. diBartolomeo (2010)

Tackle the dynamic asset allocation problem with transaction costs as follows: always invest in a mean-variance efficient portfolio, but change the risk aversion parameter according to the following rule of thumb,

which is not unlike portfolio insurance (PI),

$$\lambda = \frac{1}{2} \frac{\text{Assets}}{\text{Assets} - \text{PV}(\text{Liabilities})}$$

and add a penalty to the mean-variance optimization to account for the transaction costs

$$\frac{\text{transaction costs} \times \text{turnover}}{\text{probability that the new portfolio is better}}.$$

The present value of the liabilities is computed using a risk-free recombining binary tree of short interest rates, so that $\text{Assets} - \text{PV}(\text{Liabilities})$ is non-negative iff the probability of bankruptcy is zero.

The 401(k) retirement income risk
F. Sortino and D. hand (2011)

Since the goal of retirement investment is not to beat the market, but to “retire with dignity”, returns and volatility are not the right benchmark. Instead, to decide if you should make a catch-up contribution, you can look at:

- The probability of achieving the goal;
- The present value of the assets and liabilities;
- The *desired target return* (DTR), *i.e.*, the internal rate of return required for this present value to become positive.

Optimal investment strategies in defined contribution pension plans
D. Blake et al. (2011)

Most pension finds separate the accumulation and decumulation phases, asking the wrong questions (how much do you want to save?), using incorrect targets (performance, rather than retirement), failing at their market timing attempts (when volatility is high, returns are low: one should reduce the weight of equities) and leading to under-funded pension plans.

Only in rare cases (power utility and iid asset returns) is the 1-period optimal strategy also a multi-period optimal strategy. The Kelly principle can be generalized to account for (risky) labour income; the resulting strategy, “stochastic lifestyle”, is reminiscent of the discretionary wealth hypothesis.

Deciding if/when to annualize is an option exercise problem (it depends on age, wealth and risk aversion). Since most pensions are underfunded, most people will buy an annuity; to avoid low interest rates, it is preferable to spread its purchase over time (phased annuity purchases).

It is not advisable to seek an absolute guarantee to deliver the desired pension: such guarantees are very expensive to secure.

Duration-enhancing overlay strategies for defined-benefit pension plans
J.M. Mulvey et al. (2011)

Defined-benefit pension plans have fixed liabilities: they are bonds, with a very high duration (10 to 15 years). Since long-duration assets (long-term bonds) have lower returns than short-duration assets (stocks, etc.), you may want to invest in a core portfolio of short-duration assets (100%), and a *duration-enhancing overlay* (50% to 100%, long long-duration bonds, short short-duration bonds) to hedge the interest rate risk.

A robust optimization approach to pension fund management
G. Iyengar and A. Ka Chun Ma (2011)

The defined-benefit pension problem can be formulated as follows: find the future contributions w_t and the portfolio composition \mathbf{x}_t (equity index and bonds of each maturity) to minimize the present value of the future contributions, subject to the requirement to meet the prescribed (deterministic) liabilities at all times t , and regulatory requirements

$$\text{NAV} \geq \beta \text{PV}(\text{future liabilities}).$$

The time horizon T is sufficiently long so that liabilities beyond T are negligible. (The problem is slightly more complicated: since the liabilities have to be met, the firm has to find the money somewhere – it is a corporate finance decision, involving the use of debt vs equity vs retained earnings, taxes (interest payments are tax-deductible), debt rating, etc.).

The constraints are often replaced by **chance constraints**, asking that the probability that the constraint is breached be below some threshold ε .

Equity prices follow a geometric brownian motion; bond yields are described by the Nelson-Siegel model, whose factors follow a mean-reverting process; the innovations for those four factors are correlated.

The chance constraints $P[\text{constraint breached}] \leq \varepsilon$ are of the form $P[X_t \geq a] \leq \varepsilon$, where X_t is a stochastic process defined from the risk factors. Using Ito’s formula, you can compute its stochastic differential equation, and then linearize it at $t = 0$, *i.e.*, assume it is just a brownian motion. The constraint becomes

$$P[\text{something gaussian}] \leq \varepsilon;$$

it can be written as a second-order cone (SOC) constraint $\|\mathbf{B}\mathbf{x} - \mathbf{a}\| \leq \mathbf{d}'\mathbf{x} + c$.

To ensure that all K chance constraints are satisfied with probability $1 - \varepsilon$, use Bonferroni’s inequality: assume they are independent and set their thresholds to ε/K . The resulting (SOC) optimization problem is no longer stochastic: the contributions w_t and numbers of shares \mathbf{x}_t do not depend on the state of the world at time t .

The resulting strategy is conservative, perhaps because of the linearization of the geometric brownian motion.

**Alternative decision models
for liability-driven investment
K. Schwaiger et al. (2011)**

There are many ways of formulating the pension problem, each simplifying a different aspect of it. Here are four of them.

- A deterministic program, in which you minimize both the sum of all the contributions and the sum of the absolute values of the PV01 of the assets and liabilities (since there are two objectives, the result is not a single strategy, but an efficient frontier of strategies).
- A stochastic model (you have to generate scenarios), with two stages (to simplify), in which you match the present value (PV, not PV01) of the assets and liabilities; the two objective functions are the expected contributions and the expected absolute value of the difference in present values.
- A chance constraint can be added to this model

$$P[\text{Assets} - \gamma \text{Liabilities} > 0] \geq 1 - \varepsilon.$$

The equivalent deterministic formulation (the constraint is breached in at most εN of the N scenarios) involves binary variables.

- The chance constraints can be replaced by **integrated chance constraints** (this is similar to the difference between value at risk and expected shortfall)

$$E[\text{Assets}_t - \gamma \text{Liabilities}_t] \leq \text{PV}_t(\text{Liabilities}(\omega));$$

binary variables are no longer required.

**A liability-relative drawdown approach
to pension asset liability management
A. Berkelaar and R. Kouwenberg (2011)**

Find the portfolio weights \mathbf{w} (constant over time) to maximize the (logarithmic) utility of the funding ratio Assets/Liabilities, whose final value can be approximated as

$$\prod_t (1 + \mathbf{w}' \mathbf{r}_t - r_t^{\text{liabilities}}) \approx \exp \sum_t (\mathbf{w}' \mathbf{r}_t - r_t^{\text{liabilities}}),$$

with a constraint on the variance of the surplus (Assets – Liabilities) or on the maximum funding ratio drawdown (linear program) or on the **conditional** funding ratio **drawdown** (average of the worst 10% worst drawdowns, also a linear program)

Allow for some short-selling: many pension-funds use a return-generating portfolio and a liability-hedging overlay.

The scenarios (returns for equities, commodities, real estate, hedge funds) are generated from risk factors (“state variables”: level, slope and curvature of the yield curve, default spread (Baa – Aaa), consumption-wealth ratio) through a vector autoregressive (VAR) model:

- The yield curve is described by the **Diebold-Li model**, *i.e.*, the Nelson-Siegel model in which the parameters (level, slope, curvature) form a VAR process;
- Use a 2-step model to deal with time series with a shorter history (hedge funds, etc.): first model (VAR) the long-history variables, then model the short-history ones, adding the long-history ones as exogenous variables;
- Modify the intercept of the VAR model to avoid unrealistic reversion to the (old) long-term averages.

The term structures of return volatility, for different asset classes, are very different.

**Dynamic risk management:
optimal investment with risk constraints
S. Jarvis (2011)**

The dynamic asset allocation problem can be solved with partial differential equations (PDEs).

Asymmetric risk measures are even more important for dynamic strategies than for static ones: they can create very non-gaussian return distributions – prefer the conditional value at risk (CVaR, expected shortfall) to the standard deviation.

The optimal dynamic strategy that maximizes the expected CRRA (constant relative risk aversion) utility $((x^{1-\gamma} - 1)/(1 - \gamma))$ or $\log x$ if $\gamma = 1$) of final wealth, when asset prices follow a geometric brownian motion. is the *growth-optimal portfolio* (GOP, a generalization of the Kelly principle); with a CVaR constraint, the payoff is transformed and looks like a collar \nparallel . (This is like an asset and liability management (ALM) problem, but with no liabilities.)

The optimal strategy can be computed by dynamic programming on a scenario tree or, better, a recombining tree. Alternatively, since the probability distribution of the payoff is solution of the **Fokker-Planck equation** (Kolmogorov forward equation – not to be confused with the Kolmogorov backwards equation, which gives the option price), one can solve it numerically, for many investment strategies, and keep the one with the highest utility. (Contrary to option pricing, the payoff is unknown: we are looking for the strategy that maximizes the utility of the payoff.) The resulting distribution looks like a soft CPPI \mathbb{L} (constant proportion portfolio insurance).

While the CVaR is an acceptable risk measure for static (1-period) strategies, it is less so for dynamic ones. A measure of risk ρ can often be seen as a *capital requirement*: $\rho(X)$ is the amount of capital needed to make X acceptable, *i.e.*, $\rho(X) = \text{Min}\{m : \rho(X + m) \leq 0\}$; therefore $\rho(X + m) = \rho(X) - m$. In a multi-period setting, one would expect $\rho_t(X_T) = \rho_t(-\rho_{t+1}(X_T))$ – but this does not hold for the CVaR. The only **time-consistent risk measures** are the *entropic risk measures*

$$\rho_t(X) = \frac{1}{\gamma} \log E_t[\exp -\gamma X]$$

or, more generally (if you remove the translation invariance $\rho(X + m) = \rho(X) - m$), certainty-equivalent risk measures

$$\rho_T(X) = u^{-1} E_t[u(X)].$$

[The consequence of time-inconsistency, the fact that one is risk-seeking when the wealth is very high or very low, looks harmless to me.]

Bank asset-liability and liquidity risk management
M. Choudhry (2010)

Asset liability management (ALM), in a bank, focuses on:

- *Liquidity risk*: the dates of the assets and liabilities do not match (they are even sometimes unknown: options, current accounts, credit lines, etc.), so the bank will need to refinance some of them, and there is no guarantee that this will be possible at a reasonable price;
- *Interest rate risk*: even if the dates match, the rates need not match.

A two-factor HJM interest rate model for use in asset liability management
S. Kaya et al. (2010)

The G_{2++} short rate model (a 2-factor Gaussian model) can be generalized to a term-structure (HJM) model, and used to price structured products.

Asset liability management modelling with risk control by stochastic dominance
X. Yang et al. (2010)

Stochastic dominance (first order, second order, and their variants: interval second order, etc.) constraints can be included in optimization or stochastic optimization problems (they become *chance constraints*).

Zero-coupon yield curve estimation with the package termstrc
R. Ferstl and J. Hayden (JSS 2010)

The yield curve is often modelled empirically, from market data, either in a non-parametric way (linear interpolation of discount factors (bad) or of their logarithms (better), piecewise interpolation of the instantaneous forward rate (equivalent), splines) or by assuming that the curve has a specific shape (Nelson-Siegel, Svensson – beware, the formula is different if you model the yield or the instantaneous forward rate), sometimes with a (VAR, VARMA) time-dependence on the parameters (Diebold-Li). Here are some implementations caveats:

- To avoid identifiability problems, you may want to impose a few constraints, e.g., $\tau_2 - \tau_1 > \varepsilon$ in the Svensson model;

- Since the problem is non-convex, you may want to use a grid search (on the non-linear parameters: τ_1 , τ_2) to find good starting values;
- The problem is heteroskedastic: use weights (e.g., the inverse of the duration, or the bid-ask spread).

The implementation, in the `termstrc` package, is unusable: prefer `fBonds` (it uses a grid search, but no constraints, no weights, no time-dependence, and models forward rates rather than yields).

Foundations of the Statpro simulation model
M. Marchioro and D. Cintioli (2007)

To estimate risk (value at risk, expected shortfall), resample from the multiplicative (stock prices, implied volatility, and other positive quantities) or additive (interest rates, swaps, and other quantities that could become negative) historical changes.

For fixed income, resample the instantaneous forward rates rather than the prices. For complex instruments, price them from simple instruments. For large portfolios, pay attention to missing data (coming, e.g., from different holidays).

Pricing simple interest-rate derivatives
M. Marchioro (2008)

Clear presentation of the annoying accounting conventions (day counting convention, business day convention, compounding convention) and overview of the simplest common interest rates derivatives (forward rate agreements (FRA) and swaps). The interest rate term structure (“yield curve”) can be estimated from deposit rates (the -ibor rates: overnight, tomorrow-next, $t+2, \dots$, until 1 year) and the swap rates (beyond 1 year: since the principal is not exchanged, the risk is lower). To interpolate the term structure, linear interpolation of the logarithm of the discount factor, *i.e.*, piecewise constant interpolation of the forward rates, gives decent results.

Doing bayesian analysis, a tutorial with R and BUGS
J.K. Kruschke (2011)

Leisurely introduction to Markov Chain Monte Carlo (MCMC) computations in bayesian statistics, in which the graphical representation of bayesian models as a combination of building blocks is more pictorial than the traditional BUGS one.

Introduction to complex systems (Markov models, Lyapunov functions, random walks, Polya's urn model, chaos, network models), agent-based models (Schelling's segregation model, epidemics models (SIR, SIS), coordination game, replicator dynamics, wisdom/madness of crowds), game theory (prisoner's dilemma, auctions, colonel Blotto) with applications in economy (Solow growth model and the role of innovation), sociology, politics (voting and aggregation of preferences), etc., with examples in NetLogo – useful if you need to explain an agent-based model to a non quantitative audience.

Algorithms, design and analysis I
T. Roughgarden (Coursera 2012)

Introductory algorithms course, covering:

- Sorting: insertion, selection, bubble-sort, merge-sort, quick-sort; bucket-sort (if the data is $U(0,1)$), counting sort (discrete, repeated values), radix sort;
- Divide-and-conquer: multiplication of large integers or matrices (with the Karatsuba and Strassen improvements); number of inversions in an array; closest pair; median (adapt quick-sort; or split the data into groups of 5; recursively compute the median of medians; use it as a pivot)
- Heuristics for NP-complete graph problems: graph colouring to assign temporary variables to registers in a compiler (pick a node with at most k neighbours, remove it, iterate, backtrack if needed, remove a node if stuck), minimum cut (select an edge at random, contract it, iterate, repeat and keep the best solution);
- Graph search: breadth-first search (BFS: use a queue, FIFO), to compute distances or connected components; depth-first search (DFS, backtracking: use a stack or recursion), to compute a topological ordering (all the edges go forward) of a directed acyclic graph (you could also look for a sink vertex, remove it, and iterate) or its strongly connected components (DFS on the reverse graph, remember the finishing time of each vertex, DFS in the reverse order)
- Heaps (or priority queues): minimum paths from a vertex, running median (use two heaps); balanced binary search trees; union-find (aka disjoint-set) to store partitions, with two operations, union and find (the component an element is in, e.g., via a representative element), as a forest of trees (components), each child pointing to its parent, with short paths to the root (representative element) – for more efficiency, when running find(), have all the elements you see point to the root.
- Hash tables (if you implement your own, use a random hash function); Bloom filter (use an array of n bits and k hash functions; to insert an element, set the k corresponding bits to 1);

**Co-movement of energy commodities revisited:
evidence from wavelet coherence analysis**
L. Vacha and J. Barunik (2012)

Wavelets can be used to analyze the coevolution of two time series: let

$$W_x(u, s) = \frac{1}{\sqrt{s}} \int_{-\infty}^{\infty} x(t) \bar{\psi}\left(\frac{t-u}{s}\right) dt$$

be the continuous wavelet transform of a time series x (at time t and scale s); the squared **wavelet coherence** coefficient is

$$R_{x,y}^2(u, s) = \frac{|S[s^{-1}W_x(u, s)\bar{W}_y(u, s)]|^2}{S[s^{-1}|W_x(u, s)|^2]S[s^{-1}|W_y(u, s)|^2]}$$

where S is some smoothing operator. It measures the linear correlation at a given location and scale. The wavelet coefficient phase difference

$$\phi_{x,y}(u, s) = \arg S[s^{-1}W_x(u, s)\bar{W}_y(u, s)]$$

can highlight delays in the oscillations of the two time series (add it as arrows (as a vector field) on top of the wavelet coherence heatmap plot).

**On Hurst exponent estimation
under heavy-tailed distributions**
J. Barunik and L. Kristoufek (2012)

Empirical comparison of various Hurst exponent estimators: rescaled range (R/S), multifractal detrended fluctuation analysis (MF-DFA), detrending moving average (DMA), generalized Hurst exponent (GHE, *i.e.*, scaling of the q -moments, often with $q = 2$) – GHE has lower variance and bias.

Monte-Carlo-based tail exponent estimator
J. Barunik and L. Vacha (2012)

The Hill estimator of the tail exponent is biased on small samples – use a simulation-based estimator instead:

- Generate random samples, with the same size, from various stable distributions;
- Compute their Hill estimators, for various threshold choices;
- Compare with the Hill estimators (for all those thresholds) of the actual data (they use the L^1 norm and give the same weight to all the thresholds).

Properties of the most diversified portfolio
Y. Chouefaty et al. (2011)

A few remarks on the **diversification ratio** (ratio of the portfolio's weighted volatility to its overall volatility), a generalization of the Herfindahl index (entropy) when assets are correlated and/or do not have the same risk. that can be interpreted as the (square of the) effective number of (uncorrelated) assets (or risk factors) in the portfolio. (This approach is limited to unleveraged, long-only portfolios.)

***Orthogonalized equity risk premia
and systematic risk decomposition***
R.F. Klein and K.V. Chow (2010)

In a factor risk model, you may want the factors to be orthogonal, e.g., to have a simple risk decomposition. Gram-Schmidt orthogonalization depends on the order of the factors, but there is a symmetric variant: let $F = (f_1 | \dots | f_n)$ be the matrix of (centered) factor returns; we want S so that $\text{Var } FS = I$, i.e., $S'F'FS = I$, i.e., $SS' = (F'F)^{-1}$, i.e., $S = (F'F)^{-1/2}C$ for an arbitrary $C \in O(n)$, e.g., $C = I$.

***Derivatives and credit contagion
in interconnected networks***
S. Heise and R. Kühn (2012)

Most models of contagion in financial networks (bipartite, firms vs banks and insurance companies) only take into account who lends to whom, and neglect synthetic credit risk exposure through CDSes – it is not negligible, and taking it into account requires adding hyperedges to the network (between three nodes: firm-bank-insurance or firm bank-bank).

***Second-order price dynamics:
approach to equilibrium with perpetual
arbitrage***
E. Kempt-Benedict (2012)

The presence of arbitrageurs and rationally-bounded economic actors explains the permanent fluctuations around the equilibrium. (This is the usual informed traders vs noise traders game, expressed in terms of supply and demand.)

***A multifractal approach
towards inference in finance***
O. Løvstetten and M. Rypdal (2012)

Multifractal processes have stationary increments and satisfy $E[|X_t|^q] \propto t^{\zeta(q)}$ for some concave function ζ (linear for self-similar (i.e., stable) processes such as Brownian motion or Lévy flight). There are many ways of building such processes or their discrete equivalents. For instance (multi-fractal random walk):

$$\begin{aligned}x_n &= X_n - X_{n-1} \\x_n &\sim N(0, \sigma_n) \\ \log \sigma_n &\sim \text{Gaussian Process} \\ \text{Cov}(\log \sigma_t, \log \sigma_s) &\propto \log^+ \frac{T/\Delta t}{|t-s|+1}\end{aligned}$$

***Numerical methods and optimization
in finance***
M. Gilli et al. (2011)

The first part of the book covers many numerical topics, such as the inherent imprecision of floating-point arithmetic (for which $\sum 1/k$ converges), numerical instability (the algorithm amplifies rounding errors), ill-conditioning (small changes in the input lead

to large changes in the output), the conditioning number ($|xf'(x)/f(x)|$, or $\kappa(A) = \|A\| \|A^{-1}\|$ for linear functions), matrix decompositions (LU, QR, SVD, Cholesky), **structural rank** (the maximum rank of a sparse matrix with the same presence/absence pattern), finite differences (implicit, explicit and θ methods – Crank-Nicolson is obtained for $\theta = 1/2$), flaws in pseudo-random number generators and the way they are used (resetting the seed before each number may not be a good idea), low-discrepancy sequences, bootstrap (the **Taylor-Thompson algorithm** is a smooth non-parametric bootstrap: take a point at random, look at its k nearest neighbours, move it towards them by a random amount, iterate). Examples include European and American option pricing, time series models (with a clear interpretation of the model parameters), CPPI, VaR estimation.

The second part is devoted to (unconstrained) optimization. The **fixed point method** (rewrite the problem as $x = f(x)$ and iterate $x_{n+1} = f(x_n)$ until convergence) is more useful than one may think: it is the base of the Jacobi, Gauss-Seidel and SOR algorithms, used to solve large linear systems (e.g., those coming from PDEs) or large non-linear systems; it can also be used to compute the *S-estimator* (a robust estimator whose cost function is defined implicitly). Gradient-based algorithms (gradient descent, quasi-Newton, Levenberg-Macquardt), heuristics (local search, tabu search, simulated annealing, threshold acceptance, genetic algorithms, differential evolution, particle swarm optimization, ant colony optimization) and hybrid methods are also presented, with examples from portfolio optimization, term structure models, option pricing model calibration (via the characteristic function), robust regression (least median of squares, least quantile of squares, least trimmed squares).

The book contains many plots, but the lack of titles and labels makes them difficult to read.

A tutorial on geometric programming
S. Boyd et al. (2007)

A *monomial* is a term of the form $cx_1^{a_1} \dots x_n^{a_n}$, with $c > 0$ – but the a_i are arbitrary real numbers. A **posynomial** is a sum of monomials. A **geometric program** (GP) is an optimization problem of the form “minimize P_0 , so that $P_1, \dots, P_n \leq 1$ and $M_1 = \dots = M_m = 1$ ”, where the P_i are posynomials and the M_j monomials. The exponents can be arbitrary, but the coefficients have to be positive and the equality constraints only have one term.

Geometric programs can be solved efficiently via interior point methods: if f is a (generalized) posynomial, then $\log f(e^y)$ is convex (in terms of f , the convexity condition involves geometric averages, hence the name).

Surprisingly many problems are geometric programs, or can be reformulated as such, or can be approximated by GPs. Here are some of the transformations (defining

generalized posynomials).

$$\begin{aligned} f(x) - m(x) \leq 0 &\rightarrow f(x)/m(x) \leq 1 \\ f(x)^{2.2} + g(x)^{3.1} \leq 1 &\rightarrow f(x) \leq t_1, g(x) \leq t_1, \\ &\quad t_1^{2.2} + t_1^{3.1} \leq 1 \\ f_0(f_1(x), \dots, f_n(x)) \leq 1 &\rightarrow f_0(t_1, \dots, t_n) \leq 1, \\ &\quad f_1(x) \leq t_1, \dots, f_n(x) \leq t_n \\ \text{Max}\{f_1(x), f_2(x)\} \rightarrow t, &\quad f_1(x) \leq t, f_2(x) \leq t \end{aligned}$$

Trade-off analysis measures the impact of the constraints: replace the constraints $f_i(x) \leq 1$ and $g_j(x) = 1$ with $f_i(x) \leq u_i$ and $g_j(x) = v_j$, consider the value $p(u, v)$ of the corresponding problem, and compute the partial derivatives (the logarithm disappears because we are evaluating them in 1)

$$\begin{aligned} S_i &= \left. \frac{\partial \log p}{\partial \log u_i} \right|_{u=v=1} = \left. \frac{\partial \log p}{\partial u_i} \right|_{u=v=1} \\ T_j &= \left. \frac{\partial \log p}{\partial \log v_j} \right|_{u=v=1} = \left. \frac{\partial \log p}{\partial v_j} \right|_{u=v=1}. \end{aligned}$$

You do not have to explicitly compute those quantities: they come from the dual problem. This is also useful for infeasible problems: the sensitivities (using some measure of infeasibility as objective, or a penalized objective) tell you which constraints bear the most responsibilities.

Here are more transformations

$$\begin{aligned} \frac{p(x)}{r(x) - q(x)} + f(x) \leq 1 &\rightarrow t + f(x) \leq 1, \\ q(x) + p(x)/t &\leq r(x) \end{aligned}$$

and approximate transformations (functions whose Taylor expansions have positive coefficients – for the exponential and the logarithm, the problem can be solved exactly: after the logarithmic transformation, the function is convex).

$$\begin{aligned} \exp f(x) &\underset{f(x) \approx b}{\approx} e^b \left(1 + \frac{f(x) - b}{a} \right)^a \\ \log q(x) &\underset{a \gg 1}{\approx} a q(x)^{1/a} - a \end{aligned}$$

There are many generalizations:

- in a mixed linear GP, some variables appear as GP terms, others as linear terms: only apply the logarithm transform to the GP ones;
- GP problems with posynomial (not monomial) equality constraints can sometimes be solved by relaxation: replace $h(x) = 1$ with $h(x) \leq 1$ and try to tweak the solution (especially if it is not unique).

Many problems can be approximated with GPs: a function f can be approximated by a monomial (resp. posynomial) if $F(y) = \log f(e^y)$ can be approximated by an affine (resp. convex) function. A *monomial fit* can be obtained by Taylor expansion, least squares, penalized least squares (L^1 regularization gives fewer terms), non-linear least squares for the relative error $|g(x_i) - f_i|/f_i$, or by minimizing the maximum

relative fitting error (after the logarithm transform, the problem becomes linear). A *max monomial fit* $f(x) = \text{Max}_k f_k(x)$ can be obtained by adapting the k -means algorithm (as a starting point, use k perturbed copies of a monomial fit). A *posynomial fit* can be obtained by non-linear least squares (Gauss-Newton, sequential quadratic programming).

Some generalizations are no longer convex:

- Signomial programming removes the constraint that the coefficients be positive: start with an initial guess, use a monomial approximation of the offending terms (perhaps with a constraint to force the solution to stay close to the current one); iterate;
- Mixed integer GP can be solved with heuristics (round the solutions, perhaps after tightening the constraints; or round one variable at a time, starting with those closest to an integer; or use branch-and-bound).

**Portfolio selection problems in practice:
a comparison between linear
and quadratic optimization models
F. Cesarone et al. (2010)**

The quadratic program with cardinality constraints

$$\begin{aligned} &\text{Minimize } x'Qx \\ &\text{such that } \sum x_i = 1 \\ &\quad x \geq 0 \\ &\quad |\text{supp } x| \leq k \end{aligned}$$

(polynomial if Q is positive definite, but NP hard in general) can be solved efficiently by noticing that the minimum is obtained in the interior of a face Δ_I of $\Delta = [\sum x_i = 1]$ where the restriction Q_I of Q is strictly convex; the solution is then $x_I^* = (\mathbf{1}'Q_I^{-1}\mathbf{1})^{-1}Q_I^{-1}\mathbf{1}$. We “just” have to find I such that $|I| \leq k$, $x_I^* \subset \Delta_I$ that minimizes $(\mathbf{1}'Q_I^{-1}\mathbf{1})^{-1}$. It turns out that, as we increase k , the corresponding I 's are included into one another: this gives an incremental algorithm to solve the problem. However, since there are many possible I 's at each step (as we increase k , they form a tree, and we want one of the longest branches), the complexity is still exponential in the worst case; one can try heuristics, e.g., keeping the solutions with the best values.

**Learning from data
Y.S. Abu-Mostafa (Caltech, 2012)**

Hoeffding's inequality measures how well in-sample results generalize out-of-sample: for proportions, on a sample of size N ,

$$P[|\mu_{\text{out}} - \mu_{\text{in}}| > \varepsilon] \leq 2 \exp(-2\varepsilon^2 N).$$

It also tells us if learning is possible at all: when you choose between M (independent) models,

$$P[|\text{Error}_{\text{out}} - \text{Error}_{\text{in}}| > \varepsilon] \leq 2M \exp(-2\varepsilon^2 N).$$

But M is usually infinite. In the case of classification, what matters is not the number of models, but the number $m(k)$ of different possible predictions they can make on the data: if there are k points, there are at most 2^k dichotomies but, in general, since the models have a specific form (e.g., linear), there will be fewer dichotomies. If the **VC (Vapnik-Chervonenkis) dimension** (intuitively, the effective number of parameters, or the effective degrees of freedom)

$$d_{VC} = \sup\{k : m(k) = 2^k\}$$

is finite, $m(k)$ is polynomial. We then have

$$P[|\text{Error}_{\text{out}} - \text{Error}_{\text{in}}| > \varepsilon] = O(N^{d_{VC}} e^{-\alpha \varepsilon^2 N}).$$

The multiplicative constant is too large for this inequality to be useful in itself, but it is believed that the order of magnitude is close to optimal. As a rule of thumb, you want $N \geq 10 d_{VC}$.

VC analysis can be contrasted with bias-variance analysis: the bias (sometimes called “deterministic noise”) is the error between the best approximation, in the set of models considered, and of the (unknown) data-generating mechanism; the variance is the error between the best approximation and that derived from the sample data.

To avoid overfitting, use regularization (add a $\lambda \|w\|^2$ penalty or, equivalently (by duality), a constraint $\|w\| \leq C$) and (10-fold) cross-validation (to select the regularization parameters and/or the model complexity).

The examples covered included singular value decomposition (SVD, for recommendation systems); the perceptron, logistic regression, neural networks; soft-margin support vector machines (SVM), with details of the corresponding quadratic optimization problem and its dual, which gives the support vectors (the number of support vectors measures the complexity of the model, not unlike the VC dimension); the kernel trick ($k(x, y) = (1 + x'y)^k$, which gives polynomials of degree up to k , $k(x, y) = \exp -\gamma \|x - y\|$); radial basis functions (apply k -means on the inputs, regress $y \sim \sum \exp -\gamma \|x - \mu_i\|$, choose γ and k by cross-validation – this is very similar to SVM with a gaussian kernel, where the μ_i are support vectors instead of k -means centers).

Introduction to logic

M. Genesereth and E. Kao (Coursera 2012)

Propositional logic is the logic of truth tables: given propositional constants p, q, r , etc. and a *truth assignment*, you can check if complex sentences ($p \wedge q$, $(p \vee q) \Rightarrow r$, etc.) are true or false. A sentence is *valid* if it is always true, for all truth assignments; *contingent* if it is sometimes true, sometimes false; *unsatisfiable* if it is never true; *satisfiable* if it is sometimes true (valid or contingent); *falsifiable* if it is sometimes false (unsatisfiable or contingent). A set of sentences Δ **entails** a sentence ϕ , written $\Delta \models \phi$, if, for all truth assignments for which Δ is true, so is ϕ . Entailment is a satisfiability problem: $\Delta \models \phi$ iff $\Delta \cup \{\neg \phi\}$ is unsatisfiable.

Satisfiability (SAT) is an NP-complete problem, but there are some improvements on the naive algorithm (checking all the truth tables): arrange the possible truth assignments in a tree (each level corresponds to a literal, each node corresponds to a partial truth assignment), simplify the problem at each node by partially evaluating the formula, and prune the tree whenever possible. Besides deterministic algorithms (DPLL), there are a few heuristics (WalkSAT).

The **Fitch system** is a set of rules of inference, to draw conclusions from premisses (notation: $\Delta \vdash \phi$). Since it allows subproofs

$$\frac{\phi \vdash \psi}{\phi \Rightarrow \psi}$$

(if you are not familiar with this notation: the premisses are above the bar, the conclusions below), its proofs are shorter than those of other systems (Mendelson, etc.). A proof system is *sound* when: if $\Delta \vdash \phi$, then $\Delta \models \phi$ (i.e., if something is provable, it is true); it is *complete* when the converse holds. Fitch for propositional logic is sound and complete.

Propositional resolution provides a more algorithmic way of checking entailment: distribute $(\phi \vee (\psi \wedge \chi)) = (\phi \vee \psi) \wedge (\phi \vee \chi)$ all the premisses to put them in *clausal form* $\bigwedge_i \bigvee_j p_{ij}$, often written as

$$\begin{aligned} &\{p_{11}, \dots, p_{1k_1}\} \\ &\dots \\ &\{p_{n1}, \dots, p_{nk_n}\} \end{aligned}$$

and apply the propositional resolution principle

$$\frac{\{p, q_1, \dots, q_m\} \quad \{\neg p, r_1, \dots, r_n\}}{\{q_1, \dots, q_m, r_1, \dots, r_n\}}.$$

The empty clause is a contradiction. The propositional resolution principle is not complete (e.g., $\{p\}, \{q\} \not\models \{p, q\}$), but unsatisfiable clauses can be proven to be so: to prove $\Delta \models \phi$, show $\Delta \cup \{\phi\} \vdash \{\}$.

Relational logic adds quantifiers, variables (needed if you want to use quantifiers), relations and functions. (You will often need an equality relation, syntactic sugar for an equivalence relation with the substitution property: $\forall x \forall y p(x) \wedge (x = y) \Rightarrow p(y)$.) We can still

define the notion of truth assignment and logical entailment but, in presence of functions, the set of sentences for which you have to provide a truth value (the **Herbrand base**) is infinite. Here are a few examples: **Z/4** can be described with 4 literals and relations “same”, “next”, “plus”; **N** (Peano arithmetic) can be described with one literal 0, a “successor” function and “same”, “next”, “plus” relations; lists can be represented with a “nil” literal, a “cons” function and an “append” relation; BNF grammars; propositional logic itself (*meta-level logic*).

Finite relational logic (*i.e.*, the Herbrand base is finite, in particular, there are no functions) is equivalent to propositional logic: to see it, write everything in *prenex form*, *i.e.*, with the quantifiers on the outside. It is *compact*: every unsatisfiable set of sentences contains a finite unsatisfiable subset. *Omega relational logic* (infinitely many literals but no functions) is not compact, but is *semi-decidable*: if a finite set of sentences is unsatisfiable, it can be shown in finite time (using the prenex transformation).

The Fitch proof system is still applicable to relational logic (with a few more rules: universal and existential introduction and elimination, for which you have to pay attention to free variables; domain closure; induction): if $\Delta \models \phi$, then there exists a finite proof $\Delta \vdash \phi$ (but if $\Delta \not\models \phi$, the search for a proof will take forever).

Relational resolution is useful, but incomplete: it is based on satisfiability, but relational logic is not decidable. To put an expression in clausal form, existential elimination, $\exists a p(x) \rightarrow p(a(y))$, adds a new function (*Skolem function*) of the enclosing universal variables y . Once you are only left with universal quantifiers, on the outside, you can drop them. Unification is also trickier: you may need to substitute some of the variables and drop part of the clauses.

Relational resolution can be used for *answer extraction*: to find x such that $p(x)$, add the clause $\{\neg p(x), \text{goal}(x)\}$, *i.e.*, $p(x) \Rightarrow \text{goal}(x)$, and continue until you get $\{\}$ (no solution), or $\{\text{goal}(a)\}$ (a is a solution), or $\{\text{goal}(a_1), \dots, \text{goal}(a_n)\}$ (one of the a_i is a solution). It may also take forever (relational logic is not decidable). The algorithm can be sped up by removing tautologies ($\{p, \neg p, \dots\}$), duplications (Ψ if $\Phi \sigma \subset \Psi$) or clauses containing a literal that is never negated.

In **Herbrand semantics**, the universe of discourse contains what the logic describes and nothing else; in **Tarskian semantics**, the universe of discourse can be larger (e.g., the reals and the hyperreals (non-standard numbers) are both models of the reals). Propositional logic and relational logic are examples of Herbrand semantics. **First order logic** is the tarskian equivalent of relational logic (you can emulate first order logic with relational logic: just add a new unary function). Fitch without domain closure and induction is sound

and complete for first order logic:

$$\begin{array}{ccc} \Delta \vdash_{\text{Fitch} \setminus \{\text{DC}, \text{IND}\}} \phi & \iff & \Delta \models_{\text{FOL}} \phi \\ \downarrow & & \\ \Delta \vdash_{\text{Fitch}} \phi & \iff & \Delta \models_{\text{RL}} \phi \end{array}$$

R in finance 2012

To design a real-time (*i.e.*, you cannot look into the future) finite-sample filter approximating some idealized filter,

$$\begin{aligned} y_t &= \sum_{k \in \mathbf{Z}} \gamma_k x_{t-k} \\ \hat{y}_t &= \sum_{k=0}^n \hat{\gamma}_k x_{t-k}, \end{aligned}$$

express it in frequency space

$$\Gamma(\omega) = \sum_k \gamma_k e^{-ik\omega}$$

and find the $\hat{\gamma}_k$ that minimize

$$\int_{|\omega|=1} |\Gamma(\omega) - \hat{\Gamma}(\omega)|^2$$

You can decompose this quantity into a penalty for the delay between the real and idealized filter and a penalty for the amount of remaining noise.

The singular value decomposition (SVD) can be used to quickly test for cointegration among a large number of assets.

The **d1m** package can fit, filter (Kalman), smooth state space models: ARMA, stochastic volatility, regression with time-varying parameters (**d1mModReg**), etc. and help you cross-validate the result.

The **Rcpp** package allows you to transparently manipulate R objects in C++, eschewing the gory macros you have to put up with when using **.Call** directly – and the **inside** package simplifies things even further. But you are left with those template-related error messages... It is even more useful with the advent of reference classes (R5). In the other direction, you can use **Rinside** to, say, include R in a GUI or a web application (e.g., with the Wt framework).

To mine textual data, use Python and NLTK, of the **tm** package and its many plugings (**tm.plugin.webmining**, **tm.plugin.sentiment**, **tm.plugin.tags**).

CppBugs is faster than **MCMCpack**, and (almost?) as flexible as **JAGS**.

Evaluating the design of the R language

F. Morandat et al.

Unflattering but objective evaluation of R: the language is designed to be used interactively (named and

optional arguments); the main data type is the vector (with support for missing values); it encourages vectorized operations. It mixes seemingly incompatible programming language paradigms: functional and lazy, but dynamic, imperative and reflexive (`parse`, `eval`, `quote`, `bquote`, `substitute`, `deparse`). The current implementation is “massively inefficient”, mainly because of the laziness of the language (which also fails to deliver the performance improvements it should bring), immoderate memory usage (garbage collection is more expensive, frequent and slow than it should). The two class systems (S3, S4 – there is also R5 and a few more in separate packages) look “like an afterthought”. It is “hopelessly non-thread-safe” and lacks standard data structures (growable arrays, hash maps). “It is not the ideal language to develop robust packages.” “As a language, R is like French; it has an elegant core, but every rule comes with a set of ad hoc exceptions that directly contradict it”.

The article also provides a *formal semantics* of the language, and analyzes large amounts of code, to see how the language is actually used.

The article does not mention the ability to easily describe statistical models (`formula`), the data manipulation (`reshape2`, `plyr`) and plotting capabilities – but these are add-ons, rather than parts of the core language.

The nature of alpha A.M. Berd (2011)

Even when they do not explicitly trade options, there is often a negative correlation between the returns of a hedge fund and market volatility, at least for “convergence” (mean-reverting) strategies: indeed, those strategies are essentially a short strangle $\mathcal{A}\backslash$. It is the opposite for momentum strategies. Measure this risk, diversify your strategies and, if it is not enough, add some explicit volatility hedging.

The feedback effect of hedging in portfolio optimization P. Henry-Labordère (2004)

Delta hedging can have a destabilizing market impact: to hedge a call, you buy when the market rises. This is the opposite of portfolio optimization, which suggests to buy when the price falls.

Circadian patterns and burstiness in human communication activity H.H. Jo et al. (2011)

Human activities (phone calls, tweets, etc.) show both periodicities (circadian, weekly) and bursts. The bursts can be modeled with a **cascading Poisson process**, *i.e.*, a Poisson process $(X_t)_t$ with intensity

$$\lambda_t = \lambda_0 + \lambda_1 \sum_{s < t} e^{-(t-s)/\tau} X_s.$$

The periodicity can be modeled with a change of time $Y_t = X_{T_t}$, with dT_t/dt periodic (and positive).

Robust pricing and hedging of double no-touch options A.M.G. Cox and J. Obłój (2009)

Given a set of calls and digital call prices, with no arbitrage opportunities (there are a few conditions to be satisfied: $C(0) = S_0$, $C(\infty) = 0$, $C'(0) \geq -1$, $D(k) = -C'(k)$), how much latitude do we have to extend the market model to include other options? In the case of double-no-touch options, one can devise a few super- and sub-hedges and show that the corresponding bounds are as tight as possible.

Conquering the Greeks in Monte Carlo: efficient calculation of the market sensitivities and hedge ratios of financial assets by direct numeric simulation M. Avellaneda and R. Gamba (2000)

When pricing options via Monte Carlo simulations, you do not get exactly the market prices; however, you can put weights on the sample paths to exactly recover them (use the maximum entropy principle to have uniquely defined weights). Those weighted paths can then be used to compute sensitivities (“Greeks”).

Vibrato Monte Carlo and the computation of Greeks S. Keegan (2008)

Option sensitivities (“greeks”) can be computed via

- Finite differences

$$\frac{\partial \text{Price}}{\partial \theta} = \frac{\text{Price}(\theta + \Delta\theta) - \text{Price}(\theta - \Delta\theta)}{2\Delta\theta}$$

- Likelihood ratio

$$\begin{aligned} \text{Price} &= E[\text{Payoff}] = \int \text{Payoff}(S) p(S) dS \\ \frac{\partial \text{Price}}{\partial \theta} &= \int \text{Payoff} \times \frac{\partial p}{\partial \theta} dS \\ &= \int \text{Payoff} \times \frac{\partial \log p}{\partial \theta} p dS \\ &= E \left[\text{Payoff} \times \frac{\partial \log p}{\partial \theta} \right] \end{aligned}$$

(but the variance is too high);

- Pathwise sensitivity

$$\frac{\partial \text{Price}}{\partial \theta} = E \left[\frac{\partial \text{Payoff}}{\partial \text{Spot}} \frac{\partial \text{Spot}_T}{\partial \theta} \right]$$

- Adjoint method: discretize the PDE

$$\begin{aligned} S_{n+1} &= S_n + a(S_n, t_n)h + b(S_n, t_n)Z_{n+1} \\ &= f_{n+1}(S_n, Z_{n+1}) \\ S_N &= f_N \circ \dots \circ f_1(S_0); \end{aligned}$$

we can compute $\partial S_N / \partial \theta$ from the f_i and the $\partial f_i / \partial \theta$ (not unlike the backpropagation algorithm, to compute the gradient of the loss function in a neural network), for $(Z_n)_n$ fixed; and then integrate Z out;

- Conditional expectation: simulate the price until the penultimate time step $S_{T-\Delta T}$, consider the gaussian distribution $S_T|S_{T-\Delta T} = S_T|Z_1, \dots, Z_{T-\Delta T}$, use the likelihood ratio method, and integrate Z out

$$\frac{\partial \text{Price}}{\partial \theta} = E_{Z_1, \dots, Z_{T-\Delta T}} E_{Z_T} \left[\text{Payoff} \frac{\partial \log p_{S_T|Z_1, \dots, Z_{T-\Delta T}}}{\partial \theta} \right]$$

- The Vibrato method decomposes this expression further.

Smoking adjoints: fast Monte Carlo Greeks

More details on the adjoint method to compute Greeks.

Web search queries can predict stock market volumes **I. Bordino et al. (2012)**

It could be useful as a warning signal, but they do not seem to check for confounding variables (e.g., the day of the week).

Pricing stocks with yardsticks and sentiments **S.M. Bustos et al. (2011)**

Another variant of the CAPM:

$$E[\text{return}_i] = \frac{\sigma(\text{return}_i)}{\sigma(\text{market without } i)} E[\text{market without } i]$$

rather than

$$E[\text{return}_i] = \frac{\text{Cov}(\text{return}_i, \text{market})}{\sigma^2(\text{market})} E[\text{market}].$$

Memory effects in stock price dynamics: evidence of technical trading **F. Garzarelli et al. (2011)**

Technical trading is thought to be a self-fulfilling prophecy; one can test how efficient it is as follows. A “support” (“resistance”) is a local minimum (maximum) in a window of width τ ticks; estimate the probability that prices rebound on (rather than cross) the latest support or resistance if they enter a band of width ε around them; fine-tune τ and ε to maximize this probability (and validate on a test dataset).

Improving recommendation quality by merging collaborative filtering and social relationships **P. De Meo et al. (2011)**

The user rating matrix R can be written as a product of the user preference matrix, and the item characteristic matrix, $R = PQ'$ (“non-negative matrix factorization”). The singular value decomposition (SVD) provides such a decomposition, but does not deal well with missing values. Tikhonov regularization can help:

$$(P, Q) = \text{Argmin} \|R - PQ'\|^2 + \lambda(\|P\|^2 + \|Q\|^2).$$

You can add another penalty

$$\mu \sum_x \sum_{\substack{\text{user } y \\ \text{neighbour of } x}} \|P_{x,\cdot} - P_{y,\cdot}\|$$

to account for social relationships.

Non-conservative diffusion and its application to social network analysis **R. Gosh et al. (2011)**

PageRank is the steady state probability distribution of a random walk on a network. The *alpha-centrality* can be defined in the same way, by using a non-conservative diffusion: the process does not move from one node to a single other node, but broadcasts to each neighbouring node, as an epidemic or a fad would do (the number of viruses or of infected nodes is not conserved) – this is not unlike the difference between deterministic and non-deterministic finite automata.

Information filtering via preferential diffusion **L. Lü and W. Liu (2011)**

Most recommendation algorithms are based on similarities between users or items or both. One could also use a diffusion process on the user-object bipartite graph.

Maximum entropy random walks in complex networks with limited information **R. Sinatra et al. (2011)**

You can construct a maximum entropy random walk on a graph using only local information: make the transition probabilities proportional to some power of the degree of the target node.

From brain to earth and climate systems: small-world interaction networks or not **A. Bialonski et al. (2011)**

The omnipresent “small world property” (the average shortest path length grows at most logarithmically with the number of nodes) could be an artefact of the way we sample real-world networks.

Rewiring world trade I: A binary network analysis **T. Squartini et al. (2011)**

Local properties (node degree) are sufficient to describe the international trade network (ITN, world trade web, WTW), when viewed as a non-weighted network, but not when viewed as a weighted (trade volume) network. To see it, you can build a family of randomized variants, by **local rewiring** and look at the distribution of some global quantities, such as degree correlation or clustering coefficient. There is a less computation-intensive method, using the maximum entropy probability distribution on the set of graphs satisfying the degree constraints.

The network of global corporate control
S. Vitali et al. (2011)

The presence of cycles in the cross-holding network of transnational corporations complicates the estimation of the control structure (who controls who). (It is not clear how they address the problem: they seem to just mitigate it.) The network has a bow tie structure: financial companies (left half) control transnational companies (knot), transnational companies have tight circular crossholding relations and control smaller companies (right half).

Propagation of cascades in complex networks: from supply chains to food webs
R.D. Smith (2011)

Modelling the bullwhip effect, on a graph (supply chain, food web), using birth-death processes.

The blogosphere as an excitable social medium: Richter's and Omori's law in media coverage
P. Klimek et al. (2011)

Word frequencies have statistical properties similar to earthquake energies, before and after an event.

$$\begin{aligned} w_i &\approx (t - t_0)^{-\alpha} && \text{before} \\ w_i &\approx (t_0 - t)^{-\beta} && \text{after} \end{aligned}$$

iSAX: indexing and mining terabyte-sized time series
J. Shieh and E. Keogh

To index large databases of time series, store the time series in a tree, whose nodes correspond to increasingly finer and/or more precise discretizations. This is not unlike wavelet coefficients, R-trees (used to index spatial databases) or k -d trees.

A decision-theoretic formulation of Fisher's approach to testing
K. Rice (2010)

Statistical tests can be interpreted in a decision-theoretic framework:

- A frequentist test minimizes the type II error rate (“inaccuracy”) under a constraint on the type I error rate (“embarrassment”);
- A bayesian test assigns a cost to type I and type II errors and minimizes the expected cost.

A gentle introduction to quantile regression for ecologists
B.S. Cade and B.R. Noon (2003)

Quantile regression addresses (and measures) heteroskedasticity. It can highlight changes in the distribution that are significant, but not visible on the mean. It allows you to focus on the tail, where interesting things happen. In ecology, it can help identify

limiting factors (corresponding to distribution truncation: $\bigwedge \mapsto \bigwedge_{\dots}$)

Machine learning markets
A. Storkey (2011)

There are many ways of aggregating statistical models (“ensemble methods”: boosting, mixtures, etc.). Here is another one, inspired by financial markets. Statistical models are agents in a market, each with a utility function, trading “bets” (options on the next data point). The price formation mechanism is similar to loopy belief propagation. Linear, logarithmic, exponential utility functions lead to the median, (weighted) mean or geometric mean of the models.

Value-at-risk in portfolio optimization: properties and computational approach
A.A. Gaivoronski and G. Pflug (2004)

The value-at-risk (VaR), computed from a set of scenarios, is neither smooth nor convex – there are local extrema everywhere. Since the VaR can be expressed as

$$\text{Max}_i^{k+1} f_i(x) \propto \sum_{\substack{I \subset [1, n] \\ |I|=k}} \sum_{i \in I} \mathbf{1}_{\{x: \forall i \in I f_i(x) \leq f_j(x) \\ \forall i \notin I f_i(x) \geq f_j(x)\}} f_i(x),$$

one can replace $\mathbf{1}_{\{x: f_i(x) \leq f_j(x)\}}$ with $\phi_\varepsilon(f_i(x) - f_j(x))$ for some smooth ϕ_ε approximating $\mathbf{1}_{\{x \leq 0\}}$. The resulting smoothed VaR (SVaR) is smooth and has fewer local extrema. (The authors do not seem to be worried by the size of the sum.)

Transaction costs, trading volume, and the liquidity premium
S. Gerhold (2011)

In presence of transaction costs, even if you want to hold a constant-weight portfolio, you cannot rebalance it continuously. This suboptimality corresponds to a liquidity premium:

liquidity premium \propto bid-ask spread \times share turnover.

(The liquidity premium is the difference in expected returns between a risky asset with transaction costs and a risky asset with the same utility but no transaction costs.)

Stochastic market efficiency
O. Peters and A. Adamou (2011)

In a stochastically efficient market, it is not possible to beat the market (in terms of expected growth rate) by holding the market portfolio and playing with the leverage: the optimal leverage, from the Kelly principle, is always 1. This notion is different from that of price efficiency, which is static (at one point in time).

How efficiency shapes market impact
J.D. Farmer et al. (2011)

Market impact is concave.

***Record statistics for biased random walks,
with an application to financial data***
G. Wergen et al. (2011)

Asymptotic behaviour of the record rate $P_n = P[X_n > \sup_{k < n} X_k]$ for a random walk with drift X .

Quantitative Trading
E.P. Chan (2009)

Elementary and superficial book on how to become an independent quantitative trader – in short: do not forget to backtest your strategies, with clean, survivor-bias-free data. The book ends with a list of possible strategies (earnings or macro announcements; gold vs gold miners pairs trading; Fama-French factor model; calendar trades: January effect, gasoline May futures in April, natural gas June futures from January to April) and a frighteningly incorrect interpretation of the p -value of a cointegration test.

Financial Risk Forecasting
J. Danielsson (Wiley 2011)

Clear book on the value at risk (VaR), at a very elementary level.

***Reconstruction of financial networks
for robust estimation of systemic risk***
I. Mastromatteo (2012)

The credit network between banks can be described by a liability matrix, L_{ij} indicating the funds lent by bank j to bank i .

Only some entries (those above a regulatory threshold, reported to a regulator) and the aggregate values (total debt and credit, from the balance sheet) are known, and the matrix is often reconstructed using a maximum entropy estimator, *i.e.*, by maximizing the Kullback-Leibler divergence between L and a uniform distribution:

$$\sum_{i,j} L_{ij} \log \frac{L_{ij}}{Q}$$

But this assumes that the credit relations are as evenly spread out as possible: the real credit network is more heterogeneous, the real liability matrix is sparse.

One can try to maximize the sparsity (number of zero entries) under those constraints, and then compute the corresponding maximum entropy matrix.

***Mean-variance portfolio optimization
when means and covariances are unknown***
T.L. Lai et al. (2011)

Mean-variance portfolio optimization assumes that the expected returns μ and variance matrix V are known: often, some estimators (sample estimators, factor models, shrinkage, Bayes, Black-Litterman, etc.) are simply plugged into the optimization problem. This 2-step procedure (estimation, then optimization) is suboptimal. One can replace the optimization problem

$$\text{Maximize } E[w'r_{n+1}|\mu, V] - \lambda \text{Var}[w'r_{n+1}|\mu, V]$$

with a stochastic optimization problem

$$\text{Maximize } E[w'r_{n+1}|r_1, \dots, r_n] - \lambda \text{Var}[w'r_{n+1}|r_1, \dots]$$

The corresponding “non-parametric empirical Bayes” frontier is higher than the shrinkage or bootstrap ones.

***Risk minimization in stochastic volatility
models: model risk and empirical performance***
R. Poulsen et al. (2009)

In a complete market with a risk-free asset B and a risky asset S , any European option X can be replicated with a self-financing strategy (α, β) .

$$\begin{aligned} X_t &= \alpha_t B_t + \beta_t S_t \\ dX_t &= \alpha_t dB_t + \beta_t dS_t \end{aligned}$$

If the market is not complete (e.g., a stochastic volatility model), you can still build a replicating strategy, but it will not be self-financing:

$$\text{Cost}_t = \int dX_t - \int \alpha_t dB_t - \int \beta_t dS_t$$

is not constant. Some people just use a strategy that would be self-financing in a complete market, delta-hedging, and hope for the best. Alternatively, one could try to minimize some measure of risk associated to this cost, e.g., $E[(\text{Cost}_T - \text{Cost}_t)^2 | \mathcal{F}_t]$. The problem need not have a global solution, but a local extremum is often sufficient.

***A fuzzy pay-off method
for real option valuation***
A. Collan et al. (2009)

A *fuzzy subset* A of X is a map $\mu : X \rightarrow [0, 1]$, interpreted as $\mu(x) = P(x \in A)$ (it corresponds to a probability distribution on $\mathcal{P}(X)$ with the property that $(x \in A) \perp (y \in B)$ whenever $x \neq y$). For instance, $\mu(x) = \delta_{x, x_0}$ corresponds to a single point and $\underline{\Delta}$ or $\overline{\Delta}$ are *fuzzy numbers*. They can be used, instead of probability distributions, as the payoff of an investment, when computing its value (via MCMC) as the risk-neutral expected present value.

***The US stock market leads
the federal funds rate and treasury bond yields***
K. Guo et al. (2011)

To find which, of two time series x and y , leads the other, find a path in their **recurrence plot** (the matrix of squared distances $d_{s,t} = (x_t - y_s)^2$) from one corner to the other, that minimizes the sum of squared distances. The algorithm can be made more robust to noise by replacing the dynamic programming equation

$$C_{s,t} = d_{s,t} + \text{Min}\{C_{s-1,t}, C_{s-1,t-1}, C_{s,t-1}\}$$

with

$$G_{s,t} = (G_{s-1,t} + G_{s-1,t-1} + G_{s,t-1}) \exp(-d_{s,t}/T)$$

leading to the “thermal optimal path” (T can be interpreted as a temperature).

Econophysics – complex correlations and trend switchings in financial time series
T. Preis (2011)

Pattern conformity measures how well we can predict the evolution of a time series for the next Δt^+ instants from the previous Δt^- instants, using pattern matching on previous intervals of size Δt^- (the patterns are normalized with their range, to account for changes in volatility). It can be normalized (in a complicated way) and plotted against Δt^- and Δt^+ . It is a non-linear measure of autocorrelation.

Pattern matching can also be used to study trends and crashes, on various time scales. Consider the time series between two local extrema (extrema on centered intervals of size $2\Delta t$), reparametrize them so that the time varies between 0 and 1, find matching time series, look at the volume or intertrade time time series for those matching price time series, and average them.

Switching processes in financial markets T. Preis et al.(2011)

Shorter article on the same subject.

Dynamic generalized Hurst exponent as a tool to monitor unstable periods in financial time series
R. Morales et al. (2011)

“Scaling behaviour” refers to the relation between the volatility of the returns on some asset and the horizon τ over which it is computed. The Hurst exponent H satisfies

$$\text{Volatility} \propto \text{Horizon}^H.$$

More generally, one can look at other moments:

$$q\text{th moment} \propto \text{Horizon}^{qH(q)}.$$

If the **generalized Hurst exponent** $H(q)$ depends on q , the times series is said to be **multifractal**.

The generalized Hurst exponent $H(1)$ can be computed on a moving window, with exponentially decreasing weights, and used as a bubble detector.

Similarly, one can study the tail of the returns distribution:

$$P[\log\text{-returns} \geq r] \underset{n \rightarrow \infty}{\propto} r^{-\alpha}.$$

Is there a bubble on LinkedIn’s stock price?
R. Jarrow et al. (2011)

One can apparently detect bubbles by checking if the squared volatility increases more than linearly with the price:

$$\int_a^\infty \frac{\text{Price}}{\text{Volatility}^2} < \infty.$$

(If this condition is satisfied, the price process is only a local martingale under the risk-free measure.)

How to detect an asset bubble
R. Jarrow et al. (2011)

More details about the (kernel-based) variance estimators used.

Why is order flow so persistent?
B. Tóth et al. (2011)

The **order flow** (signed traded volume, the sign indicating whether the trade was initiated by the seller or the buyer), computed from transaction data, is persistent over several days, and its autocorrelation can be decomposed into “order splitting” and herding components (you need to know which performed each transaction): order-splitting dominates, and anti-herding (from market-makers) becomes visible at longer time scales.

Investment volatility: a critique of standard beta estimation and a simple way forward
C. Tofallis

Should the usual beta

$$\begin{aligned} \beta &= \frac{\text{Cov}(\text{Portfolio}, \text{Market})}{\text{Var Market}} \\ &= \text{Cor}(\text{Portfolio}, \text{Market}) \times \frac{\text{Sd}(\text{Portfolio})}{\text{Sd Market}} \end{aligned}$$

be replaced by the simpler and more stable

$$\text{sign}(\text{Cor}(\text{Portfolio}, \text{Market})) \times \frac{\text{Sd}(\text{Portfolio})}{\text{Sd Market}}?$$

It corresponds to the slope of a line between the portfolio-vs-market and market-vs-portfolio regression lines, and minimizes the sum of the products of the deviations in the horizontal and vertical directions (triangle areas).

Hedging the smirk
D.S. Bates (2005)

Some of the greeks (Δ , Γ) can be computed without any model, only relying on the fact that option prices are homogeneous (of degree 1) in the underlying and the strike (actually, some models do not satisfy this property): indeed, from Euler’s theorem,

$$\text{Price} = \text{Spot} \frac{\partial \text{Price}}{\partial \text{Spot}} + \text{Strike} \frac{\partial \text{Price}}{\partial \text{Strike}}.$$

(For $\Gamma = \partial^2 \text{Price} / \partial \text{Spot}^2$, use the fact that $\partial \text{Price} / \partial \text{Spot}$ and $\partial \text{Price} / \partial \text{Strike}$ are themselves homogeneous.)

Since the Black-Scholes implied volatility fluctuates much less than the option prices (which move with the underlying), it can be used instead of the price, from

$$\begin{aligned} \text{Price} &= \text{BS}(\text{Strike}, \text{Volatility}) \\ \frac{\partial \text{Price}}{\partial \text{Strike}} &= \frac{\partial \text{BS}}{\partial \text{Strike}} + \frac{\partial \text{BS}}{\partial \text{Volatility}} \frac{\partial \text{Volatility}}{\partial \text{Strike}} \end{aligned}$$

***On the assessment of Monte Carlo error
in simulation-based statistical analyses***
E. Koehler et al. (2009)

Monte Carlo simulations provide noisy estimators, but many studies do not report the error coming from the finiteness of the sample – and many use a frighteningly small number of replications. To estimate this Monte Carlo error (MCE), plot the estimate versus the number of samples (ideally for several chains); bootstrap the Monte Carlo samples you have (bootstrap after bootstrap); you can also use the fact that $\text{MCE} \propto R^{-1/2}$ to justify the number of replications you chose.

***Factor analysis for multiple testing (FAMT):
an R package for large-scale significance
testing under dependence***
D. Causeur et al. (JSS 2011)

Knowledge of the dependency structure of the data can help improve the correction for multiple testing (FDR, etc.), which usually assumes the tests are independent.

topicmodels: an R package for fitting models
B. Grün and K. Hornik (JSS 2011)

Latent Dirichlet allocation (LDA) models the occurrence of words as follows: for each topic, choose a word distribution (Dirichlet prior – the Dirichlet distribution is a distribution on $[\sum_i x_i = 1, \forall i x_i \geq 1]$); for each text, choose the distribution of the topics present in the text (another Dirichlet); to generate each word, select a topic from the topic distribution, and select a word from the word distribution of that topic. The correlated topic model (CTM) also allows for dependence between topics. Fit the model with Gibbs simulations or variational expectation maximization (VEM). In R, check the `lda` and `topicmodels` packages (Jags is more general, but slower).

***Consistently weighted measures
for complex network topologies***
J. Heitzig et al. (2011)

One often considers small finite “aggregated” approximations of large or infinite graphs, for instance, a finite mesh for the brain, finite approximations of climate networks whose vertices are points on the Earth and with an edge between two points if the the time series of (say) temperatures at those points are significantly correlated, network of IP address ranges when we are really interested in users, network of households to study people, of countries instead of consumers or companies, etc. Those aggregations or discretizations can be biased: for instance, a latitude-longitude mesh of the Earth gives undue importance to the poles. Graph-theoretic statistics (centrality, betweenness, etc.) have to be corrected for this bias: one can usually define weighted variants of those statistics by looking at how

they change under node splitting.

***Phase transition in the detection of modules
in sparse networks***
A. Decelle et al. (2011)

The formation of communities, in a graph, can be modelled with stochastic blocks: start with a set of nodes; assign each of the i to a group t_i ; add an edge between two nodes i and j with a probability proportional to the affinity $c(t_i, t_j)$ between their groups. The parameters of the model (number of groups, size of each group, edge probability) can be estimated via Monte Carlo simulation but, in the case of *sparse networks* ($O(N)$ edges in a network of size N , in particular, the graph is locally tree-like), belief propagation (BP, sometimes also called the “cavity method”) gives an asymptotically exact result in linear time.

***Infinitesimal methods
in Mathematical economics***
R.M. Anderson (2008)

Non-standard analysis for economists: ultrafilters, ultraproducts, hyperreal numbers, Loeb measure.

Programming a robotic car
S. Thrun (2011)

Presentation of a few algorithms you could use to build a self-driving car.

To estimate the position of a vehicle, you can start with an initial estimate (a probability distribution) and multiply it with the estimate from the measurement you have (this is the Bayes rule); when the vehicle moves, convolve this distribution with your estimate of the movement (this is the law of total probabilities). Iterate as the vehicle moves and you receive new measurements. The distribution of the location of the robot can be described by a discrete probability distribution (histogram filter), a sample of possible positions (particle filter) or a Gaussian distribution (Kalman filter – to understand where the Kalman filter formulas come from, just write the product and the convolution, first in dimension 1, then in general). The state space used includes position, orientation, and speed.

To plan the path the robot will follow, you can divide the world into a grid (or represent the possible paths as a graph, not necessarily a lattice) and use breadth-first search (from the starting point), dynamic programming (same idea, but from the goal) or the A* algorithm (similar to breadth-first search, but using a heuristic function that gives a lower bound on the distance, e.g., the Euclidian distance, ignoring obstacles). In the case of a car, the state space includes both position and orientation. You may want to smooth the path with an L^2 penalty: given the $(x_i)_i$, find $(y_i)_i$ to minimize $\sum_i \|x_i - y_i\|^2 + \lambda \sum_i \|y_i - y_{i-1}\|^2$.

The steering angle is often determined by PID control: a linear combination of the error (to put the robot back on track), its derivative (to avoid overshooting) and its integral (the total error so far, to take care of any systematic bias).

You can build a map using all the information accumulated so far (graph SLAM algorithm): the posterior distribution is a product of gaussians, but by expanding it, we end up with a sum of squares – getting to the estimate of the path of the vehicle and the position of the landmarks used is just a matrix inversion away.

***Constant-Q transform toolbox
for music processing***

C. Schörkhuber and A. Klapuri (2010)

On the implementation of the constant Q-transform (CQT), a wavelet transform whose frequency bins are geometrically spaced (12 to 96 bins per octave – the time-resolution of the bins is not constant, it depends on the frequency), well-suited to human music and auditory perception.

***Complex dynamics
in learning complicated games***

T. Galla and J.D. Farmer (2011)

Game-theoretic notions of equilibrium are not useful for complicated games such as financial markets, chess or go. If players learn their strategy via **reinforcement learning**, they oscillate along a chaotic attractor. While reinforcement learning may faithfully describe how people learn, it is inadequate for complicated games.

***Clarifications to questions and criticisms
on the Johansen-Ledoit-Sornette bubble model***

D. Sornette et al. (2011)

Review article on the log-periodic power law bubble model, with common misconceptions and implementation problems: it only models the expected log-price (not the log-price: there is a brownian motion in it); you should use the log-price, not the price; there are constraints on some parameters ($m < 1$, etc.); it only detects endogenous bubbles, not exogenous crashes; bubbles need not end with a crash, they can transition smoothly to another regime; the model is very sensitive to the start of the time window: try several, and look at the distribution of the results; use robust optimization algorithms (taboo search, genetic algorithms, etc.) and look at ensembles of solutions – there are many local extrema; be suspicious of solutions at the boundary of the search space; test your implementation on synthetic data, e.g., the fitted model plus AR(1) noise or reshuffled residuals – this gives confidence intervals for the critical time and tells you how robust to noise the model is; the output should be a distribution (an ensemble) of critical times, not a single value.

***A stable and robust calibration scheme
of the log-periodic power law model***

V. Filimonov and D. Sornette (2011)

Fitting the 7-parameter log-periodic power law (LPPL) bubble model

$$E[\ln \text{price}] = A + (t_c - c)^m (B + C \cos(\omega \ln(t_c - t) - \phi))$$

is not a 7-dimensional optimization problem: since 3 of the parameters are linear, you can vary the other 4 and compute those 3 via linear regression. Furthermore, by expanding the cosine, one can replace (C, ϕ) with $(C \cos \phi, C \sin \phi)$: there are then 4 linear parameters, and the quasi-periodic patterns in the cost function that were plaguing the optimization disappear.

***Detection of crashes and rebounds
in major equity markets***

W. Yan et al.

The LPPL model predicts the end of a bubble, but does not forecast what happens after: it could be a crash or just a regime change. For this, use pattern recognition (on the model parameters) and classification trees.

Role of diversification risk in financial bubbles

W. Yan et al. (2011)

The 3-factor Fama-French model (market, size, growth vs value) is sometimes replaced by a simpler 2-factor model, including the market and the **Zipf factor**, the difference in returns between the market portfolio and the equal-weighted portfolio. This factor can be added to the LPPL model.

$$E \left[\log \text{price} - \gamma \log \frac{\text{price}}{\text{equal-weighted price}} \right] = A + (t_c - c)^m (B + C \cos(\omega \ln(t_c - t) - \phi))$$

***Inferring fundamental value and crash
nonlinearity from bubble calibration***

W. Yan et al. (2010)

In the LPPL model, replace $\log p$ with $(p - p_0)^\gamma$, where p_0 is the fundamental value and γ the market over- or under-reaction. You can use statistical tests to compare this model with the LPPL one.

High frequency volatility
R. Almgren (2009)

Review of realized volatility estimators: $\hat{Q} = \sum (x_j - x_{j-1})^2$ is contaminated by microstructure noise – sub-sample, shift the window, and average.

**On covariance estimation
of non-synchronously observed
diffusion processes**

T. Hayashi and N. Yoshida (2005)

Given two diffusions x and y , observed at times t_1, \dots, t_n and u_1, \dots, u_m respectively,

$$\sum_{i,j} (x_{t_i} - x_{t_{i-1}})(y_{u_j} - y_{u_{j-1}}) 1_{[t_{i-1}, t_i] \cap [u_{j-1}, u_j] \neq \emptyset}$$

is a consistent estimator of their covariance

$$\langle x, y \rangle_{[0,T]} = \int_0^T \sigma_1 \sigma_2 \rho dt.$$

The corresponding correlation estimator is also consistent.

**A tale of two time scales:
determining integrated volatility
with noisy high-frequency data**

L. Zhang et al.

Observed high-frequency log-prices Y are contaminated with market microstructure noise ε :

$$Y_t = X_t + \varepsilon_t \\ dX_t = \mu_t dt + \sigma_t dB_t.$$

The integrated volatility $\langle X, X \rangle = \int_0^T \sigma_t^2 dt$ can be estimated with the realized volatility, *i.e.*, by summing the squared returns, either all of them, of those on a subgrid, to reduce the bias (Epps effect) introduced by the noise ε . Combining those estimators for two scales,

$$\widehat{\langle X, X \rangle} = [Y, Y]^{(n,k)} - 2 \frac{n-k+1}{nk} [Y, Y]^{(n,1)} \\ [Y, Y]^{(n,k)} = \frac{1}{k} \sum_{i=k}^n (Y_i - Y_{i-k})^2$$

is more efficient.

**Efficient estimation of stochastic volatility
under noise observations:
a multi-scale approach**
L. Zhang (2005)

Or more than two scales:

$$\widehat{\langle X, X \rangle} = \sum_k \alpha_k [Y, Y]^{(n,k)}.$$

**Estimating covariation: Epps effect,
microstructure noise**
L. Zhang (2009)

The previous-tick estimator of covariance (for asynchronous time series) is increasingly biased as the frequency increases (Epps effect): if is affected by discretization, non-synchronicity and microstructure noise. One can compute the optimal sampling frequency to minimize the mean square error (MSE) of the estimator, but 2-scale previous-tick estimators can help reduce the influence of microstructure noise even further.

**Assessing the performance of different
volatility estimators: a Monte Carlo analysis**
Á. Cartea and D. Karyampas (2012)

Volatility is often estimated from high-frequency time series by downsampling the data to remove the microstructure noise. Instead, one can model the price as a random walk (unobserved fair price), with added gaussian noise, and use a maximum-likelihood estimator (it can be implemented with a Kalman filter). Better, one can first identify and remove jumps.

**Jumps in financial markets:
a new non-parametric test and jump dynamics**
S.S. Lee and P.A. Mykland (2007)

To detect jumps, compare (look at the ratio of) the log-returns and the realized bipower variation (an estimator of the instantaneous volatility, consistent even in the presence of jumps)

$$\hat{\sigma}^2 = \frac{1}{k-2} \sum_j \left| \log \frac{S_{t_j}}{S_{t_{j-1}}} \right| \left| \log \frac{S_{t_{j-1}}}{S_{t_{j-2}}} \right|.$$

The test statistic is asymptotically gaussian in the absence of jumps, and a sum of a gaussian and (a random variable distributes as) the jump size in presence of jumps.

**Detecting jumps
from Lévy jump diffusion processes**
S.S. Lee and J. Hannig

To detect Lévy jumps (and not only large, Poisson jumps), replace the bipower variation with the truncated power variation

$$\hat{\sigma}^2 = \frac{1}{k} \sum_j \left(\log \frac{S_{t_j}}{S_{t_{j-1}}} \right)^2 1_{|\log S_{t_j}/S_{t_{j-1}}| \leq g}$$

(small Lévy jumps would bias the bipower variation). To test for small Lévy jumps, one can look for an excess of unusually large returns, when compared with the gaussian distribution. Those jumps cannot be identified (we can see that there are more large returns than expected, but we cannot say which come from the gaussian distribution and which are jumps), but one can compute a “belief” that a large return comes from a small Lévy jump.

Small, previously undetected Lévy jumps in stock prices can accumulate into previously puzzling detectable jumps in indices.

***Beta-arbitrage strategies:
when do they work, and why?***
T. Berrada et al. (2011)

A strategy long in low-beta stocks and short in high-beta stocks outperforms the market, in contradiction with the CAPM model. This can be explained with *stochastic portfolio theory*, i.e., the assumption that the market never becomes concentrated in a single stock (beta arbitrage is a form of diversity investing). The fact that some investors are leverage-constrained amplifies this phenomenon.

***A proof of the optimality
of volatility weighting over time***
W.G. Hallerbach (2012)

When investing in a 2-asset portfolio (one risky, one risk-free asset), adjust the weights so that volatility remains constant (use the implied volatility, e.g., the VSTOXX index, as a volatility forecast).

***Risk-based asset allocation:
a new answer to an old question?***
W. Lee (2010)

Review of those trendy risk-based approaches to portfolio construction: equally-weighted portfolio (very sensitive to the choice of the universe); mean variance portfolio (or equal marginal contributions to risk (MCTR)); most diversified portfolio ($\sum w_i \sigma_i / \sigma_{\text{portfolio}}$ maximal – but is only a differential diversification measure); equal risk contribution ($w_i \text{MCTR}_i$, also called parity portfolio: the problem is not convex and numerically challenging).

Liquidity of corporate bonds
J. Bao et al. (2008)

Illiquidity creates transitory price movements, and a negative autocovariance in price changes (at the transaction level). The opposite γ of that covariance can be used as a measure of illiquidity. If the bid-ask bounce is the only source of transitory price movements, the bid-ask spread is $2\sqrt{\gamma}$.

***Portfolio stochastic dominance
and bank liquidity risk***
S. Pagratis and N. Topalogou (2012)

A random variable X stochastically dominates a random variable Y if

$$\forall a \quad P(X > a) \geq P(Y > a)$$

or, equivalently,

$$\forall a \quad F_X(a) \leq F_Y(a).$$

The mean-variance portfolio optimization problem can be generalized by replacing mean-variance dominance with stochastic dominance (two gaussian random variables are stochastically comparable iff they have the same variance, and the order is given by their means). [I remain unconvinced: stochastic dominance is very, very rare: it is a partial order, and you could easily end up in a situation in which all or most portfolios are non-dominated – the efficient frontier would be too thick to be useful.] The portfolio optimization problem becomes: find λ to maximize

$$\max_z (F_0(z) - F_\lambda(z))$$

subject to

$$\forall z \quad F_0(z) \geq F_\lambda(z).$$

The article uses these notions to check if the balance sheet of banks (the assets are the loans and securities; the liabilities are the deposits, repos and off-balance-sheet commitments; the equity is the difference) is optimal, using the empirical cdf of the assets and liabilities.

***Anomalous price impact and the critical
nature of liquidity in financial markets***
B. Tóth et al. (2011)

Model to explain the square root in the price impact of large orders,

$$\Delta \text{price} \propto \sqrt{\text{size}},$$

which contradicts Kyle's linear model, based on the latent order book (for small orders, empirical evidence suggests $\text{size}^{0.2}$ or $\log(\text{size})$).

***A momentum trading strategy based on the low
frequency component of the exchange rate***
R.D.F. Harris and F. Yilmaz (2008)

Momentum trading strategies (monthly FX data) are often based on moving averages: this is suboptimal (newer observations should have more weight) and there is no objective way of choosing the parameters (it is either subjective or sample-specific). Instead, consider using kernel regression (sometimes called Savitzky-Golay filter, in digital signal processing (DSP)) or DSP analogues such as the **Hodrick and Prescott filter**

$$\text{Argmin} \sum_t (S_t - S_t^*)^2 + \lambda \sum_t (\Delta S_t^* - \Delta S_{t-1}^*)^2$$

(the first term ensures that S^* is close to the signal S , the second ensures smoothness) and just look at the slope of the smoothed signal.

Collaborative filtering with temporal dynamics
Y. Koren (KDD 2009)

Application of factor models (used to measure risk in finance) to recommender systems (Netflix, etc.).

Can we learn to beat the best stock
A. Borodin et al. (2004)

Cover's universal portfolios use frequent rebalancing to achieve large returns, especially if stock prices are mean-reverting, *i.e.*, if they have are negatively autocorrelated. They can be improved by exploiting cross-correlation.

Fiducial inference and generalizations
J. Hennig et al. (2009)

Fiducial inference is bayesian statistics with no prior: the model

$$\text{data} = f(\text{parameters}, \text{innovations})$$

can be rewritten as

$$\text{parameters} = f^{-1}(\text{data}, \text{innovations}).$$

If you observe the data and know the distribution of the innovations, you have a posterior distribution for the parameters. (In general, f is not invertible, which complicates a lot of things.)

p-value precision and reproducibility
D.D. Boos and A. Stefanski (2011)

We tend to give a confidence interval to everything: why not for p -values, as well? A look at their standard deviations, bootstrap confidence intervals, and probability of reproducibility $P(p_{\text{new}} \leq 0.05 | p_{\text{old}} \leq 0.05)$ suggests that they are very imprecise: the order of magnitude (approximately, the stars displayed by most statistical software) is the best we can hope for.

Exploring complex networks
via topological embedding on surfaces
T. Aste et al. (2011)

Planar graphs are simpler than arbitrary graphs. Instead of trying to embed graphs in the plane, one can try to embed them in surfaces of genus g (for the lowest possible g). The maximal n -vertex graphs embeddable in a genus g surface can be described from two elementary moves:

Rationality, irrationality and escalating
behavior in online auctions
F. Radicchi et al. (2011)

Lowest unique bid auctions (people bid, much less than the price of the object; pay each time, much (100 times) more than the bid; are told if their bid is the highest or not; and the lowest unique bid wins) are all-pay auctions, lotteries decided by the outcome of a minority game: they are only profitable to the auctioneers.

Models for the impact of all order book events
Z. Eisler et al. (2011)

The mid-point price is a linear superposition of the impact of the previous prices, with decreasing weights (compute those weights from the autocorrelation function). This simplistic model can be improved by allowing for volume-dependent impact, different order types (market or limit), and weights that vary slowly with time.

Identification of clusters of investors
from their real trading activity in the market
M. Tumminello et al. (2011)

Investing styles (corresponding to the informed vs non-informed or fundamental vs technical oppositions in most agent-based market models) can be identified from transaction data as follows. Build a bipartite network, whose nodes are investors and days, with three types of edges, corresponding to “buy”, “sell” and “buy and sell later in the same day”; project it to a network of investors, with 9 types of edges, and weights corresponding to the number of days; to account for different trading activities, truncate the graph to a **statistically validated network**: compute the statistical significance of each edge, with a p -value, testing if the two investors act independently (given the number of orders of each type they send in the sample), adjusted for multiple tests (Bonferroni or FDR); finally, apply some community-detection algorithm such as infomap.

Life time of correlation between stock prices
on established and emerging markets
A. Buda (2010)

To find the “best” window size to compute a correlation matrix (between stock returns), check how the following quantities change: average number of consecutive days with a correlation above 0.5 (for a pair of stocks, or average for all pairs in a market); time in which half the connections in the minimum spanning tree (MST) have disappeared; average correlation (Epps effect).

A contextual risk model
for the Ellsberg paradox
D. Aerts and S. Sozzo

Quantum interpretation of knightian uncertainty (the future is random, but you do not know from which distribution it is drawn): quantum superposition corresponds to the use of mixture distributions as priors.

Asymmetric random matrices:
what do we need them for?
S. Drożdż et al. (2011)

Random matrix theory (RMT) can be generalized to study the distribution of the diagonal and off-diagonal elements, and the (complex-conjugate) eigenvalues of cross-correlation matrices $\text{Cor}(X, Y)$. The null hypothesis is still that (X, Y) is gaussian iid [I ini-

tially thought, from the title, that they were studying the eigenvalues of $\text{Cor}(X)$ where the distribution of (X_1, \dots, X_n) under H_0 is no longer invariant under the action of \mathfrak{S}_n .

Applications include the study of time series, $X = (X_1, \dots, X_n)$, $Y = (Y_1, \dots, Y_n)$ – but I am sceptical about the effect of autocorrelation (or serial dependence in general): with real-world data, we already know that H_0 is false.

***Endogenous bubbles in derivative markets:
the risk neutral valuation paradox***
A.F. Maccioni (2011)

In an incomplete market, the presence of risk-neutral investors (technical traders) lets the prices stray far away from the fundamental value of the assets. creating endogenous depressions or bubbles; when those traders disappear (or stop trading, for an instant), prices violently bounce back to the fundamental value.

Calculation of aggregate loss distributions
P.V. Shevchenko (2010)

(Good, simple introduction to Fourier methods for numeric computations in statistics.)

A **loss distribution** is the distribution of

$$Z = X_1 + \dots + X_N$$

where the X_i are iid and N is a random variable; we are interested in their value-at-risk (VaR) and expected shortfall (ES).

Analytically, it can be computed via convolution or characteristic functions

$$\begin{aligned} H(z) &= \sum_{k \geq 0} p_k F^{(k)*}(z) \\ \chi(t) &= \psi(\phi(t)) \\ h(z) &= \frac{2}{\pi} \int_0^\infty \text{Re}[\chi(t)] \cos(tz) dt \\ H(z) &= \frac{2}{\pi} \int_0^\infty \text{Re}[\chi(t)] \frac{\sin(tz)}{t} dt \end{aligned}$$

where H is the cdf of Z , F that of X , p_k the probability mass function of N , χ and ϕ the characteristic functions of Z and X , ψ the probability generating function of N . The moments of the compound distribution Z can be explicitly computed from those of X and N (to derive the formulas, use the characteristic functions).

Monte Carlo simulation is the easiest (and slowest) way of computing the VaR or ES of the compound loss (do not forget to estimate the error of those computations).

If the individual losses X_i have a discrete distribution, the distribution of the compound loss Z can be obtained recursively, in $O(n^3)$ time. If the probability mass function $p_n = P(N = n)$ satisfies

$$p_n = \left(a + \frac{b}{n}\right) p_{n-1}$$

for $n \geq 1$ (there are generalizations for $n \geq 2$), it can be computed in $O(n^2)$ (**Panjer recursion**). Discretization and underflow can pose problem. Without discretizing the losses, the Panjer condition gives an integral equation satisfied by h .

With the fast Fourier transform (FFT), one can compute the pdf h of the compound loss from its characteristic function χ . As with Panjer recursion, this still requires discrete losses. Aliasing error (artefacts at the boundary of the loss distribution) can be reduced by **tilting** the distribution, *i.e.*, by replacing $f(x)$ with $e^{-\theta x} f(x)$.

For the cdf H , one can use numerical integration methods (H can be expressed as an integral involving the characteristic function χ : there is no need to compute the pdf h), exploiting the oscillatory behaviour of the integrand.

Since the moments of the compound distribution are known, you can approximate the distribution with a simpler one (Gaussian, translated gamma) with the same moments.

The asymptotic expansion

$$1 - H(z) \underset{z \rightarrow \infty}{\sim} E[N](1 - F(z))$$

provides a VaR estimator.

***Index cohesive force analysis
reveals that the US market became
prone to systemic collapses in 2002***
D.Y. Kenett et al. (2011)

The sample variance or correlation matrix of stock returns changes with time. To study those changes, you can look at the eigenvalues, their entropy, the average correlation, the average **partial correlation** (correlation without the market) – the ICF is the ratio correlation over partial correlation. A rasterplot of the average (partial) correlation by stock can help identify regime changes: the partial correlation became negligible in 2002.

Detecting novel associations in large data sets
D.N. Reshef et al. (2011)

The MIC (maximal information coefficient) is a measure of dependence defined (computationally) as follows. Divide the data into an $n \times m$ grid, discretize the data along this grid, compute the mutual information,

normalize it (divide by $\log \text{Min}(x, y)$); find the division that maximizes the mutual information; repeat for all values of n, m with $nm \leq N^{0.6}$ (where N is the number of observations). The MIC is the maximum value in this matrix.

It can be interpreted as a generalized correlation coefficient and can identify non-functional relations (a circle, etc.), but is misled by some patterns – for instance, both a line and a 2×2 checkerboard pattern give the maximum value. (Also, its power is apparently much lower than that of the correlation distance.)

From the matrix M of mutual information, one can derive other measures: $\text{Max}|M_{ij} - M_{ji}|$ measures monotonicity, $\text{MIC} - \text{Cor}^2$ measures non-linearity.

Brownian distance covariance **G.J. Székely and M.L. Rizzo (2009)**

The distance covariance between two random variables X and Y with characteristic functions ϕ_X and ϕ_Y is

$$\int w(x, y) |\phi_{X,Y} - \phi_X \phi_Y|$$

with $w(x, y) \propto |x|^{-p-1} |y|^{-q-1}$ (p and q are the dimensions of X and Y).

If U is a stochastic process on \mathbf{R} , let $X_U = U(X) - E[U(X)|U]$ be the U -centered version of X ; in particular $X_{\text{id}} = X - E[X]$. The **brownian covariance** is defined by

$$\text{Cov}_{W,W'}^2(X, Y) = E[X_W X'_W Y_{W'} Y'_{W'}]$$

where X' and Y' are iid copies of X and Y , and W, W' are independent brownian motions. It coincides with the distance covariance. The result can be generalized to Lévy fractional brownian motions of Hurst index $H \in (0, 1)$ and $w(x, y) \propto |x|^{-p-2H} |y|^{-q-2H}$.

Leverage aversion and risk parity **A. Asness et al. (2011)**

There are many reference portfolios: capitalization-weighted (the common approximation of the market portfolio), equal-weights, fundamental weights (since the market portfolio overweights overvalued stocks, one can try to replace the stock price with some “fair value” derived from the balance sheet – it is an accounting-motivated way of shrinking the capitalization-weighted portfolio towards the equal-weighted one), minimum variance, tangent (the CAPM theorem claims it is the market portfolio). The risk parity portfolio is yet another (robust) approximation of the elusive market portfolio, using equal contributions to risk. This is theoretically justified if some investors are averse to leverage: they would overweight risky assets (stocks) to achieve higher returns, increasing demand for riskier assets and lowering their price. Historically, a 170% bond, 30% stock portfolio performed better than the market portfolio and the classical 60% bond, 40% stock one.

Counter-point to risk parity critiques **E. Peters (2010)**

A few caveats on the implementation of risk parity strategies: avoid leveraging assets that are already internally leveraged (e.g., stocks, whose debt/equity ratio is often 2/1); hedge inflation; do no leverage asset classes with no expected returns, such as commodities – only use them to hedge inflation.

The hidden risks of risk parity portfolios **B. Inker (2010)**

Remember that the standard deviation does not measure all the risk, especially for assets with skewed returns – and leverage increases the danger.

Financial Theory **J. Geanakoplos** **Yale (2009)**

Some universities have started to put some of their undergraduate (*i.e.*, elementary) courses online: this one is an introduction to finance, describing models, examples or experiments to illustrate general economic and financial facts.

Economy

Many price-setting mechanisms (seller-derived (supermarket), haggling, price regulation, *tatonnement*, *pit* (like haggling, but with several buyers and sellers), bid/ask (as in computer-trading), specialist, etc.) lead to the same price (this is the law of one price), the price predicted by the law of supply and demand. This can be seen in the following experiment: take 10 students, 5 buyers and 5 sellers, assign a preferred price to each, ask them to trade using the “pit” method (shout the desired price, above their preferred price for seller, below for buyers, and modify your offer until you find a counterparty). Even if it were theoretically possible for everyone to find a counterparty with a profit on both sides, this is not what happens: the final price p is such that the number of sellers below p equals the number of buyers above p – the others could not find a counterparty.

In this experiment, the average price (for buyers, or for sellers) did not play any role: only the price at the margin mattered. The price is decided at the *margin*: the market price is the reservation price of the marginal buyer or seller, *i.e.*, the price for the next person to buy or sell. This also explains Adam Smith’s water and diamonds paradox: water is useful but cheap, while diamonds are useless but expensive. Price and value are not the same thing.

Economic models are usually defined with a set of agents, each with an initial endowment and a utility function, trading with one another to change their allocation and maximize their utility function. It was once thought that the resulting equilibrium was maximizing the sum of the utilities – this only happens in the unrealistic case where the marginal utility is constant. The equilibrium is just Pareto efficient: changing the

allocations would make someone worse off (but there are many Pareto-efficient allocations).

To find the equilibrium, just write the following equations:

- Markets clear, *i.e.*, supply equals demand, *i.e.*, for each good, the sum of the initial endowments equals the sum of the allocations;
- All the money is spent, *i.e.*, for each actor, the value of the initial endowment is the value of the allocation;
- Everyone maximizes their utility: the Lagrange multipliers conditions can be written as

$$\frac{1}{p_x} \frac{\partial U_A}{\partial x} = \frac{1}{p_y} \frac{\partial U_A}{\partial y}$$

for all goods x, y , and all actors A (U' is called marginal utility).

The prices are only determined up to a multiplicative constant. There is no “just” price: it depends on utilities and endowments.

Assets and time

To jump from economic models to financial models, we need to add time, assets and (later) risk.

Adding time is easy: let x and y be the same good (say, apples), but x is now and y next year. For instance, if the utility is $\log x + \frac{1}{2} \log y$, we are impatient, we value apples more today than next year, *i.e.*, we discount apples in the future.

We can also add assets: for instance, a piece of paper giving you the right to receive one apple today x and one apple tomorrow y is an asset – an apple tree is also an asset, with the same dividends $(1, 1)$.

The situation may look complicated: we have endowments of x, y , of the asset $(1, 1)$ (and of other assets, defined by their payoffs or dividends); we have the utility for each actor; we are looking for the price of each good and asset, and the allocation of each good and asset. But it can be simplified by just removing redundant assets or goods: assets such as $(1, 1)$ are just linear combinations of goods.

With the introduction of time, the notion of price becomes trickier. The prices are expressed in some currency. In the 1-period set-up, we could “normalize” the prices by assuming that the price of good x was 1 currency unit. In the 2-period setup, we can do exactly the same: assume that the price of good x is one currency unit, and look for the price of good y (the same asset next year) in the same currency – the currency *this year*. In the real world, the market price we would see would be expressed in a different currency: the currency *next year*. The difference (strictly speaking, the ratio, expressed as a rate) between the currency this year and the currency next year is the inflation. To model it, we would need to add a “theory of money” (how much money there is in the economy, how quickly it circulates, etc.) to our model. The difference between the price this year (in today’s currency) and the price next year (in today’s currency) is the **real interest rate**. This is what we are interested in. The price, in today’s currency, of next year’s good, is called its present value. The difference between the price this year in today’s currency and the price next year in next year’s currency is the nominal interest rate: it combines (muddles) both elements. We will only use today’s currency.

$$1 + \text{real interest rate} = \frac{1 + \text{nominal interest rate}}{1 + \text{inflation}}$$

The real interest rate is usually positive. It can be negative when the government tries to boost demand: it is then preferable to spend now, and even borrow to spend now, rather than wait until next year. Interest is “crystallized impatience”: we prefer goods today rather than tomorrow. It may also include differences in supply between today and tomorrow.

Bonds and rates of return

Bonds (coupon, zero, annuity, perpetuity) can be used to spread expenses over time. For instance, if a university needs 100,000,000 per year, for the next 10 years, to repair badly maintained buildings, it does not have to cut its budget by that much: if the cost can be spread over the life of the university, *i.e.*, if they are willing to pay forever, they can replace the costs with a perpetuity with the same present value (PV) and reduce the annual cost:

$$\text{PV}(10\text{-year } 100 \text{ million annuity}) = \text{PV}(\text{perpetuity}).$$

(You have to choose an interest rate for this, e.g., 5%.)

The notion of present value can also be used to measure the performance of a hedge fund: since the cash flows and the assets under management are irregular, the notion of average return can be contentious. The geometric average of the annual total returns is a biased measure: it gives the same importance to years with little capital (and amplifies little profits) and less importance to years with more capital (and reduces losses, e.g., caused by capacity constraints). The **internal rate of return** (IRR, sometimes called yield-to-maturity), *i.e.*, the constant rate for which the present value of all

the cash flows (both positive and negative) is zero, is a better alternative, though plagued by its own problems. It is also biased, because clients tend to leave after a bad year (so that there is more weight on those bad years) and invest after good years (so that there is less weight on those good years). If there is a gap, a long series of zeroes, in the stream of cash flow, everything that comes after will be discounted a lot and will have a negligible effect. The IRR is not always well-defined: for instance, $(1, -4, 3)$ could suggest either 0% or 200%. The IRR assumes that the interest rate is deterministic and constant (we are throwing away relevant information: we know the risk-free discount factors).

There is also a (uniquely defined) modified internal rate of return (MIRR). The IRR assumes that you can reinvest the money at the IRR rate, while the MIRR uses a reinvestment rate: compute the future value of the inflows, after n periods, with the reinvestment rate; compute the present value of the outflows (negative cashflows), now, with the financing rate; convert into a rate. In R, check `financial::cf`. (The classical alternative to the IRR is the present value of the stream of cash flows for the risk-free interest rate.)

Some people use the “current yield” (the bond rate divided by price) instead, especially if they want to sell you something: this is “the wrong way of measuring things, which can get you confused”. (Be wary of anything called “yield”: there are many, many definitions, and they are almost all misleading.)

Using risk-free bonds of several maturities one can compute the price today of \$1 in n years (that is a **discount factor**), and the **forward rates** (*i.e.*, the rate between years $n - 1$ and n : it would be the future interest rate, if it was deterministic and known – it is not). Some also compute the yield (and plot the yield curve), but that is misleading: it is the annual rate over those n years computed assuming that the interest rate is constant – but we look at the yield curve because it is not constant. (The yield is not unlike the implied volatility and the smile: it is computed under the assumption that it is constant, and we look at how it varies...)

Profit is sometimes incorrectly measured as the cash flow you receive after one period, forgetting the change in present value. In times of crisis, when the value of the firm drops, many banks and businesses report the cash flow instead of the profit, to hide the losses. This kind of deception is very common with bonds: this is how the “current yield” is defined.

$$\text{Profit} = \frac{CF_1 + PV_1 - PV_0}{PV_0} \neq \frac{CF_1}{PV_0} = \text{Current yield}$$

Carry trades use this idea to hide losses: for instance, if the 2-year forward interest rate is 2% and the 5-year 5%, you can buy a 5-year bond (you pay 100 and receive 5, 5, 5, 5, 105) and sell a 2-year bond (you receive 100 and pay 2, 102). More generally, a carry trade is a portfolio of two bonds, one long, one short, with a

positive cash flow at the beginning and a negative cash flow at the end, so that the portfolio value be zero (easy to do if the yield curve is not flat). If you only report the cash flow and not the present value of the outstanding bonds, it looks positive. That is why you should **mark-to-market**.

Social Security

Social security (an insurance against living too long) works as in the following parable: a son gives \$100 to his father (say, for a life-prolonging operation), later asks his own son to pay back the \$100 that helped his grand-father live a few more years, this son then asks his own son, and so on – each generation contributes the same nominal amount, which contributes to the PV of the first father, *e.g.*, $PV = 50 + 25 + 12.5 + \dots = 100$. (In case of a baby boom, the amount to repay (per person) decreases.) In other words, social security is a (beneficial) Ponzi scheme – money is another widespread Ponzi scheme.

The **overlapping generations model** can explain and quantify what happens. Generation n lives in periods n and $n + 1$, with endowments $(3, 1)$, *i.e.*, 3 units when young, 1 when old. Generation 0 only has a $(0, 1)$ endowment, but also owns land, an asset with payoff $(1, 1, 1, \dots)$: in period 1, they will consume the good produced, sell the asset to the next generation, and buy more good (from the next generation) with the proceeds. The utility is $\log x_t + \log x_{t+1}$. One can compute the equilibrium.

Social security worsens this situation: the $(3, 1)$ endowment is replaced by $(1, 1)$. This is a huge benefit for the first generation, but every subsequent generation has to pay the price; the cost does not fall, and remains the same generation after generation, because of the interest rate.

The model can be made more realistic by considering a growing population, growing land dividends, *etc.*: the situation improves, but only slightly – the interest rate would just be higher.

Some economists claim that the baby boom should not have any effect on the stock market, because we know in advance how many people will retire, and this information is already in the prices. However, the interest rate fluctuates with the population: this is what impacts the stock markets – demography has an effect on stock prices. If we compare the utility of the generations, we find that the utility of baby boomers is lower.

(The overlapping generations model for social security can be augmented with random stock dividends.)

Social security can be fixed as follows:

- Separate the legacy debt from social security;
- Create a new security, an annuity indexed on the average wage: its performance will track that of the stock market, but with fewer, slower fluctuations; the market will price it;
- If you want some redistribution, by paying 10% to

14% of your income (depending on how much you earn), 12% would go in your social security account.

Uncertainty

To fully leave Economy for Finance, we need to add uncertainty to our models: the future state of the world is a random variable, but with a known distribution (we exclude knightian uncertainty, *i.e.*, uncertainty about the probability distribution).

Uncertainty can have a surprising effect on the discount factor. We see a big difference between today and tomorrow, but very little between one year and one year and one day. But the discount factor is supposed to decrease exponentially. This can be explained if the interest rate is unknown, stochastic, and (unrealistically) follows a geometric Brownian motion: the expected discount factor decay (asymptotically) in $t^{-\alpha}$ (**hyperbolic discount**).

Evidence shows that prices already include a lot of information. For instance, prices of orange juice (concentrated, mainly from Florida) include weather information; weather forecasts cannot help forecast prices, but prices can help forecast weather. The **rational expectations** assumption goes further and claims that the current price is the expectation of the present value of the future price (this is not entirely true: we will see later how risk changes prices – the difference is the risk premium).

$$\text{Current price} = E[\text{PV}(\text{future price})].$$

From bond prices, one can estimate the probability of default of a country or company (just compare the price with a risk-free bond, *i.e.*, compute the default spread).

$$\begin{aligned} \text{Bond price} &= \frac{1 - P(\text{default})}{1 + r} \\ &= \frac{1}{(1 - \text{default spread})(1 + r)} \end{aligned}$$

With several maturities, one can check how this probability changes with time. The CDS contains the same information.

Shakespeare's play *the Merchant of Venice* is about **collateral** to control default risk (people not keeping their promises): a defaulted loan makes you lose "a pound of flesh", choosing the wrong casket forces you to remain single, losing the ring entails your death.

In the *black-and-red game*, you draw cards from a 52-card deck, receive \$1 for each red card, pay \$1 for each black card and stop when you want (in particular, you cannot lose: if you wait until the end of the deck, you are flat). What is the value of this game and what is the "optimal" (maximum expected payoff) strategy? This **optimal stopping time** problem can be solved via dynamic programming ("backward induction"): let $V(a, b)$ be the expected value of the game if there are a red and b black cards left, and compute it recursively.

$$V_{a,b} = \left(\frac{a}{a+b}(1 + V_{a-1,b}) + \frac{b}{a+b}(-1 + V_{a,b-1}) \right)_+$$

Callable bonds are another optimal stopping problem (use, e.g., a geometric brownian motion for the interest rate and compare the price of a bond and a callable bond; use a binomial or trinomial (recombining) tree): the borrower has the option to prepay the bond at any time. Mortgages are a special case.

Mortgages: history

Mortgages have been around since Babylon (1000 BC). They used to be coupon bonds (say, 7 7 7 7 7 ... 107), with a "balloon payment" at the end – but people would often default just before. After the 1929 crisis, amortizing mortgages, with identical dividends (e.g. 8 8 8 ... 8) became more popular: the present value (or "remaining balance"), and the risk for the bank, decreases with time.

Then, Freddie and Fannie pooled mortgages and sold them: the risk was limited (the loans were standardized, with stringent conditions on the borrowers), distributed (loans from different regions were pooled), and securitization made mortgages liquid (you could easily resell your Freddie or Fannie shares).

Then, CMO (Collateralized mortgage obligations) cut the pool into pieces: for instance, floaters (constant cash flow plus interest rate), reverse floaters (constant cash flow minus interest rate) and a residual piece for the defaults and the prepayments. There were arbitrage opportunities when the price of the pieces did not match the price of the pool. Hedge funds were selling the riskiest parts and hedging the rest; other investors were selling the easy parts and worrying about the risky parts remaining on their balance sheets. However, the chain from home owner to mortgage pool to CMO to investor was getting longer, and the same collateral was re-used at each step.

Then, new mortgage markets appeared, besides agency (Freddie, Fannie) mortgages: jumbo prime (large mortgages, that were previously excluded); alt-A (almost prime); subprime; uncollateralized.

Then, mortgage pools were cut into pieces (bonds): AAA, AA, A, BBB (the defaults and prepaes are put into the lowest piece first, until it is full). CDS (credit default swaps), insurance on each of those bonds, also appeared.

Then, CDOs appeared (take many BBB pieces, pool them together, and split them, into AAA, etc.), and CDO squared (do it again, take many AA CDOs, pool them together, and split them).

Mortgages

Mortgages are just callable bonds, and computing their prices should be an optimal stopping problem. However, borrowers do not prepay their mortgages optimally: banks estimate the proportion of people who will prepay in order to lower the cost of the mortgages and be more competitive – for the borrower, there can be an actual arbitrage opportunity. Modelling the prepay rate as a function of the interest rate poses a survival problem: people who have prepaid are more alert

or attentive than those who remain: the more people prepay, the less likely the remaining ones are to prepay. Agent-based models work better: Each agent has a “prepay cost” (that depends on the credit rating of the borrower) that measures how attentive he is to the interest rate, and acts rationally wrt this cost; one can calibrate the distribution of this prepay cost with the data. Other parameters can be added: attentiveness, value of the mortgage, location, pay of the borrower, etc.

The value of the mortgage depends on the interest rate, as an option does, but the shape of the payoff is tricky, dangerous, when the interest rates are low – that part should be carefully hedged.

Hedging

A **hedge fund** is an asset manager that uses leverage, hedging, is lightly regulated (*i.e.*, the clients are sophisticated investors) and has high fees. Hedge funds typically go bankrupt when they do not hedge properly or encounter liquidity problems (e.g., margin calls).

Here is a hedging example. Someone is willing to bet that team A will win at 60/40 odds, while the bookmakers offer 50/50: how do you profit from this discrepancy of views? You can accept the bet, but place an opposite bet with the bookmakers, for a carefully chosen value, so that you have a sure profit in all cases – there are no probabilities involved.

When time is involved, **dynamic hedging** may be required. For instance, imagine someone is willing to bet that team A will win over team B, over the next 10 matches, at 60/40 odds, but the bookmakers offering 50/50 odds only allow you to bet on individual matches: how do you profit? The solution is similar, but you have to change your bet after each match.

Dynamic hedging also occurs in finance: for instance, if the market price of a mortgage is lower than what your model predicts (e.g., because the market does not account for prepayments), but is extremely sensitive to interest rates, you can hedge interest rate fluctuations away.

Everyone wants to hedge, but some risk will remain (markets are not complete).

Earlier, we have claimed that the price was the expected payoff: it is actually less, to compensate for the risk. The difference is the **risk premium**. [What we really did was use the present value of the future cash flows as utility, maximize expected utility, and compute the corresponding price: that kind of utility is unrealistic, but the rest of the reasoning is correct.]

Utility should be concave, to account for diminishing utility, *i.e.*, risk aversion – this is Jensen’s inequality: we prefer \$1 for sure to \$1 on average. To avoid infinite expected utilities, you may also want utility to be bounded (for instance, how much would you pay for the game: “flip a coin until you have tails and receive 2^n (or 2^{2^n}) dollars, where n is the number of tosses needed”?).

With quadratic utility, $U(x) = ax - x^2$, the expected utility only depends on the mean and variance of x .

An **Arrow-Debreu security** is an asset that pays \$1 in one state of the world, and \$0 elsewhere. CDS and binary options are almost Arrow-Debreu securities: they are event-dependent, not state-dependent. In a complete market, the price of an Arrow-Debreu security is proportional to its probability.

The **mutual fund theorem** says that in an incomplete market, everyone diversifies by holding the aggregate economy and cash: the only thing that differentiates economic actors’s allocations is the proportion of cash.

This assumes that all investors are rational, have access the the same information and investment opportunities, know the correct expected returns and variances, and have quadratic utility (but not necessarily the same utility). Of course, we do not know what the “market” portfolio – but it is larger than we think.

The advantage of diversification can be seen with two assets: if $\text{Cor}(X, Y) < 1$, the variance of $Z = \lambda X + (1 - \lambda)Y$ can be lower than that of X and Y (try to plot those random variables, as λ varies, in the $\sigma(Z) \times EZ$ plane).

The Sharpe ratio of an asset or portfolio is the slope of the line going through it and the risk-free asset: $(EX - r)/\sigma(X)$. You should maximize your Sharpe ratio. A stock is worth more if it increases the Sharpe ratio. This can be quantified by the **covariance pricing theorem**:

$$\text{Price} = (1 + r)^{-1} EX - \alpha \text{Cov}(\text{Market}, X),$$

i.e., the risk is *not* measured by the variance, but by the covariance. The price is determined by the marginal utility, by the utility of a marginal buyer, by how much diversification the asset adds to the market portfolio – not by something intrinsic. (This still assumes quadratic utility.) This can be somewhat unintuitive. For instance, if GE and a startup have the same expected returns, which has the highest price? You might think it is GE, because it has a lower risk, as measured by the variance. It is actually the startup, because it has a lower risk, as measured by the correlation with the market.

In particular, $(EX, \text{Cov}(\text{Market}, X))$ should be on a line.

The CAPM worked well for 20 to 30 years, but no longer works. The same goes for the Black-Scholes model: the Gaussian daily returns assumption was almost valid in the 1970s, but no longer is.

Leverage cycle

The **leverage cycle** can be modelled as follows: two assets (gold, risk-free, and an oil well, with an uncertain payoff), two states, many actors, with identical endowments (1,1) but heterogeneous beliefs on the probabilities of those states. Actors can borrow gold using oil wells as collateral from less optimistic investors, with various leverages. There is not a single supply and demand equation, but many, one for each possible value of the leverage. (It turns out that only one of those loans is actually traded: the leverage is uniquely defined.) The availability of leverage increases the price.

Crashes appear in the 2-period model: after a bad news, the most optimistic investors are bankrupt, the leverage drops, marginal buyers are less optimistic and pay less, and the price drops.

This is what happened with the subprime mortgage crisis. The apparent risk was low because the securitized mortgages were collateralized (by the houses) and investors were also buying insurance, in the form of CDSes, from insurance companies. However, those CDSes were not collateralized. If the BBB mortgage bonds went, so would the CDSes, CDOs and CDO squared. High leverage creates high prices: more buyers are willing to buy at a high price, because they can borrow – the marginal buyer can afford more when leverage is high. When people noticed that something was going wrong, margin (collateral) requirements increased, leverage decreased, price fell, worry rose, collateral requirements increased, etc.

Leverage poses many problems:

- A few investors, with high leverage, control the market (they are the marginal buyers) – what if they are not rational?
- Leverage spreads inequality.
- Leverage increases (leverages) volatility, which impacts economic activity.
- Some companies are deemed “too big to fail”.
- After a leverage crash, there is a debt overhang: no investments (from home owners and businesses) and no loans (from banks).

Preventing those problems is not that hard (in hindsight, it is never hard):

- For mortgages, just write down the principal of the loans (the alternative is to evict the home owners, but this is bad for everyone: people lose their home; banks only get back part of their money, after a few years, when the house is sold, at an abnormally low price (auction), even accounting for the drop in value because it was not maintained (or was vandalized) after the eviction). This is problematic because the bond owner and the home owner are not in contact – there is an intermediary, with no incentive to write down the principal.
- To prevent the leverage collapse, banks should lend with less collateral, e.g., by forbidding quick changes in the margin requirements.
- To replace the natural buyers, the government should invest more.
- To prevent or observe the next leverage crisis, one (the Federal Reserve) should not only monitor interest rates, but also the collateral.

Hyperbolic discounting is rational: valuing the far future with uncertain discount rates
J.D. Farmer and J. Geanakoplos (2009)

In a multi-period world, we want the discount factor for future utilities to be stationary and time-consistent.

$$\text{Utility}_t(x) = \sum_{s \geq t} D_{t \rightarrow s} \text{Utility}(x_s)$$

With known, deterministic rates, the discount factor decreases exponentially. However, if the interest rate is stochastic, described by a geometric Brownian motion, then the expected discount factor exhibits a power law decay, at least after some time (a couple of generations).

$$D_{t \rightarrow s} = \prod_{\tau=t}^s (1 + r_{\tau})^{-1}$$

$$E[D_{t \rightarrow s}] \underset{s \rightarrow \infty}{\sim} (s - t)^{-\alpha}$$

There is no such effect for more realistic mean-reverting models.

Discussion of “the leverage cycle” H.S. Shin (2009) after J. Geanakoplos

Real-estate is a leveraged investment: home buyers using a mortgage with a 5% downpayment are leveraged 20 times. The leverage cycle can be modeled as follows. In a 1-period world, consider two assets, cash and stock, with the stock price distributed as $U(q - z, q + z)$ in period 1, and two types of investors, trying to maximize the same expected utility under different constraints: unleveraged investors have a leverage at most 1, leverage investors have a value-at-risk (VaR) constraint (since the price distribution is uniform and known, the constraint can be formulated as “they cannot be bankrupt”). When the asset price increases, the VaR constraint is less binding, non-leveraged investors can invest more, demand increases, and price increases even further – there is a similar downward spiral.

Demography and the long-run predictability of the stock market J. Geanakoplos et al. (2004)

Markets ups and downs, over the past century, seem to coincide with baby booms and busts: part of the effect can be explained by the equity premium, higher when the population is older. This can be modelled with an overlapping generations model, an incomplete market, and age-dependent utilities; the effects remains even after adding families (children helping parents), social security (idem), bequests (the opposite).

Game Theory B. Polak (Yale, 2007)

Game theory is the study of decision making, not when facing an unchanging world, as often in economics, but

when facing someone else, who can also take decisions that will affect your payoff.

There are many notions of a “good” (or bad) decision.

A **Pareto efficient** situation is a situation that cannot be changed to make one player better off without making the other worse off: since it usually requires cooperation between the players, it rarely happens.

A strategy is **dominated** by another strategy if it is always worse, whatever the other player does. (If you replace “worse” by “worse or as bad as”, that is a weakly dominated strategy.)

You can try to find a “good” decision, iteratively, by discarding the dominated strategies for both players, which gives a new game, and continuing to discard the dominated strategies until there are none left. However, this assumes that both players are rational, known that the other is rational, know that the other knows they are rational, etc. – *i.e.*, players are rational and this is **common knowledge**. In practice, it does not work.

A **Nash equilibrium** (NE) is a situation in which each player’s decision is a **best response** to the other player’s decision. Since the definition is circular, you can expect a few problems: it need not exist, need not be unique, need not be Pareto efficient, and weakly dominated strategies can be Nash equilibria (but strict ones cannot).

Randomized decisions can create (mixed) equilibria in situations with no pure equilibria, such as the rock-paper-scissors game. A pure strategy that is part of a mixed strategy NE is itself a best response (to the other participant’s strategy, which is usually a mixed strategy): mixed equilibria cannot be strict. To find a mixed strategy NE, look for mixes that make the other party indifferent. Mixed strategies can be interpreted as randomized strategies or as a population whose elements have different behaviours.

A strategy S is **evolutionary stable** if, when a new strategy appears, with a small proportion in the population, it disappears. Then, (S, S) is a Nash equilibrium. Conversely, if (S, S) is a strict Nash equilibrium, then S is evolutionary stable – this does not work with weak equilibria.

The payoffs of a simultaneous game can be represented as a matrix of (with two values in each cell, one for the row player, one for the column player). The decisions and payoffs in a **sequential game** can be represented as a tree. **Backward induction** gives a “good” solution to the game, but it assumes that the other player is rational – and it need not be Pareto efficient: there can be **moral hazards**.

Backward induction assumes that the other player will play it his/her best interest, *i.e.*, that they will not choose something that would be bad for them and for us. It assumes they will not “screw up”. It does not give a worst-case strategy.

You can tweak a simultaneous game by changing the payoffs (**incentive design**: give some of your payoff to the other player, in some situations, to encourage him/her to choose that path – you will get a smaller share of a larger pie), or pruning the tree of unwanted branches by restricting your choices (build a new factory, which becomes a sunk cost; burn your ships to show your **commitment**, etc.).

Zermelo's theorem says that in a sequential game with perfect information and a finite number of moves, either player 1 can force a win, or player 1 can force a tie, or player 2 can force a win.

With imperfect information, many Nash Equilibria are clearly bad choices. A Nash Equilibrium is a **subgame perfect equilibrium** (SPE) if it also induces a NE on all subgames.

Repeated games can lead to **wars of attrition**: past costs are sunk, they do not play any role in new decisions, and can accumulate, forever. This happens in wars (costly wars over very small frontier areas), companies fighting for a market regardless of the cost or bribery auctions ("all pay auction": two companies bribe a government until one out-bribes the other).

Repeated games try to enforce cooperation by balancing threat of future punishments and prospects of future rewards. If there is a time limit, they can exhibit the **lame duck** effect (politicians or CEOs approaching retirement): in the last period, you no longer need to cooperate, because there is no future – and, by backward induction, there is no reason to cooperate at the beginning either. In some cases, it can work: if there are several Nash equilibria, you can use one as a reward and the other as a punishment, to encourage cooperation.

This effect can disappear in repeated games with a random number of periods (e.g., in the prisoner's dilemma, one can use the grim trigger strategy: cooperate until the other defects – to show that it is an equilibrium, discount the future using the probability that the game will continue).

When information is asymmetric, some players may want to reveal the information while other will try to hide it – but the information has to be verifiable: claiming "our product is the best" is not sufficient, even if it happens to be true. Not revealing information is informative: it means that it is not in your interest to do so (information unravelling: "Silence speaks volume").

Revealing verifiable information can be costly. For instance, in a world with two types of workers, good and bad, and two types of pay, high and low, employers and good workers want the distinction to be known, bad workers do not. If the cost of education is sufficiently different for good and bad workers, good workers will spend time to earn a degree, but bad workers will not: this is a **separating equilibrium**. This can lead to qualification inflation: if the cost difference is too small, good workers will try to earn even more degrees. (This model assumes that education does not

teach you anything, or at least nothing useful for your future job: it is socially wasteful, uses resources but does not improve productivity)

Auctions are becoming more important (governments selling oligopoly rights (phone markets, natural resources), ebay, IPOs, microstructure of stock markets, etc.). In a common value auction, the value is the same for everyone, but it is unknown. In a private value auction, the values are different for everyone and unrelated. (Reality is between those two extremes: an oil well has a common value, but different companies may have different exploitation costs; a house has a private value (consumption), but since you eventually resell it, other people's values matter.)

In a common value auction, if everyone bids their (unbiased) estimated value, the winner will overpay: this is the **winner's curse**. If you win, it is bad news. (This often happens with IPOs.) You should bet under the assumption that you will win, *i.e.*, you should ask yourself "What is your estimate? You have won, so your estimate is too high: do you want to correct your estimate?"

There are many types of auctions: first price sealed bid auction; second price sealed bid auction (or victory auction: the highest bidder gets the good, but pays the second highest bid); ascending open auction (the price progressively rises, and people progressively drop out – very similar to the second price sealed bid auction); descending open auction (or Dutch auction: the price progressively falls until someone accepts it – identical to the first price sealed bid auction). The optimal strategies are different: in a private value second price sealed bid, you should bid your value: it is a weakly dominant strategy; in a private value first price sealed bid auction, bidding your value is weakly dominated: you should bid slightly less. Surprisingly, the expected revenue generated by these auctions is the same.

Here are some of the games or real-world situations used to illustrate those notions.

Coordination games are variants of the prisoner's dilemma: competing or colluding firms, overfishing, global warming (contractual enforcement is needed: it is not just a communication problem), etc.

In the number game, each of n participants chooses a number between 1 and 100, the winner is the one closest to $2/3$ of the average (this shows that, in practice, if you delete dominated strategies until the end, you lose: rationality is not common knowledge).

Alice and Bob both wear a pink hat but do not know the colour of their hat: "Someone is wearing a pink hat" is shared knowledge, but not common knowledge.

In the election game (linear city model), two politicians decide on their position on the political spectrum $[1, 10]$; each position has the favour of 10% of the population; people vote for the closest candidate (or one of the closest candidates, at random, in case of a tie): iterative deletion of dominated strategies leads to both

candidates choosing a medium position (5 or 6). This also applies to product placement or petrol station location (the best location is next to a competitor, not in an area with no competition).

In the investment game, each of N players can invest \$0 (no loss, no profit) or \$10; if more than 90% choose to invest, they receive \$5 more, if not, they lose their \$10. There are two Nash equilibria: everyone invests, or no one does. It is a cooperation game, but contrary to the prisoner's dilemma, there is no dominated strategy: contractual enforcement is not needed, communication or leadership often suffices to move to the better Nash equilibrium. Bank runs, monopolies (the use of Microsoft products as a de facto standard) or fashion trends are similar examples.

The **Cournot duopoly** (two firms competing on the quantity produced) is a game of **strategic substitute**, the opposite of a coordination game: if you produce more, the other party produces less (in a coordination game, if you produce more, the other party has an incentive to produce more). The Nash Equilibrium does not maximize total profit; monopoly or collusion does, but collusion is not a Nash equilibrium: the firm would have an incentive to produce more.

In **Bertrand competition**, the two firms compete on prices, not quantities: the outcome is similar to perfect competition.

In the candidate-voter model, each voter is a potential candidate, and their political opinion is in $[0, 1]$; there is a reward for the winner, a cost to run, and a cost proportional to the square of the distance between the voter and the elected candidate. There are many Nash equilibria: a single candidate exactly in the middle, two candidates symmetrically positioned around the centre (but not too far from the centre, otherwise a centrist candidate could run and win). This mimics what happens in real elections: if a new candidate appears on one side, the other side wins.

In the location model, two types of people have to choose to live in one of two cities; they prefer a heterogeneous environment, but want to avoid being isolated among too many people of the other type. The heterogeneous situation is better for everyone, but it is not stable.

Consider n lions, ranked by seniority, and one sheep. Only lion 1 can eat the sheep, but lion 2 will then have the opportunity to eat him in his post-meal nap, and so on for the other lions. Should lion 1 eat the sheep? (Use backward induction and consider the behaviour of the last lion.)

In a Cournot duopoly, if firm 2 has a spy that tells them what firm 1 will be doing, and firm 1 knows it, then firm 1 has a **first mover's advantage**. For firm 2, more information, more choices can hurt.

In the game of Nim, there are two piles of stones. You can remove as many stones as you want from either pile, but if you take the last stone, you lose. (The strat-

egy is to make the two piles equal.) There is a second mover's advantage if the two piles are equal, but a first mover's advantage otherwise. Here is a 2-dimensional variant: the stones are in a $n \times m$ array; choose a stone and remove it and all the stones north-east of it; you lose if you remove the last stone.

Two duellists are walking towards each other; if their skills (probability of hitting the adversary as a function of the distance) are known, when should they shoot? (Not too early (if $p_n < 1 - p_{n+1}$, shooting is a dominated strategy), not too late (use backwards induction to show that you should act as soon as $p_n \geq 1 - p_{n+1}$).) A similar situation appears in economics, when two companies are developing a new product, want to release it before the other to occupy the market, but do not want to release it too early because it is not completely finished.

The **chain store paradox** shows the advantage of not being rational (or, at least, having the other party believe you are not): several firms consider entering a new market, currently controlled by a monopolist; if it is more costly for the monopolist to fight the new entrants than to leave them a share of the market, the monopolist should not fight – but if they have the reputation of being irrational (systematically or randomly fighting, even if it is not profitable), they can deter new entrants.

The **dictator game** (you are given \$1, you can give part of it to the other player, who cannot do anything) and the **ultimatum game** (you are given \$1, you can give part of it to the other player, who can accept or reject the offer, in which case no one receives anything). show that we are not always rational. Bargaining is similar to the ultimatum game, but with several periods, and a discount factor (the value to share decreases with time). The first offer is always accepted; the first mover's advantage disappears as the number of periods increases; if discounting is almost negligible, and similar (and known) for both players, an even split is optimal. However, if the value for each player is not known, the result of the bargaining is suboptimal.

When designing incentives, do not overlook the strategic effects. Consider two firms competing in a Cournot equilibrium. One has the opportunity to invest in new equipment: it is expensive, but will reduce production costs. If the quantity produced does not change, it may not be profitable, but if the other firm knows that the investment has been made, there is a strategic effect: they will reduce their production, we will increase ours, and the new investment will become profitable. Similar effects appear in the tax code.

Comparison of correlation analysis techniques for irregularly-sampled time series K. Rehfeld et al. (2011)

The auto-correlation and cross-correlation of irregularly-sampled time series can be estimated by considering the time series as regular; linearly in-

terpolating to have regular time series; binning the observations pairs by lag, *i.e.*, considering a regression

$$(x_t - \bar{x})(x_s - \bar{x}) \sim |t - s|$$

with a rectangular kernel; or using a similar regression with a gaussian (this is what gives the best results) or a sinc kernel.

***A drunk and her dog:
an illustration of cointegration
and error correction***
M.P. Murray (1994)

A set of random walks

$$x_n - x_{n-1} = u_n$$

$$y_n - y_{n-1} = v_n$$

can be turned into cointegrated random walks by adding error correcting terms

$$x_n - x_{n-1} = u_n$$

$$y_n - y_{n-1} = v_n + a(y_{n-1} - x_{n-1}).$$

When looking for cointegration relations in data, make sure they are meaningful (here, $x_{n-1} - y_{n-1}$ is the distance between the drunk and her dog).

***A drunk, her dog and a boyfriend:
an illustration of multiple cointegration
and error correction***
A. Smith and R. Harrison

The model can be generalized by adding a boyfriend

$$x_n - x_{n-1} = u_n$$

$$y_n - y_{n-1} = v_n + a(y_{n-1} - x_{n-1})$$

$$z_n - z_{n-1} = w_n + b(z_{n-1} - x_{n-1}),$$

the drunk's attraction for her dog or boyfriend, the boyfriend's aversion for the dog, etc.

By looking at the data alone, you cannot always answer the question "who is attracted by whom?": you only have the subspace of cointegration relations. If the cointegration relations are $\beta' \mathbf{x}_n$ (this means that this series is stationary), the error correction model (ECM) is $\mathbf{x}_n - \mathbf{x}_{n-1} = \alpha \beta' \mathbf{x}_{n-1} + \mathbf{u}_n$; we can estimate $\alpha \beta'$ (and its rank, *i.e.*, the number of independent cointegration relations), but not α and β separately.

***Nonparametric goodness-of-fit tests
for discrete null distributions***
T.B. Arnold and J.W. Emerson
R Journal (2011)

The Kolmogorov-Smirnov and Cramér von Mises tests use the L^∞ or L^2 (or generalizations) distances between the cumulative distribution functions as test statistics: for continuous distributions, the distribution of the test statistic does not depend on the hypothesized distribution. For discrete distribution it does: the **dgof** package can compute the corresponding p -values.

***Ckmeans.1d.dp: optimal k-means clustering
in one dimension by dynamic programming***

In one dimension, the (usually NP-hard) k -means problem is amenable to dynamic programming (consider $D_{i,m}$, the minimum within sum of squares when clustering x_1, \dots, x_i into m clusters) – for situations where reproducibility is important.

***Tweets and peers: defining industry groups
and strategic peers based on investor
perceptions of stocks on Twitter***
T.O. Sprenger and I.M. Welpe (2011)

Traders tag their company-related messages with the ticker (e.g., \$AAPL, which gets indexed as @MV_AAPL): company co-occurrence can be used to define industry groups; the classification reflects structural changes more quickly than traditional methods (looking at the variance matrix of the returns, looking at analysts in common, etc.).

Zipf's law unzipped
S.K. Baek et al. (2011)

The omnipresence of Zipf's law (distribution of city sizes, word frequencies, etc.) can be explained using information theory: when putting M balls into N boxes, find $N(k)$, the number of boxes of size k to maximize the entropy (this can be reformulated in terms of mutual entropy). Contrary to the law of large numbers, it is not a process of aggregation, but of division.

***Stability of the world trade web
over time – an extinction analysis***
N. Foti et al. (2011)

Yet another study of the world trade web (WTW) dataset, modelling what happens to the trade network if one or more nodes or edges are removed or modified.

***Full characterization
of the fractional Poisson process***
M. Politi et al. (2011)

You can build counting processes (random variables $N(A)$ that count the number of points in a Borel set A) by specifying the distribution of the inter-event times: with exponential inter-event times, this is a Poisson process (Markov, *i.e.*, memory-less), but other power-law distributions, e.g., Mittag-Leffler, give a non-Markov process.

***Price dynamics
in a Markovian limit order market***
R. Cont and A. de Larrard (2011)

Most models of the limit order book are only amenable to simulations; by considering a simplified model, with the level-1 order book filled or depleted by Poisson processes for market, limit or cancellation orders, unit order sizes, unit spread, and a prescribed order book distribution after a tick changes, one can compute

many quantities of interest: distribution of the duration between price changes, autocorrelation of the price changes, volatility, etc.

A stochastic model for order book dynamics
R. Cont et al. (2010)

A more complicated (continuous time) model.

**Option pricing and estimation
of financial models with R**
S.M. Iacus (Wiley, 2011)

This book (and the accompanying `sde`, `yuima`, `opefimor` packages) explains how to estimate continuous-time models with R and use them to price options. The theoretical chapters also contain *exercises* to ensure that the reader understands the notions introduced.

R already provides `dpqr` (density, probability (cumulative density function, cdf), quantile (inverse of the cdf) and random sample) functions for standard distributions; the `fBasics` package adds a few more: `nig` (normal inverse gaussian, *i.e.*, hitting time of a random walk), `gh` (generalized hyperbolic), `stable`.

Some of those distributions are only defined from their characteristic function (this is the case for infinitely divisible distributions in general: these are the distributions whose characteristic function is given by the Lévy-Khintchine formula). The fast Fourier transform (`fft`) can be used to move between cumulative distribution function F (cdf) or the probability density function f (pdf) and characteristic function ϕ .

$$\begin{aligned} F(x) &= \frac{1}{2} - \frac{1}{2\pi} \int_{-\infty}^{\infty} \frac{e^{-itx}\phi(t)}{it} dt \\ &= F(0) - \frac{1}{2\pi} \int_{-\infty}^{\infty} \frac{e^{-itx} - 1}{it} \phi(t) dt \\ f(x) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{-itx} \phi(t) dt \end{aligned}$$

The `mle` function can be used to maximize a log-likelihood: the result itself is the same you would get with a general-purpose optimizer (`optim`), but you can call functions such as `summary`, `vcov`, `confint` on the result to have more information (`fidistrplus` provides more, moment-based, estimators, and allows censored data).

$$\begin{aligned} \text{Score} &= \frac{\partial \text{LogLik}}{\partial \theta} \\ E[\text{Score}] &= 0 \\ \text{Information} &= \text{Var} \frac{\partial \text{LogLik}}{\partial \theta} \\ &= -E \frac{\partial^2 \text{LogLik}}{\partial \theta^2} \\ \text{Var}(\text{Unbiased estimator}) &\geq \frac{1}{\text{Information}} \end{aligned}$$

Telegraph processes (random motion with constant velocity $\pm c$, and direction changes given by a Poisson process) lend themselves to explicit computations (but beware: they have finite variation and allow for arbitrage opportunities). Their limit, as the Poisson density increases, is a random walk.

Lévy processes can be defined as (limits of) the sum of a Brownian motion with drift and (several) compound compensated Poisson processes. Alternatively, they are **stochastically continuous** (intuitively: there can be jumps, but they are random, and if there are infinitely jumps on a compact (infinite activity), they are not too large) processes with stationary independent increments. They are characterized by their characteristic function. Ito's formula can be generalized to Lévy processes.

The `numDeriv` package can compute derivatives, increasing the precision by evaluating the function at more carefully chosen points (e.g., $t+h$ and $t-h$ instead of t and $t+h$) or with more general methods (Richardson interpolation).

Non-homogeneous Poisson processes can be simulated with the acceptance-rejection method ("thinning"): sample events with constant intensity $\lambda \geq \lambda(t)$; for each event, take a random number in $[0, \lambda]$; if the number is not in $[0, \lambda(t)]$, reject the event.

The `sde::sde.sim` function can sample from the solution of a stochastic differential equation, using the Euler or Milstein scheme (based on first or second order Taylor expansion); the `yuima` package generalizes this to multi-dimensional processes, Markov switching diffusions and Lévy processes (a Lévy process is a time-changed Brownian motion).

Stochastic models (the drift and sensitivity of a diffusion) can be estimated via maximum likelihood if the transition probability is known (normal, log-normal, CIR, etc.), or via **quasi-maximum likelihood**, *i.e.*, by replacing the continuous stochastic differential equation with its first order discretization (implementation in the `sde` and `yuima` packages).

Interest rates are often modelled as

$$dX_t = f(X_t)dt + \sqrt{g(X_t)}dB_t$$

where f and g are (Laurent) polynomials (of given degrees and unknown coefficients – or arbitrary functions). They can be fitted (with bias) via 2-stage regression:

$$\begin{aligned} X_{t+1} - X_t &\sim f(X_t) \\ \text{res}_{t+1}^2 &\sim g(X_t) \\ X_{t+1} - X_t &\sim f(X_t), \text{ with weights } w = g(X_t) \end{aligned}$$

The `fBasics` package provides many functions to fit non-gaussian distributions (`nigFit`, `hypFit`, `ghFit`, `stableFit`).

The Black-Scholes PDE (partial differential equation), for the price of a European option, is just a consequence of Ito's formula, for a self-financing portfolio.

More generally, since the Gaussian density is a solution of the heat equation, one can show that (functions of) expectations of functions of a random walk are also solution of some PDE.

The `fOptions::GBSOption` function computes Black-Scholes option prices.

The equivalent martingale measure can be computed in as follows.

$$\lambda = \frac{\mu - r}{\sigma}$$

$$M_t = \exp(-\lambda B_t - \frac{1}{2}\lambda^2 t)$$

$$Q(A) = E[\mathbf{1}_A M_T] \text{ (martingale measure)}$$

$$W_t = B_t + \lambda t \text{ brownian motion under } Q$$

Monte Carlo option pricing can be sped up by parallelizing the computations, e.g., with the `foreach` and `doSnow` or `doMC` packages.

```
library(doMC) # multicore
library(foreach)
registerDoMC(4) # 4 cores
p <- foreach(m=1:4) %dopar% f(m)
```

Now that the `parallel` package is a core package, the following suffices.

```
library(parallel)
r <- mclapply(
  1:1e5, f,
  mc.cores=detectCores()
)
```

Option sensitivities (“greeks”), *i.e.*, partial derivatives of option prices can be computed in many ways:

- Using simple formulas, but they often involve the derivative of the payoff, which is rarely differentiable;
- Using the same formulas, after integration by parts, to get rid of the derivative;
- By numerical approximation of $\partial C / \partial S$;
- By Monte Carlo simulation (the sensitivities can be expressed directly as integrals, without having to compute the option price);
- Monte Carlo simulation for $C(S, t)$ and $C(S + h, t)$ (using the same random seed for both to improve precision).

Asian options can be priced via an asymptotic expansion $dX_t^\varepsilon = a(X_t^\varepsilon, \varepsilon)dt + b(X_t^\varepsilon, \varepsilon)dW_t$ around a deterministic process using Malliavin calculus (?).

Options on baskets are priced in exactly the same way.

`fOptions::GBSCharacteristics` computes sensitivities, `fExoticOptions` and `fAsianOptions` implement many pricing algorithms, `GBSVolatility` computes the implied volatility, `sde::cpoint` looks for structural breaks (in the volatility of a diffusion).

American options can be priced via dynamic programming, using the grid of the finite difference method,

or using regressions to move back in time (Longstaff-Schwartz least squares method). The Monte Carlo estimator is biased, but one can easily compute an upper and a lower bound. There are also various approximations, e.g. with a sequence of Bermudan options (which can only be exercised at specific times) and Richardson’s extrapolation, or by finding an ODE approximately satisfied by the early exercise premium *i.e.*, the difference between the prices of the American and European calls (quadratic approximation).

If the price is an (exponential) Lévy process, the equivalent martingale no longer unique. Upper and lower bounds for the no-arbitrage price are known, but the interval is very large. One can try to transform the density f of Z_1 in some way, so that the density remains infinitely divisible, but turns the process into a martingale; for instance, an **Esscher transform**,

$$f_\theta(x) \propto e^{\theta x} f(x),$$

or a mean-corrected martingale measure,

$$\tilde{Z}_t = Z_t + mt.$$

The prices of European calls and puts can be expressed as integrals involving the characteristic function (of the real-world distribution) of the price at expiry, and can be computed via numeric integration or FFT.

The **benchmark approach** suggests to stay with the physical measure, but to devise a discount factor that discounts both time and risk, *i.e.*, so that the discounted price be a martingale. This stochastic discount factor (or deflator) corresponds to an asset, called a benchmark, used as a numéraire: if prices are expressed in terms of the benchmark, they are martingales. The growth-optimal portfolio is a benchmark.

The book ends with a discussion of change point detection, estimation of the covariance of asynchronously observed diffusions (Hayashi-Yoshida estimator), regularized estimators (lasso) and clustering with the Markov operator distance.

UseR! 2011

(I did not attend the conference but just read the presentations online: they were only made available six months after the conference, and only half the talks had a PDF file.)

The results of most statistical analyses are known to be “asymptotically” correct: they are only valid if you have enough data (estimators are asymptotically gaussian, the p -values displayed are asymptotically uniform under the null hypothesis, etc.). For small samples, the results are not only imprecise because there is not enough data to reduce the statistical noise, they are also biased. It is often possible to reduce this bias, with **higher order asymptotic expansions** (of the distribution of the estimators or test statistics). The `pbrktest` package does that for mixed models; the `metaLik` package does that for mixed models used for meta-analyses (*i.e.*, to aggregate data from different

studies); the **brglm** package does that for binomial GLM (“binomial” means that we are predicting proportions).

Sweave is no longer the only way of generating PDF reports from R:

- The **brew** package uses templates (not unlike Php) to generate HTML, L^AT_EX, or any other kind of file;
- The Emacs org-mode, with babel, not only helps you organize your notes (if you like to put everything you do in a single text file, that grows by 1MB every year – it is more powerful than supposedly modern note-taking applications such as Tomboy), it can also include bits of code, in any language (elisp, shell, Python, R, C, etc.), that are executed and whose results are displayed (as text, as a table, as plots), and can generate PDF, HTML, etc.
- **knitr** is a replacement for Sweave.
- The **tikzDevice** package generates plots using pgf commands, suitable for inclusion in L^AT_EX files: one advantage is the consistent use of fonts and font sizes between the text and the plots.
- Tables can be included in your L^AT_EX reports thanks to the **xtable**, **tables**, **Hmisc** (and the **latex** and **describe** commands), or **compareGroups** (for the complicated tables generated by **ddply**) packages.
- The **sparkTable** package can add sparklines to your tables.

Interactive plots remain one of R’s weaknesses, but

- the **animator** package can generate animations (e.g., to illustrate random phenomena in introductory statistics courses);
- the **googleVis** package can generate interactive plots in JavaScript or Flash, similar to the animated bubble plots popularized by H. Rosling.
- It is possible to create interactive SVG documents (that can be displayed in a web browser, or included in a web page), e.g., with the **gridSVG** package (the example also included the conversion of a PDF file (a map) to a vector format, for further processing, with **grImport**).
- The interactive graphics available with R (**iplots**, **rgl**, **rggobi**, **playwith**) still pale when compared with Javascript (D3, jit, Raphaël, processing) or even Python.

Since the development of R packages is not centralized, we often end up with several packages doing similar but complementary things, with completely different interfaces. There is some continued work to compare, standardize, refactor those implementations, but the road will be very long...

- The **betareg** package, implementing beta regression (used to model quantities in the interval (0,1): one could also use logit or probit regression, but that would model $\text{logit}(y)$, which has no interpretation – we can directly model the quantity of interest instead) can leverage the **flexmix** package for latent class (mixture) beta regression (in the **betamix** function) and the **party** package for beta regression trees

(**betatree** function).

- The **ordinal** package provides a unified interface to the various packages dealing with ordinal regression (aka ordered probit/logit): **MASS::polr**, **Design::lrm**, **VGAM::cumulative**, **MCCglmm**.
- The **binomTools** package does the same for binomial regression (predict a proportion), using some of the functions in **boot**, **faraway**, **car**, **MLDS**.
- The theme of the plots generated via base graphics, **ggplot2** and **lattice** is completely different: the **uniPlot** package can uniformize them, in case you mix them in the same document.
- The **ROI** and **optimix** packages (both) try to provide a single interface to the various optimization (mathematical programming) algorithms available.
- R, Jags and ADMB have been compared on a few dozen sample problems.
- There are no fewer than 25 density estimation functions in R: a comparison of their speed and precision suggests to use **KernSmooth** or **ASH**.

If you use R more as a programming language than a statistical environment:

- There are no fewer than three packages for unit tests: **testthat** (if you hesitate, use this one), **RUnit** and **svUnit**.
- The **ROpenCL** package (inspired by PyOpenCL) lets you program your GPU, and may supercede **gputools**, **rgpu** (obsolete), or **cudaBayesreg** (which are mostly NVidia-specific).
- CXXR is a reimplement of R in C++, in case you need to tweak R’s internals, e.g., to add new types (big integer, etc.) – could it be used to replace most R structures with out-of-memory data, in a way completely transparent to the end user?
- There are no fewer than three object-oriented paradigms in R: S3 (function-centric), S4 (class-centric) and R5 (mutable objects, à la Java, aka reference classes). The need for specific packages (**R.oo**, **proto**, **mutatr**, etc.) may disappear.
- The RStudio IDE is getting more and more popular: it may have already replaced Eclipse/StatET (which I never managed to install properly: too Javaesque). But Emacs/ESS is still there.
- R Commander still serves as a base to build domain-specific GUIs (for users who do not want to, or think they cannot, use R, but eventually will), but the **gwidgets** package (for real GUIs, for users who will not use R) is getting more widely used.
- R is now available “in the cloud”, mostly through commercial companies (some small companies, targeting niche markets, start to compete with giants like Amazon), but many universities and research organizations do the same (for instance, Rc2 is used to allow students to access R in a workbook-like fashion).
- Commercial support for R is available through companies such as Revolution Analytics, who also provides a few parallel external-memory algorithms and a GUI.
- It is now easy to perform parallel computations in R,

with the `parallel`, `foreach`, `multicore` and `snow` packages – but it is not magical: you still have to split the data or computations and merge the results yourself.

There are many, many types of regression models: the relation can be linear, non-linear (with a given functional form) or non-parametric (with no given functional form); we can try to directly predict the quantity of interest (Gaussian model), or some parameter of the model (GLM), or some quantity that depends on the model (e.g., quantile regression) or the whole distribution of those quantities (Bayesian statistics); the cost function can be a sum of squares, a robust cost function, or include a penalty term (regularized regression, e.g., ridge (L^2), lasso (L^1) or elastic net (both)); the observations can be weighted, or even dependent: the shape of the correlation matrix is usually known, and can correspond to temporal or spacial correlation, or to groups in the data; the model can have several levels, as in “for each subject, take the model parameters at random following some probability distribution, then take 10 samples from those models for each subject, and try to recover the initial probability distribution” – this is actually equivalent to imposing a correlation structure on the data; the model can have “nuisance” parameters, *i.e.*, parameters whose value we are not interested in (e.g., subject-specific parameters in the previous example, or the hidden states in a hidden Markov model, etc.).

If you just want to analyze data, you expect to be able to mix and match those blocks at will – unfortunately, it does not work like that, not only because those methods were developed independently, by statisticians (not programmers), as proofs-of-concept, for a particular application, but also because the algorithms are complicated, time-consuming, and often incompatible. Some progress is being made, not really in uniformizing everything, but in filling in the missing combinations: `lmer`, `glm`, `glmnet`, `glmer`, `glmmlasso` (penalized mixed GLM), `lqmm` (quantile regression and mixed models), etc.

I always complain that copulas are useless (or, at least, unused and difficult to use) in high dimensions, where dependency is trickier to estimate. **Gaussian Copula marginal regression** (in the `gcmr` package) is such an example. You can model a time series y_i as

$$y = F_{\theta}^{-1}(\varepsilon_i)$$

where F is the (marginal) distribution, from some family of distributions (e.g., Gaussian with mean and variance to determine – this is where you would add predictive variables, e.g., $N(a + bx, \sigma)$, with a , b , σ to determine) and the innovations

$$\varepsilon \sim N(0, \Omega)$$

are multivariate normal, with Ω describing the dependency structure, e.g., ARMA for a time series (as with GLS or mixed models). The model can be fit via maximum likelihood (there are complications for discrete data).

The `missMDA` package implements **iterative PCA**, *i.e.*, PCA (principal component analysis) with missing values, imputed via expectation maximization (EM). Multiple imputation generates several values for each missing observation (otherwise the data does not look as variable as it should): in the PCA plots (check the `FactoMineR` package), observations (or variables) are replaced by ellipses or clouds or points. The same ideas can be applied to qualitative variables (multiple correspondence analysis (MCA)).

A qualitative variable with n possible values can be described with a multinomial model, which requires $n - 1$ parameters (the probabilities). The model can be simplified (multinomial processing tree model) by describing the process leading to the outcome with a tree, whose nodes are Bernoulli trials (whose probabilities have to be determined) and whose leaves are the possible values. (I am puzzled: the number of parameters is the same, unless you assume that some of those parameters are equal – it is not really a simplification, just a rearrangement of the model parameters.)

To find the value of a parameter θ of a model $M(\theta)$ describing your data, **Approximate Bayesian Computation** (ABC) suggests to generate random data from $M(\theta)$, for various values of θ , and compare with your data, using some summary statistics. This is just a parametric-bootstrap-based generalized method of moments (GMM). The `ABCME` package chooses the moments itself by minimizing entropy.

The `ClustOfVar` package clusters variables with PCAMIX (as you cluster observations, in PCA, etc.), even if you have both continuous and discrete variables.

Emulation is the process of replacing complicated, time-consuming (deterministic) functions of many variables with a statistical approximation; it has been used in meteorology for some time now, and starts to spread to other domains.

There is a lot of activity around social media mining: data can be retrieved from the web with the `RCurl`, `XML` or `RJSONIO` packages, cleaned with `mvoutlier`, the missing data can be imputed with `mice`, modelled with regression trees with the `BayesTree` or `party` packages. Bayesian networks are sometimes used, through the `bnlearn` and `pcalg` packages.

Examples in various domains were presented, such as finance (the `robHMM` package, for robust HMM or Markov switching models, can be applied to value vs growth portfolio selection or option pricing, with two volatility regimes accounting for kurtosis and skewness), astronomy (galaxy positions, from the hyperLEDA database), business (e.g., how to manage inventory to avoid or limit the bullwhip effect: if demand fluctuates, the fluctuations are amplified along the supply chain because of the lack of visibility of the end-user actual demand), quality control (six sigmas) and metrology, biology (as usual), teaching, geographical information systems (GIS), etc.

Nomograms for visualising relationships between three variables

J. Rougier and K. Milner
(UseR! 2011)

Nomograms are an old-fashioned way of representing linear or non-linear relations between three variables, as in a $y \sim x_1 + x_2$ regression. It is sometimes easier to add more information (another response variable, differences between several groups, etc.) to a nomogram than to the more modern-looking levelplot.

Gaussian copula marginal regression

G. Masarotto and C. Varin

More details.

Implementing models in quantitative finance: methods and cases

G. Fusai and A. Roncoroni
(Springer, 2008)

The first part of the book presents algorithms you may need or find useful when implementing quantitative finance models, concisely, with non-trivial examples.

Antithetic variables can reduce the variance of Monte Carlo estimators: if X and Y have the same distribution, then $E[f(X)] = \frac{1}{2}(EfX + EfY)$, but if $\text{Cor}(fX, fY) < 0$, the variance of the corresponding estimator is lower. This is often used with $Y = -X$, to ensure that the sample points symmetrically spread out.

Control variables use a similar idea: notice that $EfX = E[fX - \alpha(gX - EgX)]$, and choose a function g close to f , but for which you can compute EgX , and select α to minimize the variance of the corresponding estimator. This can be used to price an Asian option with arithmetic average (f , no closed formula) from the price of an Asian option with geometric average (g , closed formula available). This can also be used to price options in a non-Black-Scholes model (f) using the Black-Scholes prices, *i.e.*, the value of the Δ -hedged strategy (g).

Importance sampling can be used to accurately price out-of-the-money options, by sampling from the exercise region. Option pricing usually uses drift-less processes (the risk-free measure): with importance sampling, you can actually add a drift, so that the process visits the exercise region more often, and select it to minimize the variance of the estimator.

Diffusion processes can be sampled exactly (if they can be expressed as a function of a brownian motion, $X_t = f(W_t)$, you just have to sample from a brownian motion), using the exact transition distribution $X_{t+\varepsilon}|X_t$ (if it is known), or by discretizing the stochastic differential equation: the Euler method uses a first-order approximation with gaussian innovations (you could use Bernoulli innovations: the convergence is only in law, and not pathwise, but this is sufficient to compute expectations); the **Millstein scheme** uses a second-order approximation.

Gaussian processes can be sampled for various series expansions: the Karhounen-Loeve expansion (complex sine function, that come from the diagonalization of the covariance operator, $\text{Cov}(X_t, X_s) = \text{Min}(t, s)$), the Haar function expansion ($\neg\bigwedge = \int \neg\bigwedge_{\neg}$) or the Paley-Wiener expansion (with real sine functions).

To simulate Poisson processes, you can simulate the inter-event times (exponential) until you reach the end of the desired period (countdown simulation); or first sample the number of events in the period: (since Poisson processes are memory-less) the event times are then independent and uniformly distributed (conditional simulation). This can be generalized to jump processes: if the jump intensity is variable, or even random, first sample the event times from a Poisson process with a higher jump intensity, then reject some of the events.

Stochastic dynamic programming can be used to price American options

$$\text{Price} = \sup_{\tau \text{ stopping time}} E^{\text{risk-free}}[e^{r\tau} \times \text{Payoff}(S_{\tau})].$$

There are several possible discretizations of the problem to a linear lattice or tree: you can choose the up and down jump sizes and their probabilities to give a correct approximation of $E[\Delta x]$ (first order) or both $E[\Delta x]$ and $E[\Delta x^2]$ (second order) – since there are four parameters, you can still impose equal jump sizes, so that the binomial tree reduces to a lattice.

Using stochastic dynamic programming for optimal investment requires the estimation of $V(t_k, w, s)$, the maximum value attainable in $[t_k, T]$, starting with wealth w and asset prices s , for all k – these are functions of $n + 1$ variables (w, s) .

The partial differential equations (PDE) occurring in finance are parabolic, *i.e.*, there is only one second order term, of the form ∂_{xx} , as in the heat equation (other types of PDEs include the elliptic type, like the Laplace equation, defining harmonic functions, and the hyperbolic type, like the wave equation, $\partial_{tt} - \partial_{xx}$ or $\partial_{tt} - \Delta$). To determine a solution, you need to impose some initial (or final) and boundary conditions, involving the function itself (Dirichlet condition) or its derivative (Neumann condition) or both (Robin condition).

For option pricing, the payoff is the initial condition, and the boundary conditions come from the asymptotic option price or the presence of a barrier (e.g., knock-out barrier options). (Discrete monitoring of barrier options was mentioned, but the boundary conditions did not look sufficient to me: there were too many holes in the boundary to uniquely define a solution.)

By a change of variables, the Black-Scholes equation can be reduced to the heat equation. For the heat

equation, the three approximations of the derivative,

$$\frac{f(t+h) - f(t)}{h}, \quad \frac{f(t) - f(t-h)}{h}, \quad \frac{f(t+h) - f(t-h)}{2h},$$

(forward, backward, central) lead to three algorithms, explicit (the computation of $f(t+h, \cdot)$ from $f(t, \cdot)$ is just a recurrence relation), implicit (we have to solve a tridiagonal linear system) and Crank-Nicolson (idem), of orders $O(h)$, $O(h)$, $O(h^2)$. Those algorithms are sensitive in discontinuities in the initial condition (option payoffs are rarely \mathcal{C}^1) and high values of $\alpha = \delta t / \delta z^2$ (the volatility always appears as $\alpha \sigma^2$).

Tridiagonal systems can be solved via the *LU* decomposition (it is bi-diagonal), *i.e.*, Gaussian elimination, or via iterative methods, $x_{n+1} = f(x_n)$, after rewriting the equation as $x = f(x)$, which progressively increase the precision of the result. For the Jacobi method, write $A = D + L + U$ (diagonal, lower and upper triangular) and $Ax = b$ becomes $x = -D^{-1}(L+U)x + D^{-1}b$. The **Gauss-Seidel** method uses the same formula, but with $x_{n+1,i}$ instead of $x_{n,i}$ if it has already been computed: $x_{n+1} = -D^{-1}Lx_{n+1} - D^{-1}Ux_n + D^{-1}b$. The Gauss-Seidel method can also be written $x_{n+1} = x_n - (D + L)^{-1}(Ax_n - b)$, where $Ax_n - b$ is the current error, used to correct the current estimate. The **SOR** (successive over-relaxation) method corrects a little more, $x_{n+1} = x_n - \omega(D+L)^{-1}(Ax_n - b)$, with $\omega \in]1, 2[$. There are also non-stationary iterative methods ($x_{n+1} = f_n(x_n)$, *i.e.*, the function changes each time), such as the conjugate gradient (it assumes that the matrix A is symmetric: if not, solve $A'Ax = A'b$ instead). In all cases, the speed of convergence depends on the eigenvalues of iteration matrix.

To numerically compute an integral on a small interval $[a, b]$, the **Newton-Cotes** method approximates the integrand with a polynomial of degree 1 (trapezoid rule), 2 (Simpson) or more and evaluates it at evenly-spaced points in $[a, b]$ (use the Lagrange polynomials $L_i(x) = \prod_{k \neq i} (x - x_k) / (x_i - x_k)$ to find the weights in $\int_a^b f \approx \sum w_i f(x_i)$). The precision and speed of convergence (as the intervals become smaller) can be improved with Richardson extrapolation (Romberg method) or by using the first derivative, if known (extended trapezoid). By choosing both the weights and the subdivision points, **Gaussian quadrature** $\int_a^b f \approx \sum w_i f(x_i)$ can integrate exactly polynomials of degree up to $2n - 1$. This can be generalized to products of polynomials with a given function ϕ (orthogonal polynomials wrt ϕ), and, thus, integrals on an infinite interval (which can also be estimated by just truncating the interval).

The **Laplace transform** can transform some PDEs (e.g., the Black-Scholes one) into ODEs, which can often be solved explicitly. The Laplace transform $\mathcal{L}f(x) = \int_0^\infty e^{-xt} f(t) dt$ is often considered difficult to invert numerically: indeed, its values are weighted averages of the initial function f , and the weights e^{-xt} do

not change much. But if you have an analytic expression for $\mathcal{L}f$, you can recover f , in a numerically stable way, by integrating in the complex plane (Bromwich inversion formula). As usual, convergence can be improved even further with series acceleration methods (Euler summation).

There is also a chapter on copulas and their estimation.

The second part of the book presents 17 case studies.

Random data (bootstrap) can help see the effect of estimation risk in portfolio construction (you do not have the real values of the expected returns and the variance matrix, but just estimations).

Market sensitivity (beta) can be estimated with least median of squares, least trimmed squares, iteratively reweighted least squares (IRLS), shrinkage, bayesian estimates, exponentially weighted least squares, Kalman filter.

One can test technical trading rules (MACD) (the null hypothesis is that the profits of the strategy can be explained by the model, *i.e.*, that they are not significantly different from zero) with a simulated p -value: estimate a reasonable model (GARCH, etc.) for the data, sample from this model N times, look at the corresponding distribution of profits, and compare with the actual profits (from the real, non-simulated data) and conclude.

The risk-neutral density can be estimated from option prices by parametrizing the volatility surface in some way and using

$$q(x) = e^{r\tau} \left. \frac{\partial^2 \text{Call}}{\partial K} \right|_{K=x}$$

but the resulting second derivative may present singularities, fail to be positive, or fail to integrate to 1. Instead, one can look for the density as a mixture of gaussians: the option prices are then weighted sums of Black-Scholes prices, and the problem reduces to a non-linear regression.

American options can be priced with dynamic programming, finding V_t , the value of the option at time t if it has not been exercised yet, by regression $V_t \sim V_{t+1}$ (If $Z_t = \text{Max}(K - S_t, 0)$ is the payoff at time t , V_t is $V_t = \text{Max}(Z_t, e^{-r\Delta} E_t V_{t+\Delta})$ is called the (discrete) **Snell envelope** of Z). Dually, switching from the buyer to the seller, one can compute the optimal hedge (the details are not given):

$$V = \inf_{M \text{ martingale}} S \sup_t (e^{-rt} \text{Payoff}(t) - M_t)$$

The martingale M^* minimizing this quantity is not known, but heuristic choices often give good results and acceptable hedging strategies.

Stochastic volatility models, such as the Heston model

$$dS = \mu S dt + \sigma S dW_1 \\ d\sigma^2 = \alpha(\bar{\sigma}^2 - \sigma^2) dt + \beta \sigma dW_2$$

$$\text{Cor}(dW_1, dW_2) = \rho < 0$$

(prefer the Milstein scheme to simulate it: the Euler scheme does not converge very quickly for square root processes) can account for kurtosis, negative skewness, volatility clustering, but not the price of deep out of the money options: they can be explained by adding jumps to the model. The Fourier transform of the risk-neutral probability density of the log-price at expiry is available, and can be used to calibrate the model (option prices do not have a Fourier transform: multiply them by an exponential damping factor to make them square integrable). The calibration is more numerically stable if one uses implied volatilities instead of prices. Try to minimize several loss functions, e.g., the mean square error, the relative mean square error, or the mean absolute difference.

Here are a few ways of pricing an Asian option (whose payoff depends on the average price)

- Approximate the distribution of $A_T = \frac{1}{T} \int S_t dt$ as log-normal, Edgeworth log-normal, or reciprocal gamma (this is what it is, asymptotically, if prices are log-normal) with the desired first moments (they are easy to compute).
- Use inequalities, e.g.,

$$E[X_+] = E[E[X_+|Z]] \geq E[E[X|Z]_+],$$

and choose Z so that the difference

$$0 \leq E[X_+] - E[E[X|Z]_+] \leq \frac{1}{2} E\sqrt{\text{Var}(X|Z)}$$

be small.

- Solve the PDE (it is not straightforward to derive, but with a judicious change of numeraire, you get a 1-state-variable PDE).
- The Laplace transform of the option price wrt time can be computed explicitly (either using the PDE, or using the fact that a geometric brownian motion is a time-changed Bessel process).
- You can also use the double Laplace transform, wrt strike and time (or volatility).

A **Latin square** (Latin hypercube) of size n is an $n \times n$ matrix (an n^d array) of zeroes and ones, with exactly one 1 in each row and column (in each hyperplane). To select a Latin square at random, just take two permutations $\sigma_1, \sigma_2 \in \mathfrak{S}_n$, set $a_{\sigma_1(i), \sigma_2(i)} = 1$ and leave the other elements to zero. To sample n points in $[0, 1]^2$, using a Latin square to better spread them out, take n points at random in $[0, 1]^2$, take a Latin square at random, translate and rescale the random points to put them in each cell of the Latin square.

In dimension 1, a low discrepancy sequence (van der Corput) can be constructed as follows:

- Write increasing integers (0, 1, 2, 3, etc.) in base b (0, 1, 10, 11, 100, etc.);
- Write the digits in reverse order and add a decimal point in front of them (0, .1, .01, .11, .001, etc; *i.e.*, $0, \frac{1}{2}, \frac{1}{4}, \frac{3}{4}, \frac{1}{8}$, etc.).

This is not unlike the Farey sequence ($0, 1, \frac{1}{2}, \frac{1}{4}, \frac{3}{4}, \frac{1}{5}, \frac{2}{5}, \frac{3}{5}, \frac{4}{5}, \frac{1}{7}$, etc.), in number theory Sobol sequences generalize this idea in higher dimensions. To estimate the error of a quasi Monte Carlo computation using statistical methods, you may want to scramble the sequence first (to make it random).

The discrete maximum of an (arithmetic) Brownian motion (used by look-back options) can be computed using the z -transform.

Agent-based models can be used to describe **electricity prices** – the stylized facts are different from those of stock prices: seasonality, spikes, strong mean reversion, time-dependent volatility. The times series models used to price options on energy prices (these are real options: the optionality is the ability to switch the plant or generator on) have to account for those stylized facts. Swing contracts (a kind of American option, where you can buy a commodity at a given price, in an arbitrary quantity, every day in the year) can be priced with dynamic programming.

Mortgage prepayment is important to value MBS (mortgage-backed securities): borrowers with an improving credit rating are more likely to pre-pay their debt earlier to switch to lower rates – leaving only bad borrowers. Econometric forecast of the prepayment, using historical data, does not perform well, but the behaviour of the borrower, choosing to switch to new rates or not, can be modelled as an American option, and the optimal prepayment strategy can be computed via dynamic programming.

Structural models of default, used to price CDS (credit default swaps), compare the enterprise value (a geometric Brownian motion or some other stochastic process) with the debt of the company

$$\tau = \inf\{t : \text{Enterprise Value}_t \leq \text{Debt}\}.$$

Reduced form models of default directly model the default time, with an intensity process. For basket default swaps, one usually mixes those default times with a 1-factor Gaussian copula (the factor can be interpreted (chosen?) as the business cycle, some stock index, interest rates, etc.).

Monte Carlo simulations, in high dimensions, can be sped up and simplified as follows:

- Perform a principal component analysis (PCA) on the data to simulate, to reduce the dimension;
- Replace the continuous distribution (of the factors retained from the PCA) with a small number (10 to 2, depending on the importance of the factor) of points or “scenarios”;
- Sample from the resulting (discrete) distribution,

To estimate the parameters of a diffusion (or a jump-diffusion) via maximum likelihood, you need the transition probabilities. They can be estimated via Monte Carlo simulation: just split the intervals between two observations into smaller intervals, and simulate the diffusion using the Euler scheme. (Simulated maximum likelihood, SML)

The drift and diffusion coefficients of a diffusion process are its instantaneous first moments – higher moments are zero. Jump diffusion processes produce non-zero higher instantaneous moments.

$$dX = \mu(X)dt + \sigma(X)dW + dJ$$

$$\mu(x) = \lim_{h \rightarrow 0} \frac{1}{h} E[X_{t+h} - X_t | X_t = x]$$

$$\sigma^2(x) + \lambda(x)E[Y^2] = \lim_{h \rightarrow 0} \frac{1}{h} E[(X_{t+h} - X_t)^2 | X_t = x]$$

$$\lambda(x)E[Y^j] = \lim_{h \rightarrow 0} \frac{1}{h} E[(X_{t+h} - X_t)^j | X_t = x]$$

Non-parametric (kernel) estimators of those moments give non-parametric estimates of drift μ , diffusion σ , jump intensity λ and jump distribution Y (you have to make some more assumptions on the distribution of jumps, e.g. Gaussian with zero mean).

GARCH models (and their generalizations) can be estimated from the volatility surface, by considering it as a moment (in the generalized method of moments, GMM).

***The accountant's guide to the universe
Heaven and hell by the numbers
C. Hovey (2010)***

Could accounting be made more interesting by applying it to non-conventional enterprises, such as crime, or deciding whether one should go to heaven or hell? The book presents several economic and accounting notions (bounded rationality, free markets, creative destruction, present value, double-entry book-keeping, balance sheet, income statement) for those two examples. The result is pleasantly funny, but you will not learn anything: the notions of credit and debit are not explained (I vaguely remember from my accounting courses that “debit” means the opposite of what it means for my bank account – at least, half the time), some of the numeric examples are wrong (the publisher dropped some of the credit or debit columns) or have to be accepted on faith (present value computations), and the reluctance to use negative numbers complicates things (you never know in which direction the money is going).

Computer scientists will prefer M. Kleppmann's graph-theoretic explanations.

***Quantifying and modeling
long-range cross-correlations
in multiple time series
with applications to world stock indices
D. Wang et al. (2011)***

Random matrix theory (RMT, comparing the distribution of the eigenvalues of a sample correlation matrix with the distribution coming from the sample correlation matrix of iid gaussian variables) can also be applied to cross-correlation. In a financial context, you should look at both the correlation of returns and absolute returns – the latter decay more slowly. Using a 1-factor (sic) model, the authors find 10 uncorrelated indices that may form a low-risk portfolio. (Other methods could be used, e.g., detrended cross-correlation analysis, DCCA).

***Predicted and verified
deviations from Zipf's law
in ecology of competing products
R. Hisano et al. (2011)***

Zipf's law (stable distribution with power law tails) appears in the following situation:

- A finite population of “entities” I_t changes with time, with entities entering or leaving the universe according to a Poisson process;
- Each entity $i \in I_t$ is described by a geometric Brownian motion $S_i(t)$, starting with some random value at time t_i (when i enters I);
- Then, for $t \gg 1$ fixed (and $|I_t| \gg 1$), the distribution of the $S_i(t)$, $i \in I_t$, has power law tails.

***Utility theory front to back
inferring utility from agents' choices
A.M.G. Cox et al.***

The optimal investment problem often assumes that the utility function is given, but determining which utility function faithfully describes the preferences of a given investor is tricky, and usually done by looking at her choices when faced with 1-period investment problems. This article tries to infer the utility function from the actual (observed) consumption choices in a continuous-time framework (deterministic or stochastic (Black-Scholes)). Not all consumption choices come from a utility function (they have to satisfy some PDE), and the utility function (or, even, the sign of the relative risk aversion) is not entirely determined by the consumption choices.

***Topological isomorphism
of human brain and financial market networks
P.E. V ertes et al. (2011)***

The growing graph, minimum spanning tree and the various graph-theoretical measures (modularity, etc.) of (the variance matrix of) fMRI and financial data are very similar.

***The common component
of idiosyncratic volatility
J. Duarte et al. (2011)***

One more factor should be added to the Fama-French model

returns \sim market + size + book-to-market,

corresponding to the “idiosyncratic volatility” (the first principal component of the variance matrix of the residual return – it is always a good idea to add statistical factors to your risk model, to catch anything you may have overlooked, or anything that may have changed); it can be interpreted as the position in the business cycle.

*An empirical analysis
of dynamic multiscale hedging
using wavelet decomposition*
T. Conlon and J. Cotter (2011)

You can assess the influence of the investment horizon on the minimum variance portfolio (or mean-variance, or mean-Gini – **Gini’s mean difference** is $E[\frac{1}{2}|X - Y|] = 2 \text{Cov}(X, F_X(X))$, where $X \perp\!\!\!\perp Y$ are distributed as the portfolio returns) by looking at the wavelet transforms of the returns time series and expressing the variance matrix, the portfolio weights, the higher moments of the portfolio, etc., as functions of the wavelet coefficients (maximum overlap discrete wavelet transform). Only the “optimal hedge ratio” case, *i.e.*, the 2-asset case, is treated (one asset is the portfolio you hold and want to hedge, its weight is imposed to be 1, the other is the hedge portfolio, already computed, whose weight has to be determined).

Anchor modeling
L. Rönnbäck et al. (2010)

Anchor modeling is a rebranding of entity-relation (ER) modeling, that describes a database schema in terms of actors (entities), attributes (historicized or not), knots (dimension tables, *i.e.*, attributes with a small or fixed number of values), ties (relations) and, more importantly, advocates that changes to the database be implemented as extensions rather than modifications – this ensures backward compatibility.

*Financial models with Levy processes
and volatility clustering*
S.T. Rachev et al. (2011)

The main claim of the book is that non-gaussian distributions should and can be used in practice, to model stock prices, to price options, to optimize portfolios – even if those distributions do not have an easy-to-use probability distribution function, their characteristic function is simple, and sufficient for all practical purposes – at worst, you have to compute one or two integrals, via the FFT (Fast Fourier Transform), quadratures, or Monte Carlo simulations).

(Beware: the book has apparently not been proof-read and contains innumerable incorrect formulas; many explanations are also seriously lacking – the original articles are often clearer.)

The gamma distribution $\Gamma(c, \lambda)$ is the law of $Y_1 + \dots + Y_c$ where $Y_i \sim \text{Exp}(\lambda)$ iid. The **variance gamma** distribution $\text{VG}(c, \lambda_+, \lambda_-)$ is the law of $G_+ - G_-$ where $G_{\pm} \sim \Gamma(c, \lambda_{\pm})$. The **inverse Gaussian** distribution

is the law of the first time at which a random walk reaches a given value $\tau = \text{Min}\{t : X_t = m\}$.

Stable (or α -stable) distributions can be defined by (and used through) their characteristic function. One can define many variants of the stable distributions, *e.g.*, by cutting the tails and replacing them with Gaussian tails (truncated stable distributions) or by tweaking the characteristic function (tempered stable distributions) or (equivalently) by multiplying the Lévy measure of the α -stable distribution (α -stable distributions are infinitely divisible, and can therefore be expressed using the Lévy-Khinchine formula) by some tempering function (*e.g.*, e^{-t}).

(Tempered) α -stable distributions can be fitted either by fitting their characteristic function, or via maximum likelihood, using a numerical approximation of their density function.

A **compound Poisson process** is a process of the form $X_t = \sum_{k=1}^{N_t} Y_k$, where the Y_k are iid (arbitrary distribution) and $N_t \sim \text{Pois}(t\lambda)$ is a Poisson process. A **pure jump process** is a limit of compound Poisson processes: let $S \subset \mathbf{R}$ be a countable set (jump sizes), $\lambda : S \rightarrow \mathbf{R}_+$ some function, $N_t^{\lambda(s)}$ Poisson processes of intensity $\lambda(s)$, and $Y_t = \gamma t + \sum_{s \in S} s N_t^{\lambda(s)}$. In the expression of the characteristic function of Y_t , one can replace the measure

$$\nu(A) = \sum_{s \in S \cap A} \lambda(s)$$

(expected number of jumps of size in A per unit of time) with a more general measure – it is the Lévy measure of the pure jump process.

A non-Gaussian infinitely divisible random variable X_1 (*e.g.*, gamma, α -stable, inverse gaussian, variance gamma) defines a pure jump process.

Non-decreasing pure jump processes (gamma, inverse gaussian, Poisson) can be interpreted as a “cumulated trading activity” and used to define time-changed Brownian motions: the inverse gaussian gives the **normal inverse gaussian** (NIG); the gamma distribution gives the **variance gamma** process.

A **Lévy process** is a process with independent stationary increments, càdlàg and stochastically continuous

$$\forall t \quad \forall \varepsilon > 0 \quad \lim_{s \rightarrow t} P[|X_s - X_t|] = 0.$$

It is the sum of a Brownian motion and a pure jump process. An exponential Lévy process is the exponential of a Lévy process.

It is possible to simulate a random variable from its characteristic function (if the tails are not too fat), using

$$f(x) \leq \frac{1}{2\pi} \int_{-\infty}^{\infty} |\phi| \\ f(x) \leq \frac{1}{2\pi x^2} \int_{-\infty}^{\infty} |\phi''|,$$

by rejection – it is easy to sample from

$$g(x) \propto \text{Min} \left(\int_{-\infty}^{\infty} |\phi|, \frac{1}{x^2} \int_{-\infty}^{\infty} |\phi''| \right).$$

Lévy processes can be simulated, by writing them as

$$X_t = Y_t^\varepsilon + Z_t^\varepsilon,$$

where Z_t^ε is the compound Poisson process containing the jumps of size larger than ε , and Y_t^ε is either neglected or replaced by an easy-to-simulate process (e.g., a Brownian motion). There are ad hoc algorithms to simulate from the tempered α -stable distributions and a few special cases (NIG, VG, etc.).

The Girsanov theorem links the (known) real-world probability \mathbf{P} to the risk-neutral one \mathbf{Q} (needed to compute option prices).

For elliptical distributions,

$$f(x) \propto g((x - \mu)' \Sigma^{-1} (x - \mu)),$$

the correlation completely describes the dependence. Elliptical distributions can account for the fat tails and tail-dependence in asset returns but, because of radial symmetry, not for the larger dependence in the lower tail. Elliptic distributions can be written as

$$X = \mu + RAS$$

where $S \sim U(\mathbf{S}^{d-1})$, R is a random variable in \mathbf{R}^d and A is a $d \times d$ matrix, with $R \perp\!\!\!\perp AS$. Instead, one can let the distribution of R depend on the direction AS : let $s : \mathbf{R}^d \rightarrow [0, 1]$ be a function, measuring the tail dependence in a given direction, $(R_t)_{t \in [0, 1]}$ a family of positive random variables, and consider the **multi-tail generalized elliptic distribution**

$$X = \mu + R_{s(AS)} AS.$$

The tail function s could come, for instance, from the first principal component v_1 of $\Sigma = AA'$,

$$s(x) = \alpha_+ \mathbf{1}_{\langle x, v_1 \rangle > 0}(x) + \alpha_- \mathbf{1}_{\langle x, v_1 \rangle < 0}(x).$$

Portfolios of non-gaussian assets can be optimized with a scenario-based approach (fit the data, simulate returns, optimize of those scenarios), which also allows for more flexibility the measure of risk.

Option prices can be computed for tempered stable processes, but some integrals remain – there are convergence problems with (non-tempered) stable processes: that is why **tempered** stable distributions were introduced.

Options can also be priced with GARCH models (e.g., with truncated stable innovations), in discrete time, but more technical complications emerge (non-unique risk-free measure, etc.). GARCH parameters, when used for option pricing, are usually estimated from option prices, completely ignoring the underlier – models with non-gaussian residuals may be able to reconcile the underlier and the options.

The following pictures explain why early exercise of an American call option is never optimal (it is always more profitable to sell the American option as a European one than to exercise it) and why early exercise of an American put option is sometimes optimal (if it were not, the price would be the same as that of a European put, but that is not possible because, for a deep-in-the-money option, it is more profitable to exercise it immediately rather than sell it at the same price as a European option – however, this does not tell you *when* to exercise the option).

Mixed effects models and extensions in ecology with R

A.F. Zuur et al. (Springer, 2009)

This book explains, with no mathematical overhead, what to do when the assumptions of the linear regression model (linearity, gaussian noise, homoscedasticity, independence – they can be checked by plotting the residuals versus the fitted values, the predictors, and with a Gaussian quantile-quantile plot) are not satisfied.

Additive models use splines or local regression to account for non-linearity.

```
gam: : gam(y~loess(x, span=.5))
mgcv: : gam(y~s(x, fx=FALSE, k=-1, bs="cr"))
mgcv: : gam(y~s(x)+s(x, by=g==1)+factor(g))
```

Generalized least squares (GLS) can take care of heteroscedasticity (you can also transform the data); there are many specifications of the variance (group-dependent, linear in one of the predictors, etc.); you can check that the heteroscedasticity has been removed by plotting the normalized residuals.

```
nlme: : lme(y~x*g, weights=varIdent(form=~1|g))
```

When the observations are grouped, you may be tempted by a 2-stage approach: first compute a regression in each group, then study the distribution of the corresponding regression parameters (either fit their distribution, or regress them against group-specific variables). Mixed models are a more efficient 1-step procedure.

```
# Random effects
nlme: : lme(y~1, random=~1|g))
# Random intercept
nlme: : lme(y~x, random=~1|g))
# Random intercept and slope
nlme: : lme(y~x, random=~1+x|g))
```

It turns out that mixed models can be described in two equivalent ways: either a procedural way, as above (à la Bugs), or by just specifying the shape of the variance

matrix, as in a GLS model (for instance, the random effects model corresponds to a block-diagonal correlation matrix, with ρ in all the off-diagonal entries of the diagonal blocks).

```
gls(y~x,
    correlation=corCompSymm(form=~1|g),
    method="REML")
```

This also works with splines

```
mgcv::gamm(y~x1+s(x2),random=list(g=~1)),
temporal correlation (beware of missing values: if you
remove holes in a time series, i.e., skip values, the auto-
correlation plots will be incorrect)
```

```
gls(y~x,correlation=corAR1(form=~t))
```

```
gls(y~x,
    correlation=corARMA(
        c(.3,-.3), # starting values
        p=2,q=0,form=~t))
```

```
mgcv::gamm(y~x,
    correlation=corAR1(form=~t|g),
    weights=varIdent(form=~1|g)),
temporal correlation with irregularly-spaced observa-
tions
```

```
gls(y~x,correlation=corGaus(form=~t|g))
```

or spacial correlation

```
gls(z~u,correlation=
    corGaus(form=~x+y,nugget=TRUE)).
```

Spacial correlation manifests itself by clusters of resid-
uals. The variogram,

$$\gamma(\mathbf{h}) = \frac{1}{2} \text{Var}[Z(\mathbf{x} + \mathbf{h}) - Z(\mathbf{x})]$$

is useful for weakly stationary and isotropic data:
`gstat::bubble`, `gstat::variogram`, `nlme::Vario-`
`gram`, `geoR::variog`.

The restricted maximum likelihood (**REML**) gives un-
biased variance estimators. Even for linear regression,
 $Y = X\beta + \varepsilon$, the maximum likelihood estimator of the
variance is biased – the more parameters, the larger
the bias. However, if A is a matrix such that $AX = 0$,
then $AY = A\varepsilon$, *i.e.*, $AY \sim N(0, \sigma^2 AA')$, gives an unbi-
ased estimator of the variance σ^2 . The same procedure
can be applied to a mixed model, $Y = X\beta + Zb + \varepsilon$,
 $b_i \sim N(0, D)$, $\varepsilon_i \sim N(0, \Sigma_i)$, which can be written as
 $Y_i \sim N(X_i\beta, V_i)$, where $V_i = Z_i D Z_i' + \Sigma_i$: if $AX = 0$,
then $Y_i \sim N(0, AV_i A')$ can be used to estimate the
variance.

The model selection procedure goes as follows: in-
clude as many fixed effects and interaction terms as
possible; determine the random components (REML);
determine the fixed components (ML); fit the model
(REML). Use the following functions: `drop1`, `step`,
`anova`, `lmtest::lrtest`.

Count data are not gaussian and can be modeled with
a Poisson ($\text{Var } X = EX$), negative binomial (number
of successes until k failures in a series of independent
Bernoulli trials, overdispersed: $\text{Var } x \geq EX$), or bino-
mial (count data in $\llbracket 0, n \rrbracket$, binary data) distribution.
These belong to the natural exponential family,

$$f(x, \theta) = h(x) \exp(\theta \cdot x - A(\theta)),$$

a special case of the exponential family

$$f(x, \theta) = h(x) \exp(\eta(\theta) \cdot T(x) - A(\theta)).$$

To use those distributions in a generalized linear model
(GLM), start with the description of the maximum-
likelihood estimation of the linear model

$$\eta_i = \sum_j \beta_j x_{ij}$$

$$y_i \sim N(\eta_i, \sigma)$$

and replace the gaussian distribution $y_i \sim N(\eta_i, \sigma)$
with one of the following.

$$y_i \sim \text{Pois}(\exp \eta_i)$$

$$y_i \sim \text{NB}(\exp \eta_i, k)$$

$$y_i \sim \text{Binom}(1, \text{logit}^{-1} \eta_i)$$

$$y_i \sim \text{Binom}(n_i, \text{logit}^{-1} \eta_i)$$

If there is some over-dispersion, but not too much,
you can tweak the likelihood to account for it (quasi-
maximum-likelihood).

```
glm(y~x, family=poisson)
```

```
glm(y~x, family=quasipoisson)
```

```
MASS::glm.nb(y~x,link="log")
```

```
mgcv::gam(y~s(x),family=negative.binomial(1))
```

```
mgcv::gam(y~s(x),family=binomial)
```

```
glm(y~x,family=binomial) # logit
```

```
glm(y~x,family=quasibinomial)
```

```
VGAM::vglm(y~x,family=negbinomial)
```

For binary data, prefer the clog-log link to the logit
or probit if the numbers of zeroes and ones are very
different.

Those models can be extended to zero-truncated (re-
move the zeroes), zero-inflated (mixture of zero and a
Poisson or negative binomial distribution), zero-altered
(aka hurdle or 2-part: mixture of zero and a zero-
truncated distribution) distributions.

```
VGAM::vglm(y~x,family=posnegbinomial)
```

```
pscl::zeroinfl(y~x|g,
```

```
    dist="poisson",link="logit")
```

```
pscl::hurdle(y~x|g,
```

```
    dist="negbin",link="logit")
```

The opposite of the log-likelihood, to be minimized, is
a sum; by adding some constant (the log-likelihood of
a saturated model), we can ensure that the terms are
positive, the deviances – we are minimizing a sum of
“squares”.

The generalized linear model (GLM) minimizes the
sum of deviance residuals; if, instead, we minimize the
sum of Pearson residuals, we can modify it to account
for dependency between observations, as with mixed
models: this method is called **generalized estimat-**
ing equations (GEE) (the equations in question are
the first order conditions of the minimization problem:
the derivatives of the modified sum of squared residu-
als, wrt to the parameters to estimate, should be zero).

```
geepack::geeglm(y~x,
```

```
    family=poisson,id=g,corstr="ar1")
```

It is possible, but more complicated, to merge mixed models and generalized linear models (in the log-likelihood, you have to integrate out the random effects, e.g., with quadratures or Monte Carlo simulations or simpler/faster but more biased methods).

```
MASS::glmPQL(y~x,random=~1|g,
  family=binomial)
lme4::lmer(y~x+(1|g),family=binomial)
glmmML::glmmML(y~x,cluster=g,family=binomial)
mgcv::gamm(y~s(x),random=list(g=-1),
  family=poisson)
library(help=BRugs)
```

All about high-frequency trading M. Durbin (McGraw Hill, 2010)

High-frequency traders are the descendants of yesterday's market-makers, trying to profit from the bid-ask spread, but the notion now encompasses all strategies relying on execution speed, many of which are based on the market micro-structure (the order book).

High-frequency trading (HFT) typically combines several asset classes (stocks, ETFs, futures, options) and many exchanges and alternative trading systems (ATS, the best known being the ECN, and the various dark pools – contrary to exchanges, they do not display quotes). Passive traders send **limit orders** (executed at a given price, if and when there is a counterparty) while active traders submit **market orders** (executed immediately against the available limit orders). A **quote** is the datum of the current best bid (highest limit buy order), best ask (lowest limit sell order) and the corresponding volumes. The depth of the order book (other limit orders, with their volumes) is also of interest.

There are several types of traders: the **investor** (aka buy-side, *i.e.*, they buy, and only sell as a consequence, sometimes called liquidity-taker); the **market-maker** (aka sell-side, specialist, liquidity-provider), who uses mainly limit orders, and earns the spread between the bid and the ask (he buys at the bid and hopes to sell at the offer shortly after) – there is some risk because the prices do change: market makers will reduce the spread to reduce this risk; the **arbitrageur** uses relations known to hold between the prices of different assets, for instance, the price of a stock should be the same on all exchanges, the put and call option prices should be related through the put-call parity, etc.; the predictor is similar to the arbitrageur, but relies on relations that hold on average, over time (statistical arbitrage), e.g., pairs trading. The high-frequency trader is just a market-maker; he is on the sell-side; the **algorithmic trader** is his counterpart on the buy-side, and tries to minimize market impact. Some markets impose a “minimum spread”: there is a rebate for limit orders and a fee for market orders; this is a kind of “minimum revenue” for market-makers.

Here are some investor strategies:

- Join the makers: send a limit order at the current

bid or ask, and wait for market orders to come, especially if there is a strong imbalance between the bid and ask volumes – over the long time, you will get the VWAP.

- Poke for bargains: send a (limit) order inside the spread, and see if there is any reaction – market makers may be willing to trade at a lower spread than currently displayed – some exchanges allow hidden limit orders, called reserve orders – and repeat with a price closer to the bid or ask until someone reacts.
- Iceberg order: limit order whose large size is hidden (you do not have to do it yourself: the exchange can do it for you, and only display x shares at a time).
- Time slicing: similar to the iceberg order, but wait some random time before displaying the next slice.
- Out-smart the market-makers: coax the market-makers into following one of their well-known strategies (e.g., by mimicking a sell iceberg when you actually want to buy).

Here are a few market-maker strategies:

- Wait for the other side: if you bought at the bid, send a limit sell order at the ask and wait, hoping that the price does not change.
- Lean your market: instead of sending a limit sell order at the ask, you can lower the ask, reducing the spread and your potential benefit, but increasing your chances of seeing the order filled.
- Scratch the rebate: in markets with a rebate for limit orders, you can reduce the ask down to the bid and still earn the rebate.
- Hide your best prices: keep the spread wide, wait for limit orders, and fill them with market orders (you do not earn the rebate). Market-makers have therefore two spreads: a wide passive spread, and a narrower active spread.
- Take out slow movers: market-makers' spreads moves as the prices move; a market-maker's active spread may cross the passive spread of a slower market-maker.
- Penny jump: if there is a big order in the order book, put a smaller one just before: the big order will limit your losses (if you buy the shares and the price moves in the wrong direction, you can sell them back).
- Push the elephant: when a large buy limit order comes, you may suspect a “join-the-makers” strategy, *i.e.*, that the investor is willing to pay slightly more; you can try to increase the price, by raising the ask (buy a small quantity at a higher price); the elephant may raise his bid a few times, after which you can profit from him. This is a kind of front-running, but using only public information (probably legal); it is also a form of price manipulation (which may or may not be legal).
- Tow the iceberg: same strategy, with an iceberg (hidden elephant).
- Delta-hedging: Market-maker strategies for stocks involve a round-trip: you buy at some price and sell the same asset later at another price (or the opposite). For options, because of the large number of contracts, this may not be possible: instead of com-

pleting the round-trip, you may simply delta-hedge.

- Jump the delta: Look for large option trades, estimate the amount of stock needed to hedge the position, expect a trade in the underlying, and try to get in front of it (to avoid this front-running, market-makers may prefer to hedge with an index instead of the underlier).

Here are some arbitrage and statistical arbitrage strategies:

- ETF versus basket, futures versus basket, futures versus ETF, futures versus futures (on the same underlying, with different lot sizes);
- Futures versus options (put-call parity);
- Volatility arbitrage: option prices or, equivalently, implied volatility, should be a smooth function of strike and time-to-expiry: some contracts may be over- or under-priced;
- Spread arbitrage: some composite options, such as spreads, strangles, straddles, butterflies, are quoted, and their price may differ from that suggested by puts and calls;
- Pairs trading: estimate the fair price or “micro-price” of a stock, as mid-price + α , and look for bids or asks on the wrong side of the micro-price.
- Futures lag (not explained clearly): try to estimate how much each stock of an index lags behind the futures;
- Event-driven: when a dividend is announced, the price will jump or drop almost immediately, but you may have time to buy or sell just before (or, at least, before it moves all the way); dividends also impact option prices, directly (they appear in the formula), and indirectly (through the price changes);
- Trend-following, e.g., you can compare 5-minute and 5-hour moving averages and buy or sell when they cross;
- Mean-reversion: the market tends to over-react, e.g. to imbalances in the order book.

The IT infrastructure is geared towards performance (C++, distributed programming, load balancing, TCP/IP off-load engine (TOE), GPU, parallel processing – no mention of FPGA), relies on good programming practices (design for change), an even-driven architecture (“pub-sub”, *i.e.*, “publish-subscribe”, either in hardware (TMX Message Switch) or in software (RendezVous, by Tibco)), and direct market access through collocation (put your machines in the same building as the exchange) and the use of native APIs (each exchange has its own API, faster than the FIX standard).

It has the following components:

- Thinkers contain the strategies, their parameters, the universe (set of assets), the compliance rules.
- Listeners receive data from the exchange, filter it for erroneous or unnecessary data (large changes, small quantities, changes that immediately revert), keep track of the state of the market (open/closed, high/low volume, etc.).
- Pricers compute prices, alphas, micro-prices (price +

α + correction for the inventory we have), bids, asks; for options, the implied volatility (volatility curve or surface, corrected for inventory) is first computed, and then used to compute the option prices (if the model is complicated, they may be precomputed), bids and asks.

- Traders send trades to the exchange; they usually ask the exchange to perform some safety controls (automatically remove the quotes if there is too much activity), and check the heartbeat of the system (remove all the quotes if the exchange does not receive the next heartbeat). The passive trading (limit orders) part is called the “quoting engine” and the active trading (market or IOC (immediate-or-cancel) orders) part is the “electronic eye”. There is also a component to locate assets we may want to short, and another one to perform (delta-, and also rho-) hedging.
- Managers keep track of the positions (inventory), look out for bad trades, measure risk (exposure, *i.e.*, size of the positions, Greeks, what-if analyses, etc.), compute the P&L (the theoretical (“front office”) one, using the micro-prices, used for trading, and the “mark-to-market” (“back-office”) one, using actual market prices), ask the traders to stop trading or reduce their position if some risk limits are exceeded, completely stops the system in case of a problem (the connection to the exchange was lost, one of the components crashed, etc.).

High-frequency trading (HFT) leads to lower bid-offer spreads, better price consistency (faster information transfer between various exchanges), and is not subject to human panics (I do not entirely agree on this point: the failure mode is just different, but can be as dramatic); however, many strategies are akin to price manipulation, increase volatility (I partly disagree: HFT stabilizes volatility, but maintains it above a certain level), bad trades can lead to contagion and cascade effects, most of the trading now seems to be unrelated to the underlying companies.

Securities lending, shorting and pricing **D. Duffie et al. (2002)**

Short selling has an impact on prices: the price is the value of the stock plus that of the option to lend it to short sellers. The value of the option depends on supply, demand, and the bargaining power balance between lenders and borrowers.

Portfolio consumption choice with stochastic investment opportunities and habit formation in preferences **C. Munk (2007)**

To ensure that future consumption does not fall below the habit level, increase the weight of bonds reduce that of stocks.

Dynamic asset allocation with stochastic income and interest rates

C. Munk and C. Sørensen (2009)

Considering labour income in optimal long-term portfolio choice seems to suggest that labour income is equivalent to a bond, so that you can reduce or completely remove bonds from your portfolio. This is no longer true if income or interest rates are stochastic and dependent, e.g., if your income (employment status) fluctuates with the business cycle.

***The variance gamma process
and option pricing*
D.B. Madan et al. (1998)**

A gamma process is an infinitely divisible process X_t with $X_1 \sim \text{Gamma}$.

A variance gamma process is a brownian motion with drift evaluated at random times given by a gamma process (a subordinated process). Since it has finite variation, it can be decomposed as the difference of two non-decreasing (gamma) processes.

***Modelling the spacial dynamics
of culture spreading
in the presence of culture strongholds*
L. Lizana et al. (2011)**

Information spreads on a network (or a lattice), randomly, from a central source, with new information replacing old information, creating a concentric wave pattern. The same phenomenon also describes word distribution, newly-coined words replacing older ones – for instance, Japanese swear words (ばか, あほ, etc.) seem to emanate from the old capital, Kyōto.

***Temporal patterns of happiness and
information in a global social network:
hedonometrics and twitter*
P.S. Dodds et al. (2011)**

For each tweet, the authors compute:

- A happiness level, between 0 and 10, defined as a weighted average of the happiness level of the words it contains – the words were assigned a happiness level manually, using volunteers (or underpaid workers) at Amazon’s Turk. (The article suggests that the data is available online.) Stopwords should be removed: they muddy the signal.
- The word diversity, measured by entropy $\sum p \log p$ or some of its generalizations $\sum p^\alpha$ (e.g., $\alpha = 2$ is related to the Gini coefficient); it can be converted into an “effective number of words” (the number of words yielding the same entropy if they all have the same frequency). Word diversity and happiness seem unrelated.

One can look at seasonal changes (there are weekly and daily patterns), the effects of some events (Christmas, financial crises, etc.), or compare texts that contain a given word or expression with the background happiness and word diversity. The differences are displayed in a *word shift graph*, that shows the words with the largest contributions to the change in happiness, and whether it is an increase or a decrease in the frequency of a positive or negative word.

The lack of context may pose problem: “children” is a positive word, but when it appears together with “victim”, it (incorrectly) reduces the negativity. Since words are not stemmed, there can be an increase in “dead” and a decrease in “die” (this may be meaningful: it is a change in tense).

Classical optimization studies problems of the form

$$\begin{aligned} &\text{Minimize } \phi(x) \\ &\text{Where } x \in K \end{aligned}$$

If ϕ is \mathcal{C}^0 and K compact, the problem has a solution. The continuity condition can be relaxed to **lower semi-continuity**, *i.e.*,

$$\liminf_{x \rightarrow x_0} \phi(x) \geq \phi(x_0)$$

instead of

$$\lim_{x \rightarrow x_0} \phi(x) = \phi(x_0),$$

i.e., there can be some noise in the function, but it must be “upwards”, so as not to affect the minimization problem.

If ϕ is differentiable and $K = \mathbf{R}^n$, a necessary condition for x to be a solution is that the gradient in x be zero: $D\phi = 0$. If the problem is constrained, *i.e.*, $K \subsetneq \mathbf{R}^n$, the condition becomes

$$\forall y \in T_x K \quad D\phi(x) \cdot y \geq 0$$

where $T_x K$ is the tangent cone of K at x (in particular, it is \mathbf{R}^n if x is interior). If, in addition,

$$\forall h \in T_x K \setminus \{0\} \quad D^2\phi(x)(h, h) > 0$$

then the point is a (local) minimum.

The **Kuhn and Tucker condition** (aka **Lagrange multipliers**) translate these conditions into useable formulas (by explicitly describing the tangent cone) when the set of admissible solutions is of the form:

$$K = \{x \in \mathbf{R}^n : \forall i \in \llbracket 1, p \rrbracket \quad b_i(x) \leq 0\}.$$

The **Lagrangian** is

$$L(x, \lambda) = \phi(x) + \lambda \cdot b(x).$$

If x is a solution, then there exists $\lambda \in \mathbf{R}^n$ such that

$$\begin{aligned} DL(x, \lambda) &= 0 \\ \lambda \cdot b(x) &= 0. \end{aligned}$$

(You may need to remove a few pathologies, such as linear dependencies between the $Db_i(x)$.)

Calculus of variations is still interested in minimization problems, but this time, we are looking for a function that minimizes some integral:

$$\begin{aligned} &\text{Find } x : [t_0, t_1] \longrightarrow \mathbf{R}^n \mathcal{C}^1 \\ &\text{to minimize } \int_{t_0}^{t_1} F(t, x(t), \dot{x}(t)) dt \\ &\text{such that } x(t_0) = x_0 \text{ and } x(t_1) = x_1. \end{aligned}$$

(The final condition can be replaced by a set of equalities or inequalities on the coordinates of $x(t_1)$.) Penalized regression can be formulated in this way. The

local Euler equation is a necessary condition, in the case of equality constraints ($x(t_1) = x_1$):

$$\frac{d}{dt} \frac{\partial F}{\partial \dot{x}} = \frac{\partial F}{\partial x}.$$

(To prove it, assume that x is a solution, take a \mathcal{C}^1 function h with $h(t_0) = h(t_1) = 0$, consider the cost of $x + \varepsilon h$, integrate by parts.) This condition remains valid if you are looking for a piecewise \mathcal{C}^1 function instead, provided you write it as an integral

$$\frac{\partial F}{\partial \dot{x}} = \int \frac{\partial F}{\partial x} dt + \text{constant}.$$

The constraints $x(t_1)_i = x_{1i}$ or $x(t_1)_j \geq x_{1j}$ or $x(t_1)_k \leq x_{1k}$ lead to the **transversality conditions**: $\frac{\partial F}{\partial \dot{x}_i} \geq 0$ or $\frac{\partial F}{\partial \dot{x}_i} \leq 0$ if the condition is binding (for a minimization problem, the inequality is in the same direction as the constraint); $\frac{\partial F}{\partial \dot{x}_i} = 0$ if the condition is not binding or if there is no constraint (there is no transversality condition for equality constraints).

If the $F(t, \cdot, \cdot)$ are convex for all t , then those conditions are sufficient.

A **Lagrange problem** is a generalization of calculus of variation:

$$\begin{aligned} &\text{Find } u \\ &\text{to minimize } \int_{t_0}^{t_1} F(t, x(t), u(t)) dt \\ &\text{where } \dot{x}(t) = f(t, x(t), u(t)) \\ &\text{and } x(t_0) = x_0 \end{aligned}$$

Since u controls x via the ODE, this is sometimes called an **optimal control** problem. There are equivalent formulations where the cost function only depends on the final value of x (Mayer formulation). One usually imposes some conditions on f to avoid explosions, *e.g.*, Lipschitz and linear growth. The **Hamiltonian** of the problem is

$$F(t, x, u, p) = F(t, x, u) + p \cdot f(t, x, u).$$

If u is a solution of the Lagrange problem, then there exists a function p , called the adjoint state, such that

$$\begin{aligned} \dot{p}(t) &= -\frac{\partial H}{\partial x}(t, x(t), u(t), p(t)) \\ p(t_1) &= 0 \text{ (transversality condition)} \\ H(t, x(t), u(t), p(t)) &= \min_v H(t, x(t), v, p(t)). \end{aligned}$$

These equations (if you want to solve them, also add $\dot{x} = \partial H / \partial p$, which comes from the definition of H) are called the **Pontryagin principle** (or the hamiltonian system, if you remove the one with the minimum). By adding a few more conditions, you can have a set of sufficient conditions.

One can use dynamic programming to solve the same (Lagrange) problem. Let $J(t, \xi, u)$ be the cost on $[t, t_1]$

if $x(t) = \xi$ and $J(t, \xi)$ the next cost on $[t, t_1]$ if $x(t) = \xi$. Then, the dynamic programming principle states that

$$J(t, \xi) = \inf \left(\int_t^s + J(t, x(s)) \right).$$

The dynamic programming equation (a PDE involving J : the Pontryagin principle was a system of ODEs) is a necessary condition, under some continuity assumptions:

$$\inf_v H(t, \xi, v, \pi) = -\frac{\partial V}{\partial t}.$$

(Those continuity assumptions are not reasonable, but you can get rid of them if you consider viscosity solutions.)

Let $X^{t,x}$ be the solution of

$$\begin{aligned} dX &= \mu du + \sigma dW \\ X_t^{t,x} &= x. \end{aligned}$$

For $f : \mathbf{R}^n \rightarrow \mathbf{R}$, let

$$Af(x) = \lim_{h \rightarrow 0} \frac{E[X_{t+h}^{t,x}] - f(x)}{h}.$$

The operator A is called the generator of the diffusion,

$$A = \mu \frac{\partial}{\partial x} + \frac{1}{2} \text{tr} \left(\sigma \sigma' \frac{\partial^2}{\partial x \partial x'} \right).$$

The expectation $v(t, x) = E[g(X_T^{t,x})]$ satisfies

$$\begin{aligned} \frac{\partial v}{\partial t} + Av &= 0 \\ v(T, \cdot) &= g \end{aligned}$$

(This result can be generalized to $\dot{v} + Av + kv + f = 0$ with initial conditions (Cauchy problem and Feynman-Kac representation) or to $Au - ku + d$ with boundary conditions (Dirichlet problem).) This gives a correspondence between expectations and solutions of PDEs: we can use PDE tools (e.g., finite elements) to estimate expectations or use stochastic tools (e.g., Monte Carlo simulations) to solve PDEs.

Let X be the stochastic process describing the price of an asset, u be a trading strategy (control process, to be determined), $J(t, x, u)$ the expected utility on $[t, T]$ of the wealth resulting from the trading strategy u if the initial price is $X_t = x$, and $V(t, x)$ the expected utility of the optimal strategy. By changing X , we can assume that the cost J only depends on the final value: $J(t, x, u) = E[g(X_T) | X_t = x]$. The control process can be: deterministic (open loop control), Markovian (u_s depends on the current price X_s , but not on previous prices) or adapted to \mathcal{F}_X (feedback control: it can depend on all previous prices). If V is smooth (it is, under restrictive but reasonable assumptions: Lipschitz, bounded),

$$V(t, x) = \sup_u E[V(t + \varepsilon, X_{t+\varepsilon}^u)]$$

(dynamic programming principle, directly applicable in a discrete-time framework). By letting $\varepsilon \rightarrow 0$, we

have the Hamilton-Jacobi-Bellman (HJB) partial differential equation. If V is not smooth, we still have inequalities of the form (for $s > t$)

$$\begin{aligned} V(t, x) &\geq \sup_u E[\liminf V(s)] \\ V(t, x) &\leq \inf_u E[\limsup V(s)] \end{aligned}$$

and would look for viscosity solutions of the PDE.

The optimal stopping problem, *i.e.*, finding a stopping time τ to maximize

$$J(t, x, \tau) = E[g(X_\tau^{t,x})]$$

where X is a diffusion

$$\begin{aligned} dX &= \mu dt + \sigma dW \\ X_t &= x \end{aligned}$$

(not a controlled process: that would be a mixed stochastic control and stopping problem) can also be solved via dynamic programming. Once

$$V(t, x) = \sup_{\tau} J(t, x, \tau)$$

is known, the optimal strategy follows: just check if you are in the **stopping region**

$$\{(t, x) : V(t, x) = g(x)\}$$

or the continuation region

$$\{(t, x) : V(t, x) > g(x)\}.$$

If V is smooth (this is the case under restrictive but reasonable assumptions),

$$V(t, x) = \sup_{\tau} E[\mathbf{1}_{\tau < \theta} g(X_\tau) + \mathbf{1}_{\tau \geq \theta} V(\theta, X_\theta)]$$

for all stopping times θ . (In discrete time, let $\theta = t + 1$.) Using Ito's formula, one can show that V is a solution of

$$\text{Min}\{-(\partial_t + \mathcal{A})V, V - g\} = 0$$

where \mathcal{A} is the infinitesimal generator of the diffusion X ,

$$\mathcal{A}\phi = \mu \cdot D\phi + \frac{1}{2} \text{tr}(\sigma \sigma' D^2 \phi).$$

Control problems can also be solved by verification, but the conditions can be difficult to check; it can be used for the optimal allocation between a risky asset (whose price follows a known but arbitrary diffusion) and a risk-free asset under terminal power utility. A more theoretical example of a verification argument is given to study the asymptotic behaviour of a double stochastic integral $\int_0^t \int_0^u b_v dW_v dW_u$ at $t = 0$.

A super- (resp. sub-)solution of a partial differential equation (PDE) $F = 0$ is a smooth function u such that $F(x, u, Du, D^2u) \geq 0$ (resp. ≤ 0). Whether a \mathcal{C}^2 function is a supersolution of a PDE can be determined by looking at \mathcal{C}^2 test functions:

$$\forall x_0, \phi \quad x_0 = \text{Argmin } u - \phi \implies F(x_0, u, D\phi, d^2\phi) \geq 0.$$

(Rigorously speaking, we need a technical condition: F should be **elliptic**, *i.e.*, non-increasing in D^2u .) The notion of super- or sub-solution can therefore be generalized to non-smooth functions (only the test functions have to be smooth). A **viscosity solution** of a PDE is a (non-necessarily smooth) super- and sub-solution. [Question: how does this differ from distributions and Sobolev solutions?] Some symmetry arguments are no longer valid: $F = 0$ and $-F = 0$ need not have the same solutions. There is a change of variable formula (but you have to replace F by $-F$ if the change of variable is decreasing) and a stability theorem (you can take limits). If $Du \geq 0$, then u is non-decreasing; if $-D^2u \geq 0$, then u is concave (here, ≥ 0 means “is a viscosity solution” – there is no specific notation).

The condition “ x_0 is a minimizer of $u - \phi$ ” can be replaced by “ x_0 is a local minimizer of $u - \phi$ ”, which only involves x_0 , $p = D\phi(x_0) \in \mathbf{R}^d$ and $A = D^2\phi(x_0) \in S_d$ (symmetric matrices). The corresponding sets of (x_0, p, A) triplets are called superjets and subjets, and may lead to simpler proofs. For instance, one can prove the unicity of viscosity solutions (on a bounded open set, if the value on the boundary is given).

The dynamic programming equation (DPE) for the stochastic control and optimal stopping problems remains valid in the viscosity sense when V is not continuous (under some harmless assumptions: continuity).

Fuzzy clustering of short time-series and unevenly distributed sampling points C.S. Möller-Levet et al.

Commonly-used measures of distance between time series (Euclidian distance, correlation, etc.) do not take the temporal order into account. Instead, one can use the Euclidian distance between the slopes of the time series,

$$d(f, g)^2 = \int |f' - g'|^2$$

(this also works for unevenly-spaced time series): this is the **STS distance**.

It can be used by clustering algorithms, e.g., **fuzzy clustering**: find cluster centers (prototypes) v_i and cluster memberships u_{ij} (with $u_{ij} \in [0, 1]$ and $\sum_i u_{ij} = 1$) to minimize

$$\sum_{ij} u_{ij} d(x_j, v_i)^2.$$

The problem is usually solved iteratively: select the v_i at random; estimate $u_{ij}|v_i$; estimate $v_i|u_{ij}$; iterate.

Dynamic orthogonal components for multivariate time series D.S. Matteson and R.S. Tsay (2011)

Multivariate times series modeling studies the time

evolution of μ_t and σ_t :

$$\begin{aligned}\mathcal{F}_t &= \sigma(y_t, y_{t-1}, \dots) \\ y_t &= \mu_t + e_t \\ \mu_t &= E[y_t | \mathcal{F}_{t-1}] \\ \Sigma_t &= \text{Cov}(y_t | \mathcal{F}_{t-1}) = \text{Cov}(e_t | \mathcal{F}_t)\end{aligned}$$

Traditional dimension reduction (PCA), when applied to time series, remove the cross-sectional dependencies, but not the dependence accross time.

To compute dynamic orthogonal components (DOC) in volatility: find a linear transformation of the data $s = Ax$ such that $\text{Cov}(s_t, s_{t-\ell})$ be as diagonal as possible; model the s_i (univariate time seirs) as ARMA processes.

To compute DOC in volatility: remove the trend (e.g., using DOC in mean), find a linear transformation $s = Ax$ such that $\text{Cov}(s_t | \mathcal{F}_{t-1})$ and $\text{Cov}(s_t^2, s_{t-\ell}^2)$ be as diagonal as possible; model the (univariate) time series s_i using a GARCH or stochastic volatility model.

R Journal (2010)

Inverse problems are problems for the form “find x such that $y = f(x)$ ”, *i.e.*, “find the inverse of f ”. If $f : E \rightarrow F$ is linear, injective, then f^{-1} exists, but need not be continuous in infinite dimensions. The Radon transform (tomography) is one such example: it is too sensitive to noise (observation errors). If $f : E \rightarrow F$ is linear with E finite-dimensional and F infinite-dimensional, the problem is overdetermined: some form of *regularisation* is needed. An inverse problem is **well-posed** if the solution exists, is unique, and depends continuously on the problem; if it is not unique or not continuous, it is **ill-posed**. Well-posed problems can be **ill-conditionned**: even if they are continuous, they can amplify observations errors; the *condition number* is the factor by which they amplify those errors.

The following packages can solve differential equations: **deSolve** (initial value problems (IVP), differential algebraic equations (DAE: differential equations plus conservation law), delay differential equations (DDE)), **ReacTrans** (some partial differential equations (PDE): diffusive-advective transport equation), **bvpSolve** (boundary value problems (BVP)), **rootSolve**, **PBSddesolve** (DDE), **sde** (stochastic differential equations (SDE)), **pomp**. (The **odesolve** package is deprecated.)

The **codetools** package provides some functions for code source analysis. Objects have a **source** attribute, that contains their unparsed code (otherwise, we would have to deparse it, and it could end up being slightly different), and a **srcref** attributes that points to the code (it is used by IDEs). They can be used when displaying errors or when setting breakpoints. Check the following functions: **traceback** (call stack after an error), **browser** (explicitly insert a breakpoint), **recover**, **dump.frames**, **sys.calls**, **setBreakpoint** (to set a breakpoint, without explicitly adding a

`browser()` in the code). You may also want to check the `tools` and `utils` packages.

The `hglm` package fits hierarchical generalized models, (e.g., mixed models with heteroscedastic residual variance; Poisson model with gamma random effects; etc.). The interface is still awkward, immature: you have to provide the matrices to describe the model, rather than the model itself; providing the model (say, in the Bugs/Jags syntax) and having the computer *parse* it to extract the matrices would be more user-friendly.

Data cloning is the use of MCMC software for maximum likelihood estimation (the output is not a distribution but a point estimate and a confidence interval). Since MCMC simulations require a prior (when doing bayesian computations by hand, you can remove the prior, which is often just a factor in a formula, but you cannot remove it from MCMC simulations – strictly speaking: replace it by an improper prior), you can reduce its influence by cloning the data $k \gg 1$ times (progressively increase the value). The `dclone` package (with `rjags`, `code`) provides some low-level functions for data cloning.

The `stringr` package provides consistent functions to manipulate strings: names, argument order, behaviour with factors, etc. will no longer be unexpected. All the function names start with `str_`.

The `bayesGARCH` package can fit GARCH(1,1) models with Student T innovations.

Case study: `cudaBayesreg`, bayesian computations in CUDA.

Group testing (aka pool testing) is used when studying low-prevalence diseases: patients are pooled into groups and you only know if someone from the group is affected, *i.e.*, instead of observing $X \in \{0,1\}$, you only observe $\exists i \in [1, n] : X_i = 1$. The `binGroup` package extends the `binom` package to this setup.

A **spike and slab prior** for a Bayesian model is a prior in which each parameter is constrained to be either 0 or in some interval, with only a limited number of non-zero parameters. The `spikeslab` package approximates it with a 3-step process: dimension reduction, model averaging (BMA) and variable selection (elastic regression path, computed with `gnet` – you will also see graphically which parameters are important).

Data compression using dynamic Markov modelling

G.V. Cormack and R.N.S. Horspool
The Computer Journal (1987)

Huffman coding is not optimal: for a binary message and words of size n , it assumes that the probabilities of the words are multiples of 2^{-n} ; in addition, it assumes that the words are independent. This can be improved by increasing the word length, but this also increases the size of the frequency table: some compromise has to be found.

It is easy to fit a Market model to a stream of (bi-

nary) characters, once you know the structure of the Markov chain: just use the sample frequencies, biased to ensure that the probabilities are neither 0 nor 1. Updating the probabilities as we receive the stream of characters gives an *adaptive* algorithm.

To find the structure of the Markov chain (we do not want the best (highest penalized likelihood) one, just a sufficiently good one), start with a simple model, such as

or

and, when a node has enough data, split it. (This is a bit unclear.)

To encode a message knowing the Markov model that generated it, transform it into an *interval* as follow (**Guazzo algorithm**): start with $[0, 1]$; as a new character arrives, split the interval in two proportionally to the probabilities from the Markov model and keep the subinterval corresponding to the character. The bounds of the interval require an increasing precision: it may be helpful to replace the probabilities by approximations (rounding) that do not require that much precision. The compressed message is the final interval, or any number (a simple fraction) in it (you may need the length of the message as well).

Point and figure charting: a computational methodology and trading rule performance in the S&P 500 futures market J.A. Anderson

“Point-and-figure charting” is a technical analysis method method that uses price time series after a change of time: only price jumps above a threshold are included.

Time consistency and moving horizons for risk measures

S.N. Cohen and R.J. Elliott (2009)

Risk measures are often studied for a fixed horizon: you should check how they (and the optimal decision you made using them) change when the horizon changes.

Econophysics: empirical facts and agent-based models

A. Chakraborti et al. (2009)

Contrary to the systems studied by statistical mechanics, systems in social sciences are very far away from equilibrium: this explains why there are no universal laws and why the individuality of economic actors does not completely disappear.

Most statistical properties (stylized facts) of financial data disappear after a change of time (*subordination*) from calendar time to even time (reception of orders), transaction time (execution of order), tick time (price change instants), volume time, return time.

Tick data are *asynchronous* and call for non-trivial variance matrix estimators. The **Fourier estimator** uses the relation between the Fourier coefficients of the returns time series (easy to compute) and those of the coefficients of the variance matrix; the **Hayashi-Yoshida estimator** uses a variant of this idea. Random matrix theory can be used to “denoise” the sample correlation or variance matrix: only keep the eigenvalues that are significantly larger than those you would expect in a random matrix. The distribution of the coefficients of the sample variance matrix; the minimum spanning tree (and its invariants: mean occupation layer (use a large company as the center, or one involved in several sectors), etc.) can also be of interest.

The article ends with a review of agent-based models for the market order book, wealth distribution (and wealth exchanges), herding (minority game and its many variants).

Impact of random failures and attacks on Poisson and power law random networks
C. Magnien et al. (2009)

(Very clear article explaining mean-field approximation to non-physicists; in a nutshell: assume that the (large) graph you have is a tree.)

Real-world networks are often modelled as random networks with a predefined degree distribution (Poisson (exponential decay, *i.e.*, in practice, rates are close to the average) or power law (slower, polynomial decay: larger values are not uncommon)): start with a set of nodes, add edge stubs (according to the chosen distribution), and link them at random. This is a generalisation of the Erdős-Rényi model (limited to the Poisson distribution).

Many theoretical results about random graphs are asymptotic: they are approximations, valid when the graph grows unreasonably large. In this context, whether we are looking at truncated distributions ($X|X \leq k$) or not makes a big difference, especially for power law distributions: if you use the truncated distribution instead of the real one, the asymptotic results you obtain are more likely to be valid for large finite (real-world) graphs as well.

The **mean-field approximation** assumes that the probability that two neighbours of a given node are linked is negligible. In other words, the network locally looks like a tree. The properties of the network can be

examined using **generating functions**, for instance

$$G_0(z) = \sum_k P(X = k)z^k$$

$$G_1(z) = \sum_k P(X = k + 1 | X \geq 1)z^k$$

$$\langle X \rangle = E[X] = G'(0)$$

Since the graph is (sufficiently close to) a random tree, looking at the existence of a *giant component* is akin to studying **branching processes** – hence the omnipresence of generating functions. More precisely, the generating function H of the (asymptotic) distribution of cluster sizes satisfies

$$H(z) = 1 - G_1(z) + zG_1(H(z)).$$

(Generating functions are just a way of encoding distributions and expressing recurrence relations that would otherwise be horribly complicated.) The same equation can help you compute the proportion of nodes to remove to break down the giant component.

The notion of giant component is an asymptotic notion: it is a component that grows linearly with the graph (the mean-field approximation uses a similar but non-equivalent notion: the average size of the components tends to infinity). For finite graphs, you can use the relative size of the largest component: if it is above 5%, you can call it giant.

Experimental results are sometimes in contradiction with the theoretical ones, perhaps because they are just asymptotic, perhaps because we have overlooked some important properties of the graphs – we only looked at the degree distribution, assumed that nothing else mattered, and claimed that the graphs were random. To better model real-world graphs, one can use:

- Constructive models, e.g., preferential attachment (Barabási-Albert);
- Rewired random networks.

Robustness of a graph to failure (random node removal, random edge removal) or targeted attacks (remove nodes with the highest degree, randomly remove nodes of degree at least 2, remove edges between nodes of degree at least 2) can be evaluated using:

- The existence of a giant component (or the proportion of nodes to remove to break it down);
- The average inverse geodesic distance (harmonic mean), which remains meaningful for non-connected graphs.

$$\left(\frac{1}{N(N-1)} \sum_{i \neq j} \frac{1}{d_{ij}} \right)^{-1}$$

Random power law networks are robust to random failures: you have to remove almost all nodes or edges to break down the giant component.

Random graphs with arbitrary degree distribution and their applications
M.E.J. Newman et al.
Physical Review (2001)

For more on the use of generating functions to study random graphs.

Introduction to membrane computing
G. Păun

There are many biology-inspired algorithms (neural networks, evolutionary computing, ant colony optimization, etc.) or computational models (DNA computing). Membrane computing, aka *P*-systems, is another such computational model, based on the remark that in a living body (made of cells, *i.e.*, membranes, containing organelles, *i.e.*, membranes, sending and receiving vesicles, *i.e.*, membranes, contained in organs, *i.e.*, membranes, etc.), almost everything happens on or through a membrane. A membrane computing system is a tree (each node can be thought as a membrane, contained in the parent node, each node contains a set of symbols and rewriting rules (think of \TeX , or random grammars: only one of the applicable rules, selected at random, is applied in each node at each time step), with a few specific symbols to create or destroy membranes, or absorb/secrete symbols from/to neighbouring nodes.

This is just a computational model (not unlike a Turing machine or a quantum computer), with no real world applications.

Lagrange multiplier tests for parameter instability in non-linear models
B.E. Hansen (1990)

To test for structural change, one can:

- Split the sample into, estimate the parameters on each subsample, and compare them;
- Compare (Anova, AIC, etc.) the model with a breakpoint with the model without;
- Idem, but for all possible breakpoints (the breakpoint is rarely known);
- Model the parameter as a random walk and test if its variance is zero;
- Use a Lagrange multiplier test (the estimation problem can be formulated as “minimize the likelihood ratio such that the parameter be constant”): you consider all possible breakpoints but do not have to reestimate the model for each of them.

Jumps and microstructure noise in stock price volatility
R. Sen (2007)

Functional data analysis (FDA) can be used to separate the jump component (microstructure noise) from the realized volatility (*i.e.*, the volatility estimated from high frequency data), after removing the drift by smoothing: FDA is just principal component analysis (PCA) on functions rather than (finite-dimensional) vectors, here, to model the autocovariance structure of the continuous part of the variance process.

Commodity modelling: Schwartz 2-factor model
P. Erb (2009)

Commodity prices can be modelled as:

- A mean-reverting process (Ornstein-Uhlenbeck);
- A geometric brownian motion whose drift is a mean-reverting Ornstein-Uhlenbeck process.

(There is also a 3-factor model, and HJM-type models that also account for the term structure (Hinz), but no details are given).

You can use those models to price options on commodities.

A Few notes on book design
P. Wilson (2009)

This used to be the first part of the `memoir` document class user guide.

Besides the usual advice, the book also provides some font-related vocabulary:

- Serif or sans serif;
- Bracketed serif (smooth transition between the stem and the serif) or unbracketed serif; slab serif (egyptian) fonts can be bracketed or not;
- Vertical or inclined axis (angle of the nibbed pen);
- Small or large counter (loop of some letters: a, e);
- Gradual or abrupt contrast (width difference between thick and thin strokes);

and, less clearly, some font classifications (there are several overlapping or inconsistent classifications, and few actual examples are given):

- Gothic, or blackletter fonts (used by Gutenberg) include the textura (square characters: Goudy Text, Cloister Black), rotunda (round characters: Goudy Thirty) and bastarda (the most common: Fraktur, etc.) families;
- Oldstyle, venitian (Centaur, Berkeley Oldstyle, Jenson);
- Oldstyle, Aldine/French (Bembo, Garamond Palatino, Sabon);
- Oldstyle, Dutch/English (Calson, Janson);
- Transitional, or neoclassical (baskerville, URW Antiqua, Bell);
- Transitional newspaper (better legibility, larger counter, higher x-height, increased contrast) (New Century Schoolbook, Times);
- Modern (exaggerated contrast: Didot, Bodoni);
- Square serif or Victorian (Clarendon, Bero Serif);
- Sans Serif or grotesque or gothic (Helvetica, Futura, Gill Sans);
- Script, Cursive (Brush Script, Zapf Chancery);
- Display or decorative fonts.

R Journal
(June 2011)

It has become difficult to follow the development of all the packages, identify those that are useful, well-

maintained, and reliable (many are just “proof of concept”):

- The task views, cranberries and crantastic tend to be too exhaustive;
- The easiest is to look at the packages most often mentionned on R-help or R-planet (?); you can also check how this changes with time;
- Check the code quality, as measured by the `codetools` package (cyclomatic complexity, coding convention consistency, etc.), from the package metadata itself (licence, number of authors, how many other packages they are maintaining, how active they are on R-help, etc.), or from the version control system (frequency of the releases, number of authors, etc.);
- One could also apply some graph algorithms to the package dependency graph, e.g., looking at the node degree, or applying the page rank algorithm to find the most influencial (used) packages.

The `testthat` package helps you write regression tests as easily as if you were using `stopifnot`, but is more verbose (for instance, you can group the tests, display helpful error messages when they fail, etc.)

Social network analysis (with the `sna` and `tm` packages) can be combined, for instance to analyze mailing lists (thread-author-text triplets)

- Build a network of authors;
- For each word (discard rare words), look at the sub-network of authors using it;
- Build a bipartite graph of authors and words, with edge weights given by the centrality of the authors in the previous graph (the centrality can also help you identify and discard common words);
- Remove the words from the bipartite graph.

Differential evolution (with the `DEoptim` package) is just the traditional algorithm genetic algorithm, but the various operations are no longer combinatorial but modified to be meaningful for real numbers: four instance, “mutation” could be

$$x'_1 = x_1 + F(x_2 - x_3)$$

where x_1, x_2, x_3 are random members of the population. Compared to traditional optimization algorithms (`optim`, `nlminb`), it more efficiently avoids local extrema.

Differential optimization can be applied to portfolio optimization, for instance, when you include the contribution to risk (standard deviation or expected shortfall) in the optimization problem: **risk-parity** portfolio or **equally-weighted risk contribution** (ERC) portfolios (since `DEoptim` does not allow constraints, you can turn them into L^p penalties).

Bayesian model averaging (BMA), which combines several models to yield better forecasts, can be used as a post-processing step and does not need any knowledge of the model details (`ensembleBMA` package); it can be used for weather forecasting.

The `rasterImage` and `grid.raster` function can efficiently plot pixmaps (heatmaps of microarray data, image processing, etc.). You may want to add `interpolate=FALSE`.

Parametrizing correlations: a geometric interpretation F. Papisarda (2006)

Estimators of the correlation matrix need not be correlation matrices at all (e.g., the sample correlation matrix, if there are missing values). Instead, you can parametrize the matrix as $C = BB'$ with

$$b_{ij} = \begin{cases} \cos \theta_{ij} \prod_{k=1}^{j-1} \sin \theta_{ik} & \text{if } j < n \\ \prod_{k=1}^{n-1} \sin \theta_{ik} & \text{if } j = n \end{cases}$$

The n th column of B can be interpreted as the k th basis vector, rotated by angles θ_{kj} , in the (e_j, e_{j+1}) planes.

Statistical properties of world investment networks D.M. Song et al. (2008)

Properties of the network that looks at which country invests in which country (CPIS data from the IMF).

Crossing Intervals of non-Markovian gaussian processes C. Sire (2008)

$\text{Persistence}(\tau, M) = P[\forall t \in [0, \tau] \quad X_t < M]$.

Behavioural and dynamical scenarios for contingent claims valuation in incomplete markets L. Boukas et al. (2009)

In an incomplete market, the no-arbitrage argument does not lead to a unique risk-neutral probability and a unique price for contingent claims: there is a whole interval of arbitrage-free prices. However, the market price is unique: how do we arrive at that unique price?

- Among all the risk-neutral probabilities, take that with the minimum entropy
- Both buyer and seller have some belief (subjective real-world probability) about the future state of the world and are trying to maximize some utility function; by comparing the maximum utility with or without the ability to buy/sell the claim, we can compute a maximum/minimum acceptable price for the claim; if the buyer’s price is higher than the seller’s, a transaction can occur, for instance, with a 1-bid sealed (blind) auction; each party, not knowing the other’s price, will choose a bid that minimizes the maximum **regret** (?); we can imagine that this transaction

- If the buyer's price is lower but both parties are compelled to engage in the transaction, they can enter some kind risk-sharing scheme, minimizing their combined risk, measured as the average (some convex combination) of the drop in utility of each party (but they have to be honest and trust each other);
- If the parties do not have strong beliefs about the future state of the world (real-world probability), but a set of probabilities instead, they can change their beliefs (as little as possible, as measured by the price difference) to come to an agreement (this also requires honesty and trust).

R in Finance 2011

Programming

Functional programming is possible in R, with the `futile.paradigm` package and new operators: `%when%` (for guards), `%must%`, `%isa%`.

Beyond S3 and S4 classes, several packages provide object-oriented facilities: `R.oo`, `proto`, `mutatr`, `futile.paradigm`. While object-oriented programming involves both classes and objects, **prototype programming** (popularized by Javascript) only deals with objects. In R, this can be achieved with *environments*:

```
parent <- new.env()
parent$x <- 1
parent$y <- 3.14
child <- new.env(parent=parent)
child$y <- 2.71
child$x      # Does not work
with(child, x) # 1
sibling <- list2env(
  as.list(child),
  parent=parent.env(child)
)
```

The `proto` package does the same thing, but you do not have to know anything about environments. Possible applications include GUI programming (the code may look simpler than using directly, say, `gWidget`) or the `gsubfn` package.

The `rparallel` package can parallelize computations (on several threads, on a single multicore machine, for embarrassingly parallel problems), with applications to Monte Carlo simulations or boosting.

CUDA-C can speed up SDE simulations (stochastic volatility model) to calibrate the volatility smile (“calibration” means “moment estimator”: you play with the model parameters until something simple computed from the output (a “moment”) matches the same quantity for the real-world data).

The `xtime`, `xts`, `xtdf`, `indexing`, `mmap` packages can help you deal efficiently with time series.

The R ecosystem

Dexy is a tool to generate software documentation and

reproducible research, that claims to be the next generation Sweave: it works with any programming language (R, Python, etc.) or markup format (HTML, L^AT_EX, etc.), is aware of dependencies between datasets and documents, caches intermediate results to avoid having to rerun lengthy computations if nothing changed, lets you reuse the result of the computations in different documents. Contrary to Sweave, it encourages you to separate code and documentation. It can be seen as a combination of Make and Sweave (or templating systems, such as Jinja) or, simply, as a document-oriented Make.

R can run “in the cloud”, thanks to packages such as `Rhive` (Map/Reduce, Hadoop) or `segue` (simplicistic, to run CPU-bound computations on Amazon’s EMR (Elastic Map Reduce)).

R can be used in web applications (from `Rhttpd` (the internal web server, used to display the documentation) or `rApache`) with the `rook` package.

Repast Symphony is a framework to simulate agent-based models (Java, Groovy, Logo); the results can be analyzed in R.

NEOS (Network-enabled Optimization system, an API to send optimization problems over the network, as a web service, in standard formats such as AMPL or GAMS) can be used from R, thanks to the `XML`, `XMLRPC` and `RCurl` packages.

RStudio was mentioned several times.

R can be interfaced with Python (`Pysampler` (?), `PyNum`, `PySci`).

Column stores (e.g., Sybase IQ) are becoming more widespread.

RServe can now be accessed from .NET

R can be used from OneTick, a (commercial) visual data-flow environment.

Finance

R can be used as a quantitative strategy development platform, with the following packages: `quantstrat`, `FinancialInstrument`, `quantmod`, `blotter`, `TTR`, `xts`, `indexes`, `RTAQ`, `signalextraction`, `lspm`, `PortfolioAnalytics`, `PerformanceAnalytics`.

Betfair is a UK betting website, with an API, accessible from R: for instance, you can look at the order book of an event (say, a horse race) and see how it changes with time. Methods from quantitative finance (e.g., algorithmic trading) may be applicable.

Jumps in high frequency data can be identified by looking at the returns/volatility ratio for some robust volatility estimator (e.g., `spotVol` in `RTAQ`); one can also look for jumps in the liquidity, as measured by the order imbalance

$$\frac{\sum \text{Order Sign} \times \text{Order Size}}{\sum \text{Order Size}}$$

or the order book depth

$$\frac{\text{Mean Ask Depth} - \text{Mean Bid Depth}}{\text{Mean Depth}}.$$

The `twitterR`, `RGoogleTrends`, `Infochimps`, `tm`, `XML`, `RCurl` packages can be used to infer the *market sentiment*.

Cap-weighted indices do not perform that well: you may prefer a minimum variance, minimum expected shortfall, or *tangential* (maximum Sharpe ratio) portfolio instead. Try to estimate the returns and the variance matrix robustly: time series factor model (the risk factors are known time series: oil, etc.), cross-sectional factor model (the exposures to the risk factors are known, e.g., industries), statistical models (PCA, ICA). For the minimum expected shortfall portfolio, they use the sample expected shortfall: this is a simple linear optimization problem. The presentation does not explain clearly how they suggest to robustly estimate the returns, needed to compute the tangent portfolio (which quickly disappeared from the discussion).

If two assets X and Y are thought to be related, one can estimate the regression $Y = \alpha + \beta X$ and buy the portfolio $Y - \beta X$. But this **hedge ratio** is asymmetric: instead, replace the least squares regression by the (PCA-based) total least squares (TLS).

Hawkes processes are used to model earthquakes; they account for mainshocks, potentially preceded by (often a single) foreshock and followed by (several) aftershocks, and can also account for dependence between earthquakes in different regions. (They are simply point processes whose intensity depends on previous shocks.) They are strangely similar to volatility time series, and can be used to model financial times series, as the sum of two Hawkes processes, one positive, one negative; the more positive (resp. negative) the process becomes, the larger the intensity of the negative (resp. positive) process becomes (mutually exciting Hawkes processes). One can easily compute the expected realized volatility at a given scale τ and tune the parameters to replicate the observed relation between realized volatility and scale. With two assets, you can also calibrate the relation between realized correlation and scale.

Optimization based on the expected shortfall (ES, aka expected tail loss (ETL) or conditional value at risk (CVaR)) is getting more and more popular for *risk budgeting*. Any homogeneous risk measure (standard deviation, semi-standard deviation, VaR, ES) can be decomposed into a sum of risk contributions (Euler):

$$\text{Risk}(\mathbf{w}) = \mathbf{w} \cdot \frac{\partial \text{Risk}}{\partial \mathbf{w}}.$$

Factor Model Monte Carlo (FMMC) was mentioned several times, with terse details: first fit your factor model (using robust and/or non-parametric methods if possible), use it to simulate data (and backfill missing values), use the simulated data to estimate the distribution of the returns of your portfolio or strategy, use

this (empirical) distribution to compute the risk measures you are looking at. It is not very clear whether they simulate (from an estimated distribution) or resample (*i.e.*, shuffle the data) – both make sense.

The variance matrix of assets returns can be easily estimated even if the assets have a different history, via repeated regressions: start with the assets with the shortest history; for each asset i , estimate the regression $r_i \sim r_{i+1} + \dots + r_n$ (parameters $\hat{\beta}_i$ and variance \hat{v}_i); the variance matrix can be computed, recursively, from the $\hat{\beta}_i$ and \hat{v}_i . If there are not enough data, you can use shrinkage (ridge regression, lasso) or a Bayesian prior, which also provides you with confidence intervals (implementation in the `monomvn` package);

Dependence between Financial Models

D.S. Matteson

R In Finance 2011

The **distance covariance** between two random variables X and Y ,

$$V^2(X, Y) = \|\phi_{X,Y}(t_1, t_2) - \phi_X(t_1)\phi_Y(t_2)\|_w$$

where ϕ is the characteristic function, w a weight function (use t^{d+1} , where X has values in \mathbf{R}^d – X and Y can have different dimensions) is a measure of dependence. It can easily be estimated (just use the empirical characteristic functions).

$$\begin{aligned} a_{ij} &= \|x_i - x_j\| \\ b_{ij} &= \|y_i - y_j\| \\ A_{ji} &= a_{ij} - \bar{a}_{i.} - \bar{a}_{.j} + \bar{a}_{..} \\ B_{ji} &= b_{ij} - \bar{b}_{i.} - \bar{b}_{.j} + \bar{b}_{..} \end{aligned}$$

$$\hat{V}(x, y) = \frac{1}{n^2} \sum_{ij} A_{ij} B_{ij}$$

It depends on the marginal distribution, but you can make it distribution-free by forcing the margins to be uniform (this is sometimes called the *probability integral transform*), *i.e.*, by looking at the copula of (X, Y) .

The distance covariance can be used as a (distribution-free) test of serial dependence

$$H_0 : X_n \perp (X_{n-1}, \dots, X_{n-p})$$

and tell you when to stop adding elements to a time series model.

The distance covariance can be used to define a joint dependence test of (X_1, \dots, X_n) (it is not symmetric):

$$\sum_i \hat{V}(u_i, (u_{i+1}, \dots, u_n)).$$

Minimizing the test statistic leads to an independent component analysis (ICA) – a competitor to the classical FastICA (maximize some (robust) measure of non-gaussianity) and ProDenICA algorithms. This also gives a test for the existence of independent components (the alternative hypothesis of the test is that no matter how you rotate the data, you cannot get rid of the dependence).

Definition of the distance covariance and distance correlation.

Statistical Analysis of financial time series and option pricing with R

S.M. Iacus

R In Finance 2011

Cluster analysis often requires some notion of distance: for time series, one can use the Euclidian distance (it will not give good results but is useful as a benchmark), the correlation, the short time series distance (STS, the Euclidian distance between the slopes of the price time series, $\int |f' - g'|^2$: it also works for irregularly-sampled time series), the dynamic time warp distance (DTW), or the Markov operator distance. The transition operator of a (discrete) stochastic process X is

$$Pf(x) = E[f(X_{n+1})|X_n = x].$$

It is entirely defined by the scalar products

$$\langle P\phi, \psi \rangle = \frac{1}{2} E[\phi(X_n)\psi(X_{n-1}) + \psi(X_n)\phi(X_{n-1})].$$

Evaluated on the functions $1, x, x^2, \dots, x^n$, this gives a matrix: the **Markov operator distance** is the Euclidian distance between such matrices. This can help identify time series with a similar dynamics (e.g., diffusions with a similar drift and volatility), but completely disregards the relation between the innovations driving those time series (most of this talk is about estimating the drift and volatility of a diffusion). This is implemented in the `MODist` function in the `sde` package.

Parameters of financial models, e.g., μ and σ in a geometric brownian motion

$$dX = \mu X dt + \sigma X dW$$

or θ in a CIR model

$$dX = (\theta_1 + \theta_2 X)dt + \theta_3 \sqrt{X}dW$$

(there is a very long list of such models in the presentation) can theoretically be estimated by maximizing the likelihood

$$\prod_{i \geq 0} p(x_{i+1}|x_i)p(x_0).$$

The transition probabilities are rarely known, but approximations are available, leading to Quasi-MLE estimators (the `qmle` function in the `yuima` package).

They can also be estimated with a **2-stage regression** (the shape of the functions f and g will depend on your model):

- Estimate the drift with a regression

$$X_{t+1} - X_t \sim f(X_t)$$

- Estimate the volatility by regressing the squared residuals: $\varepsilon_{t+1}^2 \sim g(X_t)$

- Recompute the first regression, with weights set to the inverse of the variance predicted by the second regression

Model selection often uses the AIC, *i.e.*, the likelihood penalized by the number of parameters in the model. Instead, one can use an L^1 penalty, as in the lasso regression; to choose the coefficients of the L^1 penalties, just use the inverse of the absolute value of the unconstrained parameter estimates. (This is implemented in the `yuima` package.)

Least squares can be used to look for structural changes: estimate the model (e.g., a diffusion) before and after the change point and compute the sum of the squared residuals, for each possible change point; choose the point that minimizes this sum of squares. (The approach presented was different but not very clear: it is limited to breaks in the volatility (the drift is unaffected by the structural change) and does not require the drift to be evaluated). This is implemented in the `cpoint` function in the `sde` package or the `CPoint` function in the `yuima` package.

The `yuima` package can simulate and estimate the stochastic processes most commonly encountered in finance: diffusion,

$$dX = \mu dt + \sigma dW$$

fractional gaussian noise,

$$dX = \mu dt + \sigma dW^H$$

and diffusions with jumps (Levy processes).

Option pricing in R often relies of Rmetrics (`fOptions`, `fAsianOptions`, `fExoticOptions`) or RQuantlib, but is mostly limited to the Black-Scholes model: if you need to go beyond that (jumps, etc.), you have to rely on Monte Carlo simulations. The `yuima` package provides an alternative: **asymptotic expansions**; it allows you to estimate some integral (say, the payoff of the option) of a stochastic process that is “close” to one that is manageable (e.g., deterministic), for instance

$$dX_t = \mu X_t dt + \varepsilon X_t dW_t$$

for ε small.

Modeling microstructure noise with mutually exciting point processes

A. Bacry et al. (2010)

Classical approaches to high frequency data include:

- The **latent price** is a diffusion process, but only a noisy version of it is observed
- Models of the evolution of the whole order book (rather than the price alone)

A difference of two **Hawkes processes** (marked point processes, used to model earthquakes), linked (the more positive the difference becomes, the more the intensity of the negative process increases) can reproduce some stylized facts of high frequency time series:

- Strong macroscopic mean reversion

- Signature plot: the realized volatility on a window of scale τ depends on τ (it is higher at smaller time scales)
- Epps effect: idem for the realized correlation between the returns of two assets (it is lower at smaller time scales)

Sampled at large time scales, those processes look like diffusions.

What is the shape of the Risk-Return relation? **A. Rossi and A. Timmermann (2010)**

One expects the risk-return relation to be monotonic, but the evidence is not compelling.

The question can be settled using boosted regression trees (BRT, regression trees allow for non-linear, non-monotonic relations, and boosting, or more generally ensemble methods, can cope with a large number of variables without overfitting). First, estimate (using BRT) conditional returns and conditional volatility (“conditional” means “using all the information available at that time”, as in “ $E_t[\cdot]$ ”)

$$\text{Stock Return} = f(\text{Risk Factors}) + \text{noise}$$

$$\text{Conditional Return} := f(\text{Risk Factors})$$

$$\text{Conditional Volatility} := \sqrt{\text{Var noise}}$$

(risk factors can include market or sector returns, macroeconomic variables, etc.). Then, still using BRT, estimate the relation between the conditional returns and the conditional volatility: it is not monotonic.

This unintuitive result may be due to the choice of the risk measures. Alternatives include investment opportunities (I wonder how one would measure that) or

$$\text{Cov}(\text{Returns}, \text{Consumption Growth}).$$

Daily consumption growth is not available, but if one replaces it with a **business activity index** (the ADS index combines 10-year and 3-month treasury spreads (daily), initial jobless claims (weekly), employment (monthly), production (monthly), personal income (monthly), sales (monthly), GDP (quarterly) in a dynamic factor model estimated with a Kalman filter), the relation looks monotonic. Such a measure of risk can be seen as “volatility corrected for consumption or business activity”.

Think Positively **K. Pluto and D. Tasche (2005)**

Probabilities of default (PD) can be estimated using the **maximum entropy** principle; to be more conservative, one can look at confidence intervals instead of estimators, or even 1-sided confidence intervals – this approach can give useable results even if there are few or no defaults (low default portfolios), but does not work for small portfolios (or isolated assets).

The article presents a related approach, the **most prudent estimate**. Dependence (between assets, or over time) can be modeled with a Tobit model: defaults

events are triggered by a (component of a multivariate) gaussian random variable exceeding some threshold; for cross-sectional dependence, a 1-factor model is sufficient (?); for intertemporal dependence (the random variables $(X_{it})_t$ can be interpreted as the price, or the “latent value” time series) the correlation suffices: $\text{Cor}(X_{is}, X_{it}) = \rho^{|s-t|}$.

You may want to rescale those estimates, so that the average of the probabilities of default be the probability of default of the whole portfolio: you usually end up with the probability of default of all grades above that of the portfolio.

Twitter mood predicts the market **J. Bollen et al. (2010)**

The vocabulary used in tweets seems to have some predictive power on future DJIA returns: Opinion-Finder uses a positive versus negative lexicon, while Google Profile of Mood States (not public) uses the 6-dimension (calm, alert, sure, vital, kind, happy) (commercial) PoMS lexicon used by psychometricians and extended to include commonly cooccurring terms.

The numeric results look too high.

Dynamic Asset Allocation Using Stochastic Programming and Stochastic Dynamic Programming Techniques **Gerd Infanger (2010)**

Dynamic asset allocation, for individual investors, often reduces to “keep the same portfolio $x\%$ stock, $(100 - x)\%$ bonds”, or sometimes “ $(100 - \text{age})\%$ stock”. This is clearly suboptimal. Stochastic programming can provide the optimal strategy for a given utility function. This can be done in two ways:

- Dynamic programming: recursively compute $V(t, w, x)$, the expected final utility of the best strategy if your wealth is w at time t and you invest $x\%$ of it in stocks on $[t, t + 1]$.
- Simulate 10,000 to 100,000 scenarios and transform the stochastic program to a non-stochastic one (the author wrote a software, GAMS/DECIS, to perform this transformation). As often with that kind of problem, the number of constraints is too large (10^{20}), but one can easily identify breached constraints and add them to the problem, until a solution is found.

GraphLab: a new framework for parallel machine learning **Y. Low et al.**

High-level abstractions for graph-based computations, such as Map/Reduce, are too restrictive: they impose the shape of the graph.

Low-level abstractions (MPI, PThreads) are too low-level. GraphLab is in-between: the shape of the graph is arbitrary.

- Contrary to DAG (directed acyclic graph) models, the graph need not be acyclic, and can model iterative algorithms;
- Contrary to the *systolic abstraction*, the decision on which computations should be done next is not made beforehand, but as the algorithm progresses;
- Contrary to MPI/PThreads, the programmer is isolated from synchronization, data race and deadlock problems.

The framework also provides some scheduling facilities (but they could be optimized). The data is stored in the nodes or in the vertices (for data shared by two nodes). Since it is based on PThreads, it is limited to a single machine.

***Pregel: A System
for Large-Scale Graph Processing***
G. Malewicz et al. (Google)
SIGMOD 2010

Pregel is another abstraction for graph-based (?) bulk synchronous parallel computations (BSP): each node (on a separate machine or processor) runs its computations and can send messages to its neighbours, a master keeps track of the progress and of changes in the graph structure (you can add or remove vertices), the computations stop when all nodes tell the master they want to stop. I do not really see the link between graphs and BSP.

***Statistical Approaches
for Network Anomaly Detection***
C. Callegari (2010)

Networks attacks can be detected by:

- Clustering, *i.e.*, unsupervised classification: smaller clusters are attacks;
- Markovian models (e.g., to model TCP states; first-order, time-homogeneous models are simpler and have a better ROC curve);
- Entropy (compress the incoming (log) data with LZW (Lempel-Ziv-Welch), Huffman coding, or dynamic Markov compression, and look at its size)';
- Count-min sketch (use a counting Bloom filter to estimate the average traffic from each IP address and identify deviations from this average, you do not have to store the data separately for each IP address (there are too many): the data is aggregated and distributed);

- Principal component analysis;
- Wavelets (or rather framelets, that provide several time series showing features at different scales; this is very similar to several band-pass filters; that is the most intuitive method presented).

Learning for stochastic dynamic programming
S. Gelly et al. (2009)

Estimating the cost function $V(t, x)$ in a continuous-time dynamic program is untractable in high dimensions, but learning algorithms (neural networks, k -nearest neighbours, kernel regression, regression trees, adaptive discretization, mixture model, etc.) can help.

***On a stochastic knapsack problem
and generalizations***
A.P. Morton and R.K.Wood (1998)

The problem (a knapsack problem where the value of the items is random, the cost function is some expectation or quantile function, but the weight of the items, *i.e.*, the constraints, are deterministic) can be reformulated as a (deterministic) integer program.

***Lectures on stochastic programming:
Modeling and theory***
A. Shapiro et al. (SIAM, 2009)

The notation used to describe stochastic optimization problems (the cost function to optimize is defined as an expectation, the constraints involve quantiles (value at risk), the problem has a time dimension and we are looking for an optimal (feasible) strategy) is very, very heavy. The book deals with the theory underpinning stochastic optimization (duality, etc.), rather than the algorithms that could be used to solve those problems. It assumes that you are already well-versed in classical optimization, for instance, that you understand that duality gives an equivalence between constrained optimization (or regression) and penalized optimization (or regression). The problem can sometimes be recast as a classical optimization problem (e.g., when the random variables have a discrete distribution) but the number of variables explodes. Dynamic programming is a valid approach if the dimension of the problem is sufficiently low (2), but studying the convexity of the quantities to optimize can help overcome the curse of dimensionality.

SIGMOD 2010

Temporality

Databases keep track of the quantiles of the data they contain but rarely keep the history of those quantiles as the database evolves: this could be useful to optimize queries in temporal databases.

Recommendation systems (Amazon, Netflix) could be improved by looking at *temporal patterns* (after buying volume 2 of a series of novels, volume 3 is a good recommendation, but volume 1 is not).

Because of accountability requirements, bitemporal databases (that keep track of all the changes (corrections) that occur on the data) are getting more common (there are almost-standard temporal extensions of SQL and XQuery), but keeping track of *schema changes* (there is a limited number of operations: create, drop, split, merge, copy, join tables; add, remove, rename columns) is trickier: you can keep all tables and columns that ever existed, add a `start_time` and `end_time` to all tables and somehow coalesce the data from the various versions.

Versioned databases ((bi)temporal databases, for text) lead to specific queries, e.g., the durable top- k : the first k elements that were always in the top N in the $[t_1, t_2]$ time interval (with N as small as possible).

Incorrect or imprecise data or results

Sensor data can be turned into *uncertain databases* (aka **probabilistic databases**): instead of storing a value, store a probability distribution (e.g., $U(25, 35)$ instead of 30), which can be multivariate and/or discrete, e.g.,

$$P(\text{foo}, \text{bar}) = .3 \quad P(\text{foo}, \text{baz}) = .6 \quad P(\text{bar}, \text{baz}) = .1.$$

A **probabilistic threshold query** (PTQ) returns all the tuples satisfying the condition with probability above a given threshold.

Approximate evaluation of boolean expressions in (correlated) databases.

Use online algorithms for long-running SPJG (select-project-join-group) queries: users want to see the first results quickly; early result can be approximate

To anonymize time series data (which tend to present temporal correlation), use *Fourier perturbation*: do not add noise to the data itself, but to some coefficients of its discrete Fourier transform.

Relational operations (join, etc.) for incomplete, imprecise or erroneous databases, using mixtures of gaussians to model the data in the tables and choose the confidence intervals

To provide consistent answers from an inconsistent database (resulting from the integration of several databases), use a minimally repaired version of the database and flag the results as “inconsistent” or “consistent”.

To explain why a given tuple is not in the result of a query, you can: represent the query as a tree and identify the node that rejected it; minimally transform the database to include the tuple; minimally transform the query to include the tuple.

When presenting the “top results” of a query to a user, one may want to use a user-specified ordering,

```
SELECT TOP 10 ...
ORDER BY  $\sum_i w_i A_i$ 
```

where the attributes A_i are part of the data, and the weights w_i defining the preference function are given by the user. If the user is unsure of his weights, we

can display the **skyline** (efficient frontier) results, *i.e.*, those that are at the top, for some choice of weights (actually, this is *not* equivalent) and try to infer the weights from the skyline results the user prefers. The resulting weights, for one or several choices, can be displayed on a *parallel plot*.

Non-tabular data types (graphs), new types of queries

To search for a graph or a subgraph in a graph database, look at frequent and infrequent *graph fragments*. The same idea applies to supervised classification of graphs (e.g., to distinguish program flow graphs with and without bugs): look for discriminative subgraphs, *i.e.*, subgraphs frequent in one set but not in the other.

The *frequent itemset* problem can be extended to graphs with a bag of labels on their vertices: you then look for itemsets that appear on nearby nodes. For each node and each label, look at the number of neighbours at distance k with that label; this can be approximated by a Markov model (influence propagation, film recommendations in a social network, etc.).

Unstructured or textual data is often explored through k -nearest neighbour (k -NN) queries.

Knowledge is increasingly represented as RDF statements (aka subject-verb-object (or subject-attribute-value) sentences, or directed graphs with coloured edges), e.g., DBpedia.

Statistics

Hidden Markov models can be used to infer the internal state of a system (intrusion detection using log files).

You can identify outliers in relational data as follows: turn the foreign key constraints into a **graphical model** (*relational dependency network* (RDN)); approximate the conditional probability distributions of the nodes, e.g., using regressions (this may automatically identify missing constraints); use the resulting confidence intervals to identify outliers and/or clean the data.

Optimizations

Very long boolean expressions can be evaluated efficiently, without having to convert them to disjunctive/conjunctive normal form (DNF/CNF, “normalized” means that the alternating AND/OR tree has depth at most 2), which requires exponential space: you can lazily convert the expression to a normal form; you can encode the boolean tree as a list of *Dewey ids* (number the children of each node from 1 to n , use a special symbol $*$ for the last child of an AND node, and process them in order); you can encode the boolean tree as a set of intervals, the expression begin satisfied if those intervals cover $[0, 1]$ (use $[0, 1]$ for the root, the children of an OR node have the same interval as their parent, the intervals of the children of an AND node for a partition of the interval of their parent), for the implementation, discretize the intervals (replace $[0, 1]$

by $\{1, 2, 3, 4, \dots, n\}$). Those algorithms are used by *advertising exchanges*, in which websites, advertisers and intermediaries form a graph, with boolean conditions on the edges describing the desired profile of the clients (they could be static or automatically generated and modified to optimize the number of clicks) and one wants to evaluate the expressions on all the paths (not just the edges) between a website and all advertisers.

Most databases process queries independently of one another: exploiting dependencies between queries (from different users, or subqueries of a single large query involving many aggregations) can speed up data retrieval.

Computing the correlation of N time series of size T can be done faster than $\Omega(TN^2)$.

Some people write Ajax-producing SQL queries.

***Distilling free-form natural laws
from experimental data***
**M. Schmidt and H. Lipson
Science (2009)**

Symbolic regression is an evolutionary algorithm that searches a space of mathematical expressions, less constrained than linear or non-linear regression; instead of producing a single solution, it can provide a set of solutions on the accuracy–parsimony Pareto front. It can be used to identify *invariants* (conservation laws) in physical systems.

Trivial or approximately trivial invariants ($\cos^2 \theta + \sin^2 \theta$, $17 + 1/(1 + x^2)/100$) can be discarded by looking at how predictive the conservation law is:

- Given \mathbf{y} and a conservation law $f(x, \mathbf{y}) = 0$, you should be able to find x ;
- The conservation law $f(\mathbf{x}) = 0$ produces other conservation laws $\partial f / \partial x_i = 0$, which should be predictive as well.

The laws you find depend on the data provided to the algorithm:

- For instance, for a physical system, with only positions, you will have the description of the manifold in state space; with velocities, you will have energy laws; with acceleration, you will have the equations of motion;
- With restricted datasets, you will have approximations (e.g., if you only have small angles, the conservation laws will replace $\sin \theta$ by θ);
- With a limited set of building blocks, you will have approximations (e.g., $\sin \theta \approx \theta - \theta^3/3!$, if there is no sine function) or equivalent formulations ($\sin \theta = \cos(\theta - \pi/2)$ if you have cosine but not sine);
- With several datasets, you can have more general laws (e.g., with datasets corresponding to different masses, you can identify the role the mass plays).

The algorithm can be made aware of units.

Knowledge discovery can be made incremental:

- You can seed the algorithm with known formulas

(e.g., the conservation laws for a double pendulum are likely to contain quantities that look like those for a single pendulum);

- Looking at subexpression frequencies across different systems can help identify meaningful quantities (momentum, potential energy, etc.);
- Since many formulas contain repeated terms, the laws are not coded as an expression tree (it would have to have identical subtrees, which is not very parsimonious), but as a list of assignments of the form $x_{i+1} \leftarrow f(x_1, \dots, x_i)$.

The time to convergence is exponential in the complexity of the formula and quadratic in the number of variables.

***Can a biologist fix a radio?
or, What I learned studying apoptosis***
Y. Lazebnik (2002)

To understand the stagnation of research in biology (thousands of articles published every year on very narrow subjects (often, a single protein or gene), failing to lead to new drugs or a better understanding of biological phenomena), the author suggests to imagine how a biologist would try to study and fix a radio (open it, describe it, try to manually remove elements, randomly destroy some elements (by shooting the radio), etc.). Biologists lack a *quantitative* language, with which they could make predictions; they lack a *systems approach* (when graphically representing the subject of their research, they put it at the center of a diagram and come to the conclusion that it is related to everything else).

Can a systems biologist fix a tamagochi?
L. Cardelli (2007)

(Epistemology in the information age)

The previous article focused on hardware reverse engineering (a radio), but does not work with biological organisms, which are more like software (the article uses the tamagochi as an example):

- Principle approach: try to find the principles that govern the organism: creator, documentation, function, etc.;
- Mechanistic approach: identify the parts, check how they are connected, how they react to perturbations;
- Behavioral approach: reactions to stimuli, in a population;
- Environmental approach: how the organism evolved; behaviour in and interactions with its environment.

(Biological analogues of) software reverse engineering tools may be useful: tracing, breakpoints, core-dumps, stackdumps, packet sniffing, reverse compilation, power analysis, etc.

Categories for the practicing physicist
B. Coecke and E.O. Paquette

***The R Inferno*
P. Burns (2009)**

Very long list of common problems and caveats for (not only) beginning R users.

***From the fundamental theorem of algebra
to astrophysics: a “harmonious path”*
D. Khavinson and G. Neumann
Notices of the AMS (55)**

The effect of gravitational lenses can be described by polynomials in z and \bar{z} (of the form $h(x + iy) = P(z) + Q(\bar{z})$, $P, Q \in \mathbb{C}[X]$; they are actually harmonic, *i.e.*, $\Delta h = 0$). The number of images is the number of roots. It is trickier than with (analytic) polynomials: for instance, $h(z) = z^n - \bar{x}^n$ has an infinite number of roots.

***Missing data: our view of the state of the art*
J.L. Schafer and J.W. Graham
Psychological methods (2002)**

To deal with missing data, avoid old methods (case deletion, simple imputation) and prefer:

- Maximum likelihood, *i.e.*, including the missingness of the data in the model; just discarding the factors (in the formula for the maximum likelihood) involving missing data is not a good idea; the estimation can be performed with the EM algorithm;
- Bayesian multiple imputation: replace the missing values with an estimate of their distribution (not a single value, as with simple imputation), or a set of values, yielding several plausible complete datasets – surprisingly few such surrogate datasets are sufficient (3 to 10).

You should be aware of the distinction between:

- Data missing completely at random (MCAR): missingness does not depend on X or Y ;
- Data missing at random (MAR): missingness does not depend on X , but may depend in Y ;
- Data missing not at random (MNAR): missingness depends on Y .

Also check the Multiple imputation FAQ.

***Hash visualization: a new technique to
improve real-world security*
A. Perrig and D. Song**

Humans are bad at comparing hash strings: instead of strings, one can use images, generated by an expression tree, built from the hash string and a (stochastic) grammar (use the hash string to choose which branch of the grammar you should take). This is not unlike L-systems.

***Continuity analysis of programs*
S. Chaudhuri et al.
POPL 2010**

It is not too difficult to decide whether a mathematical expression represents a continuous function (formal algebra systems should be able to simplify most expressions of the form $f(x) - \lim_{h \rightarrow 0^+} f(x + h)$); for imperative programs, it is trickier, but can be done (in most cases).

***Mathematics and the internet: a source of
enormous confusion and great potential*
W. Willinger et al.
Notices of the AMS (56)**

The popular claim that “the internet is a scale-free network; it is robust to random attacks but very vulnerable to targeted attacks” may be incorrect:

- It is based on `traceroute` data, that ignores the fact that routers have multiple interfaces and cannot see the low-level infrastructure (below the IP layer – this is used, invisibly, to make the network faster and more robust);
- It assumes that the network is random: this is not true, since the addition of a small number of edges can greatly increase robustness – ISPs are probably already doing that, to increase their quality of service (QoS);
- Vulnerabilities are at the edge of the network: if an ISP disappears, all its clients are disconnected.

***Genetic optimization using derivatives:
the `rgenoud` package for R*
W.R. Mebane and J.S. Sekhon**

Genetic optimization algorithms can be improved by modifying each candidate solution by a local search, so that they all be local extrema.

***Gestion d’arbres
par représentation intervallaire*
SQLPro (2003)**

Trees, in SQL, can be efficiently represented by intervals:

- Leaves are 1-element intervals, (from 1 to n);
- A node is represented by the set of leaves it leads to;
- The order on the leaves is chosen so that each node is represented by an interval; in particular, leaves with the same parent are adjacent.

This is very efficient if the tree is static, but insertion is $O(n)$ (you have to shift half the tree on average).

***Music: broken symmetry,
geometry and complexity*
Gary W. Don et al.
Notices of the AMS (57)**

Gabor transforms (aka spectrogram, sonogram, short-time Fourier transform: the FFT on a sliding (smooth) window of constant size) has musical applications, such as:

- Help singers analyze and improve their vibrato;
- Analyze reverberation;

- Show (quantify) beatings between overtones;
- Decompose a piece into sections (and perhaps also identify similarities between sections);
- Show the structure of those sections (in a more graphical, directly understandable way than traditional notation);
- Transcribe birdsong (zoomusicology);
- Analyze acoustic phenomena, such as the Shepard tone (it does appear in Renaissance music, as voice painting for an infinite upward movement).

The Gabor transform can be seen as the dot products with a set of vectors, the **Gabor frame** (it is not a basis because the windows overlap); the generalized inverse (the dual Gabor frame) can be used to define filters (amplify some region of the spectrogram, remove noise, slow down without changing the pitch, change the pitch, etc.) or for synthesis (draw the spectrogram and transform it into sound – it is a form of *granular synthesis*, the elements of the Gabor frame being the grains).

The **scalogram** (continuous wavelet transform, CWT) is similar but lets the window size vary.

The **percussion scalogram** is obtained as follows: filter the signal (e.g., only retain frequencies in a given band, to isolate an instrument); compute its spectrogram; build a pulse train (a 0-1 signal) by comparing the intensity of the spectrum with a given threshold; take the scalogram of the pulse train. This can help compare the rhythm of various instruments.

The **entropy** of the intervals between two percussive strikes is a measure of the complexity of the rhythm. However, this discards time: you may prefer the **Markov-1 entropy** (average of the entropy of the transition probabilities) (?).

There is no mention of the **cepstrum**, more appropriate to study pitch classes (rather than pitches), or the **Mel-frequency cepstrum** (MFC), used in speech recognition.

Time-frequency analysis of musical rhythm X. Cheng et al. (2010)

More details on the percussion scalogram, and examples of combined analysis of rhythm and melody, using both the spectrogram and the percussion scalogram:

- It can distinguish between strong and weak beats: there is no amplitude information in the pulse train, but strong beats happen to be longer;
- The Haar CWT may look more appropriate to study a pulse train, but it leads to less readable a picture, with “cubist” artefacts;
- The article ends with some advice on the choice of parameters.

The percussion scalogram is only a first step towards a better graphical notation or representation of the hierarchical rhythmic structure of a piece – the article uses (ugly) ascii art to mimick the already inadequate traditional notation, only replacing the hierarchi-

cal cues (measures, slurs) with parentheses. The task looks similar to the (automated) genome annotation problem in biology.

Music and mathematics T. Fiore

Music can (sometimes) be analyzed as combinatorics or group actions on the following sets:

- Pitch classes: $\mathbf{Z}/12$ or $\mathbf{Z}/7$;
- Pitch class sets: $(\mathbf{Z}/12)^n/\mathfrak{S}_n$;
- Chords: $(\mathbf{Z}/12)^3$.

You can build group actions from transposition (translation) and inversion

$$(a, a + b, a + b + c) \mapsto (a, a - b, a - b - c);$$

this defines an action of the dihedral group D_{24} on $(\mathbf{Z}/12)^3$.

The PLR group acts on the set S of major and minor chords (the orbits of $(0, 4, 7)$ and $(0, 3, 7)$ under the action of $\mathbf{Z}/12$ acting by addition) and is generated by the following transformations: P (parallel major or minor, e.g., $C_{maj} \mapsto C_{min}$), R (relative major or minor, e.g., $C_{maj} \mapsto A_{min}$), L (leading tone change, e.g., $C_{maj} \mapsto E_{min}$). This is another action of the dihedral group D_{24} . Chord progressions are paths in S , and often follow elements of the PLR group.

The formulas do not seem to make sense.

$$\begin{aligned} P(a, b, c) &= (c, \cdot, a) \\ L(a, b, c) &= (c, \cdot, b) \\ R(a, b, c) &= (b, a, \cdot) \end{aligned}$$

Musical actions of dihedral groups A.S. Crans et al. (2007)

More details on the two actions of D_{24} on $(\mathbf{Z}/12)^3$.

The topos of triads T. Noll (2005)

Instead of group actions on $\mathbf{Z}/12$, you can consider monoid actions. For instance, the affine transformations $z \mapsto az + b$ on $(\mathbf{Z}/12)^3/\mathfrak{S}_3$ that preserve the major triad $(0, 1, 4)$ (the author encodes pitch classes with the circle of fifths: $0=C$, $1=G$, $2=D$, etc.) for an 8-element monoid T . The topos of triads is \mathbf{Set}^T ; some of its properties (subobject classifier, etc.) have musical interpretations.

[The math review is more readable than the article.]

Visual hierarchical key analysis C.S. Sapp (2005)

To graphically represent modulation and harmony changes in a piece of music, plot it in a triangle, with the colour of point (x, y) representing the key (from

the Krusmansl-Schmuckler key-finding algorithm) of the subset of the piece of length $1 - y$ centered on x (where $y \in [0, 1]$, $2x \in [1 - y, 1 + y]$, and the total length of the piece is 1).

***Midi Toolbox: Matlab tools for music*
T. Eerola and P. Toivainen (2004)**

Once your mathematical software can read, play, write Midi files, you can also:

- Plot a piece as a piano roll,
- Look at the distribution of pitch classes or intervals,
- Look at the pitch class transition matrix,
- Look at the autocorrelation of the melodic contour,
- Apply key-finding algorithms: the Krusmansl-Schmuckler algorithm just compares, by looking at the correlation, the distribution of pitch classes with corpus-based references for major (♭♭♭♭♭♭) and minor (♭♭♭♭♭ – proportions of C, C#, D, etc.); there are also SOM-based algorithms (self-organizing maps) and meter-finding algorithms (look at the autocorrelation of the note-onset time series);
- Compute the melodic complexity (entropy),
- Compare pieces in a corpus, etc.

***Statistical methods for corpus exploitation*
M. Baroni and S. Evert (2006)**

Introduction to statistics (tests, estimators, etc.) for linguists.

In R, use `binom.test` for tests about proportions (e.g., the proportion of passive sentences in English).

For a longer introduction to statistics (anova, tests), check *The Foundations of Statistics: A Simulation-based Approach*, by S. Vasisht and M. Broe (Springer, 2010).

EuroSciPy 2010

Scientific computing in Python relies on SciPy; specific bundles of modules, targeted at a given domain, are packaged into “SciKits”.

***Supply and demand shifts
in the shorting market*
L. Cohen et al. (2006)**

Comparison of short supply, short demand and future returns: in markets with bad information flow, there is a relation, suggesting that short selling plays a role in price discovery.

***Asset prices under short-sale constraints*
Y. Bai et al. (2006)**

Short sale constraints have contradictory effects on the markets:

- It limits the ability to share risk, limits the supply of stocks, and leads to an increase in price;
- It limits how much information flows into the prices (some informed investors cannot invest as much as

they would like to), increases uncertainty and volatility, drives investors away and decreases prices (as usual: opacity in financial markets leads to price drops and crashes).

The authors use a model of the market with two periods, two investors, with different endowments and utilities.

***The large scale structure
of semantic networks: statistical analyses
and a model of semantic growth*
M. Steyvers and J.B. Tenenbaum (2005)**

Natural language semantic networks (WordNet, Roget’s thesaurus, word associations) are not completely unstructured: rather than a rigid structure, they have some statistical properties (small world, scale-free, etc.) that can be explained by a preferential attachment model.

***25 years of IIF time series forecasting: a
selective review*
J.G. De Gooijer and R.J. Hyndman (2005)**

Review of recent and not-so-recent progress in time series forecasting: state space models (exponential smoothing, Kalman filter, structural models aka dynamic linear models), ARIMA (VAR, ECM), seasonality, non-linear models (threshold, regime switching, neural nets), long memory (ARFIMA: $0 < d < \frac{1}{2}$), GARCH (GARCH(1,1) if often sufficient), evaluation of the quality of a forecast, combining forecasts (simple average (robust), weighted average with weights from OLS or OLS with a $\sum w_i = 1$ constraint, time-changing weights), prediction intervals or densities (bootstrap) (do not forget to account for power uncertainty).

There has been little progress on: count data forecasting, panel data.

***Domain-specific languages:
an introductory example*
M. Fowler (2007)**

Java is too verbose to implement simply a state machine: XML can help, low-overhead markup languages (YAML, JSON) are better, but DSL (domain-specific languages), which add some simple control structures, are even better – M4 was an early example. A “program” in a DSL is often simpler than a program in a general language, and can be easily represented graphically (cf. graphical programming languages: PureData, Scratch/Etoys/Squeak).

***Economics needs a scientific revolution*
J.P. Bouchaud (2008)**

Economics is based on very strong assumptions (axioms), that prevail on empirical evidence: the marketplace has been deified. These dogmas are perpetuated through the education system: we need more natural

sciences in the curriculum. For instance, models based on those incorrect axioms actually assume that there will be no crisis. markets are wild: they are not in a state of equilibrium and will never be. Financial innovations should be tested by independent agencies, as for all potentially dangerous industries.

***Trust! Why it has been lost
and how to regain it*
D. Sornette (2008)**

The recent crises (ITC, housing, MDS), each feeding the next, are the result of a loss of trust and a lack of governance, rather than incorrect mathematical formulas. They come from *endogenous* instabilities (speculative euphoria) rather than exogenous factors: they are therefore predictable. Crises are often beneficial: they create an excess capacity that has a long-term impact on new technologies (rail in the UK just before the industrial revolution, the IT bubble, etc.). Market movements, business cycles, unexpected downturns will not disappear: they are part of a healthy economic system.

Regulations are needed, but they are often too simple or too complex, and have unintended consequences – they give an illusion of control to regulators. We need to develop a “culture of risk” (I would call it “risk literacy”) for managers in governments, regulatory bodies, financial institutions – and also in the general public.

***Dynamics of market correlations:
taxonomy and portfolio analysis*
J.P. Onnela et al. (2003)**

The minimum spanning tree built from the correlation matrix of daily asset returns is unstable: to see if it is significantly different from one period to the next, we can look at numerical properties of the graph (akin to topological invariants, in algebraic topology), such as its degree distribution (or just the tail of the distribution, if the graph is scale-free: $f(n) \sim n^{-\alpha}$)

or the average distance to the “central” vertex (e.g., that with the highest degree, the highest weighted degree (use the correlation coefficients as weights) or that giving the lowest average distance). One can also look at the proportion of edges present in the tree on two consecutive months. (The authors use a 4-year window: crises will create a discontinuity twice, when they enter and leave the window.)

The branches of the MST may be similar to some sector classifications.

The minimum portfolio (based on the sample covariance matrix, *i.e.*, the same matrix used to build the minimum spanning tree), mainly contains leaves of the MST; the maximum return portfolio is still far from the center, but not as much. This just says (graphically) that optimal portfolios are diversified (far from the center).

***The virtues and vices of equilibrium
and the future of financial economics*
J.D. Farmer and J. Geanakoplos (2008)**

Equilibrium theories usually arise from game theory: models with several agents (producers and buyers), each with some initial goods (*endowment*), some ability to transform those goods (*technology*), and some convex *utility*; they claim that there is a supply-demand (Arrow-Debreu) equilibrium. But this equilibrium may be unnatural or problematic: at equilibrium, supply magically matches demand: at the end of the day, there is no unsold inventory; the equilibrium need not be stable or even unique; there could be some attractor (the economy is a dynamical system) preventing you from reaching the equilibrium; it may change with time; the convex utility is contradicted by behavioural economics.

There are two justifications for the economy being in an equilibrium: the *tatonnement* mechanism (economic agents progressively adjust their consumption and production and approach the equilibrium) and *omniscience* (if everyone knows the equilibrium and everyone knows that everyone knows about it (and knows that everyone knows, etc. – common knowledge), it is in everyone’s interest to use the equilibrium prices).

The economic equilibrium theory can be extended into a *financial equilibrium theory*, by adding time, uncertainty and financial securities; because of uncertainty, utility is often replaced by *expected utility*.

Equilibrium often entails *efficiency* (in complete markets, *i.e.*, if it is always possible to offset any future risk): Pareto efficiency (there is no change in prices that would benefit everyone); information efficiency (prices are unpredictable, e.g., are martingales, *i.e.*, all the information available is already included in the prices; this implies that the price of assets coincide with their *fundamental value* – the present value if there is no uncertainty); arbitrage efficiency (absence of arbitrage).

Contrary to the large number of macronomic empirical laws that stress mere correlations, equilibrium theories (based on an agent model) can produce cause-consequence relations: they are useable for policy decisions. They do not incorporate psychological biases and the bounded rationality of economic agents: this is unrealistic, but parsimonious and hopefully sufficiently good.

Even if equilibrium models are wrong, they are useful: one can use them to find and exploit deviations from equilibrium; one can assume that there is no arbitrage in one market (e.g., interest rates) to help exploit arbitrage opportunities in another market.

Equilibrium theories emphasize understanding over predictability, and often make auxiliary assumptions: they are (almost) not falsifiable. The presence of *power laws* is often advanced as an argument against equilibrium, because in physics, power laws appear in phase transitions and never in an equilibrium – but they are

not incompatible with the notion of equilibrium. The progress towards equilibrium is unnaturally slow (de-cause instead of years, if one only has daily market data).

The causes of the recent crisis are manifold: structural changes (regulatory changes supposed to protect people with a bad credit record), statistical mistakes (looking at the mean instead of the whole distribution), perverse incentives (rating agencies), people trying to hide what was happening. Even if they are wrong, equilibrium theories and game theory can be useful (e.g., to study perturbations around equilibrium) but should be combined with behavioural and experimental finance and more structural models (e.g., how does the continuous double auction mechanism (*i.e.*, the use of limit orders and markets orders, as in most financial markets) influence prices?). Biology can provide some inspiration as well: for instance, one could study the taxonomy and evolution of financial strategies, or the market environment (investors, brokers, regulators, banks, governments, etc.). Financial markets are a complex system.

R in Finance 2010

Indirect inference suggests to use an auxiliary model, farther away from the data, but easier to fit.

R can interact with more and more third party systems: iBrokers, OneTick, etc.

Repast Symphony is a (free, Java) tool to simulate **agent-based models**; the results can then be analyzed in R.

Esper is an SQL-like processing language for asynchronous data; the callback functions run when an event is received can be written in R; it can use Redis as a key-value store.

R can provide a complete toolchain for fund managers: data (`quantmod`, `indexes`, `RTAQ`, `xts`), simple computations on data (`TTR` (technical analysis), `signalextraction`), trade selection (`quantmod`, `quantstrat`), risk control (`PortfolioAnalytics`, `lspm`), backtest or performance monitoring (`blotter`, `FinancialInstrument`, `PerformanceAnalytics`), etc.

The `indexing` package provides direct access (using the `[]` operator) to vectors stored on disk and mapped to memory on demand (MMAP); an index is kept in memory to speed up data access.

The following packages were also mentioned: `signalextraction`, `ghyp` (for non-gaussian distributions), `Rhive` (Map/Reduce with Hadoop, on Amazon's EC2 cluster), `tm` (text mining, the computations can be distributed with Hadoop/Hive).

GPUs can be used for high-performance programming.

Les nouvelles formes d'organisation du travail Xavier de la Vega (SH, 2010)

Company structures can be classified into one of the

following four types, which can be expressed in terms of graph theory:

- Clique (unstructured company, often very small);
- Trees (strong vertical structure: taylorism, pioneered by Ford, dominant in southern Europe and emerging countries);
- Graphs full of small clusters or cliques and with a small diameter and average distance (horizontal structure: lean production, pioneered by Toyota, dominant in the UK and the US, combining low inventory (just-in-time production), diversity of the products/tasks (a given employee can perform several tasks, so as to better adapt to changes in demand), and quality; it became more widespread with the advent of computers);
- Dynamic networks, *i.e.*, graphs changing over time (learning organizations, dominant in Northern Europe, based on autonomy (you are given objectives, but are free to choose how to achieve them) and communication between workers).

Multiple testing corrections Silicon Genetics (2003)

When performing multiple statistical tests (often, tens of thousands), p -values have to be corrected, for instance with the following methods:

- Bonferroni correction: $p^* = \text{Min}(1, np)$;
- Bonferroni step-down (Holm) correction,

$$p^* = \text{Min}((n - k + 1)p, 1),$$

where k is the rank of the p -value (sort them in ascending order);

- Westfall and Young correction: resample the data to have an estimate of the distribution of the sorted p -values under the null hypothesis, and consider the sorted p -values significant as long as they are under their resampled estimates;
- Benjamini and Hochberg correction:

$$p^* = \frac{n}{n - k} p.$$

The first 3 methods control the familywise error rate (FWER), while the last controls the false discovery rate (FDR).

Maximum entropy distribution inferred from option portfolios on an asset C. Neri and L. Schneider (2009)

Maximum entropy estimators make no distributional assumptions: given a set of option prices for the same underlier and maturity, one can compute the distribution of prices at expiry that maximizes entropy and agrees with the option prices. The article provides detailed computations for calls and digitals, with theoretical justifications.

***Social effects in science: modelling agents
for a better scientific practice***
A.C.R. Martin (2009)

Scientific discovery can be seen as an *opinion dynamics* model on a social network, endowed with two error-correcting mechanisms:

- Experiments, *i.e.*, interaction with nature, seen as an external field;
- Retirement of old scientists.

The bivariate normal copula
C. Meyer (2009)

20 pages of formulas.

Estimation of the instantaneous volatility
A. Alvarez et al. (2010)

Study of the speed of the convergence of

$$\varepsilon^{1-p/2} \sum_i |X_{i\varepsilon} - X_{(i-1)\varepsilon}|^p \longrightarrow m_p \int_0^t \sigma_s^p ds$$

where $dX_t = a_t dt + \sigma_t dW_t$ is a stochastic volatility model (σ_t is a càdlàg martingale) and m_p a constant,

$$m_p = E |Z|^p, \quad Z \sim N(0, 1).$$

***Most efficient homogeneous
volatility estimator***
A. Saichev et al. (2009)

Common estimators of volatility based on OHLC prices, such as

$$\hat{\sigma}_{RS} = \sqrt{\frac{(H - O)(H - C) + (L - O)(L - C)}{T}}$$

$$\hat{\sigma}_{GK} = \sqrt{\frac{k_1(H - L)^2 - k_2((C - O)(H + L) - 2(H - O)(L - O)) - k_3(C - O)^2}{T}}$$

(for some magic values of k_1, k_2, k_3) are not the most efficient. This article studies quadratic estimators (*i.e.*, quadratic forms on $H - O, L - O, C - O$) or more generally homogeneous estimators, and identifies the best one, depending on the model describing the underlying stochastic process.

***Impact of the tick size
on financial returns and correlations***
M.C. Münnix et al. (2010)

The distribution of stock returns (e.g., tail behaviour), the correlation between stock returns, are known to depend on the horizon in a non-obvious way. This could be due to rounding, *i.e.*, to the tick size (either imposed by the exchange, or through psychological reasons leading to clusters at some multiples of the tick size – the *effective tick size*) and can be compendated for.

***A new composite index
of coincident economic indicators in Japan***
S. Fukuda and T. Onodera (2001)

Coincident indicators (that give the state of the economy, *i.e.*, the position in the business cycle) such as industrial production, sales, employment, income (income is used in the US but not in Japan) are naively combined (average growth rate) by the Japanese Economic Planning Agency to produce a “composite index (CI) of coincident indicators”. It is biased towards industrial production, can be inconsistent with leading indicators (that try to predict the state of the economy in the coming year) or even the economic situation. It can be replaced by a less naive model, assuming that all those indicators come from a single hidden factor, that can be estimated with a Kalman filter (Stock-Watson’s “single index dynamic factor model”).

***Multiscaled cross-correlation dynamics
in financial time series***
T. Colon et al. (2010)

Correlation matrices of stock returns have been studied in the following situations:

- Whole spectrum of the sample correlation matrix, estimated on a fixed period of time;
- Evolution, with time, of the largest eigenvalue of the correlation matrix estimated on a moving window of fixed size.

This article suggests to:

- Look at the whole spectrum, not just the first eigenvalue;
- Look at the dependence on both window position and window size, as in wavelet analysis, or look at the matrix of **wavelet correlations** instead: the correlation between the wavelet coefficients at a given location and scale.

***The effect of discrete vs continuous-valued
ratings on reputation and ranking algorithms***
M. Medo and J.R. Wakeling (2010)

Iterative refinements of user and object reputation (à la PageRank) give more accurate ratings than naive averages, but restricting the ratings to a discrete set of values (e.g., a 5-star system) significantly degrades the performance of the algorithm.

***Using Permia and Nsp for constructing
a risk management benchmark
for testing parallel architecture***
J.-P. Chancelier et al. (2009)

Premia is a non-free library developed by the Inria to price derivatives. Nsp is a free Matlab-like language developed by the École des Ponts, not unlike Octave, Scilab or R. They also use MPI for parallelism.

Recurrence networks – a novel paradigm for non-linear time series analysis
R.V. Donner et al. (2009)

There are many ways of constructing a graph (or network) from a time series (or a (single) trajectory of a dynamical system):

- The **recurrence network**, whose adjacency matrix is given by the recurrence plot,

$$R_{ij}(\varepsilon) = \mathbf{1}_{\|x_i - x_j\| \leq \varepsilon}$$

(you may want to remove self-loops; as you change ε , you actually have a family of networks);

- The visibility graph (whose vertices are points in time, and there is an edge between t_1 and t_2 if the $[x_{t_1}, x_{t_2}]$ segment remains above the curve);
- The transition matrix (a weighted graph), whose vertices are discretized values of the time series, and whose weights are the transition probabilities;
- The correlation network (whose vertices are segments $[t, t + T]$, and whose edge weights are $\text{Cor}(x_{t_1, t_1+T}, x_{t_2, t_2+T})$.

Some properties of the time series may be visible on the network (for instance, the recurrence plot of an ergodic time series represents the invariant density, in the phase space), and some graph-theoretic metrics may be informative:

- Degree (number of neighbours);
- Edge density (average degree);
- Local clustering coefficient (testing if there are more triangles around a vertex than in a random network);
- Average clustering coefficient;
- Local degree anomaly (difference between the degree of a node and the average degree of its neighbours);
- Assortativity (measuring if links tend to form between vertices of similar or dissimilar degree – this is similar to the local degree anomaly, but based on edges rather than vertices);
- Matching index (how many neighbours two vertices have in common);
- The matrix of shortest path distances; the average path length; the network diameter;
- Closeness centrality of a vertex (inverse of the average distance to other vertices);
- Betweenness centrality of a vertex (on how many shortest paths it is);
- Edge betweenness (idem, with an edge).

Financial crises and the evaporation of trust
A. Anand (2009)

Financial crises can be modeled with a *credit network*: a dynamic network, whose nodes represent lenders and whose vertices represent loans. From time to time, information about a node (bank) is revealed (leaked) and other lenders may then decide (in a game-theoretic way) to foreclose their positions with it. In this model, the only cause of default is the breakdown of trust. The opacity of the network increases the risk of a bank run: it makes it easier to fall into an “equilibrium”

leading to a bank run than to leave it or to fall into an “equilibrium” that does not lead to a bank run (there are many “equilibria”, most of which break down when information is leaked).

Crises are a financial example of **hysteresis** – trust is easy to lose, but hard to restore.

Optimal split of orders across liquidity pools: a stochastic algorithm approach
S. Laruelle et al. (2009)

Application of **stochastic approximation** (a continuous-time analogue of reinforcement learning – used here in a discrete setting) to splitting orders across several dark pools – the algorithm progressively learns which pool is the best, in terms of volume and price. The article details an alternative algorithm, based on *optimization under constraints*.

Continuous-time trading and the emergence of probability
V. Vovk (2009)

<http://www.probabilityandfinance.com/>

There are two main approaches to probability theory: the axiomatic approach (measure theory) and the frequentist approach. This article uses a third one: game theory. Even without explicitly giving a probability distribution, one can define a game-theoretic notion of “almost surely”, *i.e.*, identify events of probability 1 (on the space Ω of continuous functions $[0, \infty) \rightarrow \mathbf{R}$): “with probability one” means “unless there exists a trading strategy (it has to be adapted to the filtration \mathcal{F}_t generated by Ω – there is no measure, just a filtration) that increases the capital it risks manyfold”.

The article does not really introduce this framework, but it uses it to state and prove that the process of quadratic variation exists, and that replacing the time by this quadratic variation process gives a brownian motion – the result is known for martingales, *i.e.*, if you have a probability distribution. (Informally, this says that in *market time* log-prices are a Brownian motion.)

Nonparametric methods for volatility density estimation
B. van Es and P. Spreij (2009)

In a model of the form

$$Y = X + \text{noise},$$

if you know the distribution of Y , of the noise, and want that of X , you have a *deconvolution problem*,

$$\mathcal{D}_Y = \mathcal{D}_X * \mathcal{D}_{\text{noise}}.$$

With enough independence assumptions, kernel estimators or wavelet estimators are fine. To estimate the density of the volatility in a GARCH or stochastic volatility model, the lack of independence calls for extra caution – but kernels can still do the job.

**Admissible strategies
in semimartingale portfolio selection
S. Biagini and A. Černý (2010)**

A self-financing strategy H is a predictable stochastic process satisfying

$$H \cdot S_t = V_0 + \int_0^t H_s dS_s$$

where S is the semimartingale of discounted prices and V_0 is the initial wealth. This definition is not restrictive enough and includes undesirable or unrealistic strategies: one usually adds further restrictions, such as “never be bankrupt” or (more commonly) “ H is a supermartingale”. This article examines those restrictions and how they arise from the choice of a utility function. (The article uses the notion of Orlicz space: the L^p spaces can be generalized by replacing $|\cdot|^p$ by any non-decreasing function, for instance the lower tail of a utility function $-U(-|\cdot|)$). Strictly speaking, since the utility is not homogeneous and can even take infinite values, there are two spaces: the **Orlicz space** contains functions which have a scalar multiple of finite norm; the **Moore subspace** contains functions all of whose multiples have a finite norm.)

**Modelling financial risk
R. Pfaff
R in Finance 2010**

Overview of the tools one may need to model risk, from one or two time series.

The **PerformanceAnalytics** package provides various estimators of the most common measures of risk, value at risk (VaR) and expected shortfall (ES), e.g., assuming that the distribution is gaussian, and adding a correction for skewness and kurtosis (Cornish-Fisher).

Extreme value theory suggests to refine those estimators in one of the following three ways:

- By looking only at the tail of the data (*i.e.*, the observations above a certain threshold – the peaks-over-threshold (POT) method) and fitting it to a generalized Pareto distribution (GPD). The mean-residual-life plot (aka conditional mean exceedance (CME) plot), $E[X - a | X \geq a] \sim x$, can help select the threshold: the plot will often have a non-linear part, a linear part, and noise; you want to fit the GPD to the linear part (check the POT package and its vignette).
- An alternative, but less efficient use of the data, is to look at the distribution of the maximum return for each year or month (the block-maxima method) and fit it to a generalized extreme value (GEV) distribution (under reasonable assumptions, the limit distribution is in this family).
- Poisson Point Processes are mentioned, with no details.

You may also want to check the **VaR**, **ismev**, **QRMLib** packages (the last two accompany books on quantitative risk management).

To fit the whole distribution, you can use a generalized hyperbolic distribution (GHD, with 3 parameters in addition to the location and scale, check the **ghyp** package), or a special case, such as the normal inverse gaussian (NIG), the hyperbolic distribution (HYP, check the **HyperbolicDist** package for the pdf functions and some fitting algorithms), etc. (also check the **SkewHyperbolic** package). The **actuar** package contains common loss distributions (with fewer parameters).

Serial dependence skews the estimators or risk (VaR, ES) that rely on iid returns: check the **tseries::garch** (GARCH), **fGarch::garchFit** (ARMA-GARCH), **bayesGARCH** (MCMC estimation of a GARCH(1,1) model with Student innovations), **rgarch** (on RForge). packages. There are also some multivariate GARCH packages, as well: **ccGARCH** (conditional correlation GARCH), **gogarch** (generalized orthogonal GARCH).

To account for dependence, do not rely on correlation (there are many fallacies, such as the meaning of a zero correlation or the extreme values not being -1 and 1) but prefer the rank correlation, Kendall’s tau, the index of upper (and lower) dependence

$$\lambda_{\text{upper}}(X, Y) = P[Y > F_Y^{-1}(q) | X > F_X^{-1}(q)]$$

or a copula. (e.g., Gaussian, Gumbel, Clayton or Student, estimated by the method of moments from the rank correlation or Kendall’s tau, or by maximum likelihood). Non-symmetric copulas are not mentioned; no R packages are mentioned.

A copula-GARCH model can be estimated as follows:

- Fit the time series independently, as GARCH(1,1) models with Student innovations, S unless you have a very good reason to think that the serial dependence is negligible;
- Estimate the copula of the residuals;
- Compute the chosen risk measure (VaR, ES, draw-downs, etc.) using simulations.

**RQuantLib: interfacing QuantLib from R
D. Eddelbuettel and K. Nguyen
R in Finance 2010**

QuantLib is a C++ library, using Boost, with bindings for many languages (Python, etc. via Swig; the R binding is manual), for option pricing. implementing various products and methods (Black-Scholes, finite differences, binomial, Monte Carlo, Monte Carlo with low discrepancy sequences, etc.).

```
example(EuropeanOption)
example(BinaryOption)
demo(OptionSurfaces)
```

Fixed income products were recently added: you can build a discount curve (**DiscountCurve**, **FittedBondCurve**) and price bonds (**ZeroCouponBond**, **FixedRateBond**, etc.). A GUI (**RQuantLibGUI**), currently only for bonds, based on the **traitr** package

(inspired by Python's traits UI module) has also been added.

Extending and embedding R with C++
D. Eddelbuettel
R in Finance 2010

To speed up computations in R, you can:

- Use faster functions, that only compute the data needed and none of the diagnostics, for instance `lm.fit` instead of `lm`
- Use `.C` to call a C function: you have to cast the arguments to the right type in R, to compile the shared library (`R CMD SHLIB`) and load it (`dyn.load`); the C code only deals with pointers;
- Use `.Call` to call a C function: it is more transparent on the R side, you can use arbitrarily complicated types, but you have to cast the arguments in C from the `SEXP` type using macros, leading to hard-to-read code; you still have to compile and load the shared library;
- Use `Rcpp`, that relies on the STL to replace those macros and enhance code readability, at the expense of speed (it will be faster than pure R code, but slower than `.C`);
- Use the `Inline` package, that uses any of those three approaches, but transparently compiles and loads the shared library;
- Combine any of the above with optimized libraries, such as GSL or the C++ Armadillo linear algebra classes (the Gnu Scientific Library (GSL) is a C library, with no platform-specific optimizations and a sometimes awkward C-like syntax; it is not limited to linear algebra; Armadillo is a (LGPL) C++ wrapper around Lapack and Atlas, with (compile-time) delayed evaluation of some operations to more efficiently combine them, using templates).

RInside works in the other direction: it allows you to call R from C++.

***Statistical finance for investors
unfamiliar with quantitative methods
using stockPortfolio in R***
N. Christou and D. Diez
R in Finance 2010

Three functions to download stock returns from Yahoo; estimate the variance matrix and the expected returns; and compute "the" optimal portfolio (they mean the tangential portfolio), with or without short-selling. They provide several (mostly undocumented) estimators of the variance matrix and the expected returns:

- Sample variance matrix;
- Constant correlation model: the correlation of any two stocks is always the same;
- Multigroup model: the correlation can take two values, depending on whether the stocks are in the same industry or not; industry membership has to be provided;
- Single index model (a 1-factor model, where the risk

factor has to be provided).

***Business objectives
and complex portfolio optimization***
P. Carl et al.
R in Finance (2010)

Simple optimization problems (linear, quadratic, conical) are well addressed by the **fPortfolio** package, but for real-world problems and less trivial business objectives, such as the expected shortfall (aka conditional value at risk (CVaR), often the Cornish-Fisher CVaR computed from historical data) or the conditional drawdown at risk (mean of the worst $p\%$ drawdowns), and constraints, such as position limits (no single asset should be more than $x\%$ of the portfolio) or CVaR limits (no single asset should have a contribution to the CVaR over $x\%$), the **PerformanceAnalytics** package provides an "approximatively correct [solution] rather than [a] precisely wrong [one]", using two methods:

- Random portfolios: start with random weights and modify them so that the constraints are met (this is an optimization problem with constraints but no objective functions); this will give a set of portfolios on the boundary of the feasibility domain and some in the interior;
- Differential Evolution, *i.e.*, a genetic algorithm used to evolve a population of portfolios to optimize several objective functions (maximize return and minimize risk), so as to cover the (efficient) boundary of the feasibility domain.

Since those computations deal with many (independent) portfolios, they can easily be parallelized.

The package also provides many plots: portfolios in the risk×return space (you can compare your portfolio with an equal-weighted or *equal-risk* (equal-contribution-to-CVaR) benchmark); cumulative returns; monthly returns (and expected shortfall) over time; drawdown; portfolio weights by asset (or asset type) over time; contribution to the portfolio expected shortfall (or value at risk) by asset, over time.

RProtoBuf: Protocol Buffers for R
R. Francois and D. Eddelbuettel
R in Finance 2010

Protocol Buffers is a serialization format (like JSON, BSON (binary JSON, used by some unstructured databases, such as MongoDB), YAML, ASN, or even XML) and corresponding C++ library, developed by Google. The **RProtoBuf** packages allows you to read and write data in this format, and can be used when your data does not easily fit in a CSV file. It is possible to (manually, for the moment) use `Rcpp` to speed up data access.

***Testing, monitoring and dating
structural changes in FX regimes***
A. Zeileis

The **strucchange** package can be used to assess when a country changed the control on its currency:

- Consider FX returns with respect to a currency not involved in the affair, e.g., CHF;
- Regress the returns against those of currencies potentially involved (USD, EUR, GBP, JPY);
- Test if the coefficient for the dollar is significantly different from 1, if the other coefficients are significantly different from 0;
- Look for a regime change.

[duplicated?]

**Portfolio optimization
with CVaR budgets**

K. Boudt et al.

R in Finance 2010

The risk budget (risk is measured by the expected shortfall (ES, CVaR), estimated from historical moments via the Cornish-Fisher estimator) can be used in the portfolio construction process (with the DEOptim package):

- As an objective: minimize the CVaR of the portfolio, or minimize the maximum contribution to CVaR;
- As a constraint: equal-risk portfolio (all assets are required to have the same contribution to the portfolio CVaR, to downweigh “hot spots”) or 60/40 allocation between (the contribution to CVaR of) equities and bonds.

**Entropy correlation distance method
applied to study correlations
between the gross domestic product
of rich countries**

A. Ausloos and J. Miśkiewicz (2009)

Another distance between positive time series (for clustering, minimum spanning tree, etc.): the correlation between their moving-window entropies.

**Spiraling towards market completeness
and financial instability**

M. Marsili (2009)

There seems to be a singularity (like S. Hawking’s black holes) in the space of possible financial markets, as we increase the complexity of financial instruments to increase market completeness – this also increases any market imperfection (lack of transparency, asymmetric information, etc.).

The premium of dynamic trading

C.H.Chiu and X.Y.Zhou (2009)

The efficient frontier of a set of assets is usually computed for a single period. It can be generalized to a multiperiod (or even continuous-time) setting. The efficient frontier is (unsurprisingly) higher but is still a line if there is a risk-free asset.

**Characterizing individual
communication patterns**

R.D. Malmgren et al. (2009)

Human-generated events (e.g., sending emails) can be modeled as a 2-state Markov chain (active/inactive), the agent emitting a signal (Poisson process) with a different rate in each state.

**Personalized recommendation via integrated
diffusion on user-item-tag tripartite graphs**

Z.-K. Zhang et al.

Many recommendation algorithms are just diffusions (random walks) on bipartite (user-item and user-tag) or tripartite (user-tag-item) (hyper)graphs.

**Hypergraph topological quantities
for tagged social networks**

V. Zlatić et al. (2009)

Another article on the same subject – nothing new.

**Understanding
the Lee-Carter mortality forecasting model**

F. Girosi and G. King (2007)

The Lee-Carter mortality model approximates the matrix $m_{a,t}$ of the logarithms of mortality rates in (age) group a and year t as a rank-1 matrix (use the singular value decomposition (SVD) to find it)

$$m = \beta \gamma'$$

where β is the base mortality in each group and the mortality index γ models the time evolution of the mortality rates, often as a random walk. The resulting process $(m_{\cdot,t})_t$ is a multi-dimensional random walk with strong constraints on the variance matrix. If the rank-1 assumption is not valid (look at the eigenvalues), you may want to consider a rank- k approximation or an unconstrained random walk.

**The Lee-Carter model
for forecasting mortality, revisited**

S.H. Li and W.S. Chan

The Lee-Carter model is not robust. You may want to add a contamination model that looks for:

- Additive outliers: 
- Innovational outliers: 
- Level shifts: 
- Temporary changes: 

**The role of a matchmaker
in buyer-vendor interactions**

L. Lü et al. (2009)

Around the stable marriage problem: match men/women, employers/job seekers, landlords/tenants, buyers/sellers to maximize some total utility

$$u = (x^y + y^k)^{1/k}$$

(changing k creates more or less inequality). The “matchmaker” is just a personification of the perfect knowledge of all utilities, as opposed to auctions or the (potentially never-ending) quest for a sufficiently good match.

***A dynamic model of
time-dependent complex networks***
S.A. Hill and D. Braha (2009)

We have acceptable models of (random, static) networks, but few of *dynamic* networks. Here is one, in which the hubs (highly connected nodes) can change quickly, as observed in daily email datasets:

- Start with a (static) underlying network;
- For each day, build a subnetwork via a node-reinforced random walk: choose the next node of the random walk among the neighbours of the current node, with probabilities

$$p \propto 1 + \lambda \times \text{number of visits.}$$

***Effective and efficient similarity index
for link prediction of complex networks***
L. Lü et al. (2009)

One can try to predict missing or future links in a network (the recommendation system of an online shop is a link prediction system in the bipartite client \times item graph; there are applications in gene \times protein networks as well) by looking at node similarity measures, such as:

- The number of common neighbours $(A^2)_{xy}$;
- The *Katz index*, *i.e.*, the weighted number of paths between two nodes, with less weight on longer paths,

$$\left(\sum_{k \geq 2} \beta^k A^k \right)_{xy};$$

- The first two terms of this series, $(A^2 + \varepsilon A^3)_{xy}$.

***Limits of declustering methods for
disentangling exogenous from endogenous
events in time series with foreshocks, main
shocks and aftershocks***
D. Sornette and S. Utkin (2009)

A time series of events (earthquakes, financial crises, etc.) can be modeled as a *Hawkes process* (aka ETAS (epidemic-type aftershock) model)

$$\lambda(t, M, \mathcal{H}_t) = \mu(t, M) + \sum_{t_i < t} h(t, M, t_i, M_i)$$

where M is the magnitude of the event, the first term is the background density (alone, it would lead to a Poisson process), the second term is the response function to past events (measuring their propensity to trigger aftershocks). Algorithms to disentangle those events (*i.e.*, label them as “exogenous” (background) or “endogenous” (aftershock)) do not perform well.

***Detecting network communities
by propagating labels under constraints***
M.J. Barber and J.W. Clark (2009)

The label propagation algorithm (LPA) to identify communities (assign a label to each vertex at random; change the label of a vertex to that of the majority of its neighbours, iterate until convergence) finds a local optimum of some optimization problem – it turns out that the global solution is the situation in which all vertices have the same label... A penalty can be added to bring the optimization closer to what we expect.

Structure of shells in complex networks
J. Shao et al. (2009)

Exercise on generating functions and networks; the shell (wrt a node) is the set of nodes ℓ edges away from it.

Market bubbles and crashes
T. Kaizoji and D. Sornette

A readable, non technical, superficial review article:

- Bubbles are frequent and follow the following pattern: new opportunity (beware when the media start to talk about “new ...” – you could try to build a bubble index by counting the number of occurrences of the word “new” in the press – add synonyms, as well), rising prices, investments in increasingly illiquid assets, crash.
- Markets are not efficient: current prices are not the present value of future cash flows.
- Evidence that this can be explained by limits on arbitrage (e.g., short sales restrictions) are mixed: some look convincing (such restrictions should lead to overvaluation), but so is the evidence that those limits can be circumvented (by using options instead of short sales: the put-call parity, from tick data (rather than close prices, which are quotes on which one cannot trade), is valid);
- Rational investors do ride bubbles; by anticipating them, they actually create them: they know that noise (irrational) traders will follow them;
- Rational investors do not arbitrage bubbles out, because then do not know *when* to do so – the bubbles therefore continues to grow;
- Physicists use statistical mechanics to model markets as the aggregation of many “agents” and describe bubble bursts as phase changes;
- Bubbles are characterized by faster-than-exponential growth

$$\log(\text{price}) = \alpha + \beta(t_0 - t)^\gamma + \text{noise}, \quad \gamma < 1, \quad \beta < 0$$

(this is often visible on a 6-month window; you could use this to build a bubble detector)

- ODE with “explosive” behaviour can be generalized to SDEs (“stochastic finite time singularities”);
- The log-periodic power law model is just mentioned.

Financial bubbles, real estate bubbles, derivative bubbles and the financial and economic crisis

D. Sornette and R. Woodard (2009)

Another similar review article, with historical data,

- To explain the causes of the crises, do not spend your time identifying the first domino to fall: instead, try to understand why the dominoes were laid out like that.
- Technical and rational mechanisms (what is rational for a single investor need not be so for the market as a whole) play a small role, behavioral mechanisms dominate.
- More details on the log-periodic power law, and actual examples

$$\log(\text{price}) = \alpha + \beta(t_0 - t)^\gamma (1 + \varepsilon \cos(\omega \log(t_0 - t) + \phi))$$

Complex systems: from nuclear physics to financial markets

J. Speth et al. (2009)

Log-periodic oscillations (à la Sornette) can result from a **Weierstrass random walk**: take a step of length $b^j a$ with probability proportional to $1/M^j$ ($b > 1$, $M > 1$, vary $j \in \mathbb{N}^\times$).

The Markov modulated Poisson process and Markov Porsson cascade with applications to web traffic modelling

S.L. Scott and P. Smyth (Bayesian Statistics, 2003)

A Markov modulated Poisson process (MMPP, or Markov Poisson cascade, when the states are ordered to make the model identifiable) is a Poisson process whose rate varies according to a (finite-state, hidden) Markov process, used to model events with irregular bursts of activity (an n -state MMPP is equivalent to a superposition (sum) of n (fixed-rate) Poisson processes, some of which may be inactive, the inactivity being controlled by an n -state Markov chain). They can be fitted with the EM algorithm or MCMC data augmentation.

Causal links between US economic sectors
G.H.T. Lee et al. (2009)

To analyze a bubble or crash (after the fact), take hourly sector log-returns, segment each of them by recursive regime change tests (likelihood ratio test of a gaussian distributions versus two gaussian distributions; you can reoptimize the segment boundaries at each step), stop when some threshold is reached, assign the segments to either a “high” or a “low” volatility regime, plot all segmented time series (the segments are different for each sector) with a level of grey indicating the volatility level, try to spot the beginning of the crisis and the recovery (a month of high, resp low, volatility), compare the start and end of the crisis for

each sector – often, the first to enter is also the last to leave.

The Stress VaR: a new risk concept for superior fund allocation

C. Coste et al. (2009)

The risk of a (portfolio of) hedge fund(s) can be estimated as follows:

- Select several good 1-factor risk models (rather than a single multi-factor model – this can be seen as a form a bayesian model averaging (BMA) or a regularized multifactor model);
- Take the *maximum* of the value-at-risk (VaR) predicted by those models (rather than the VaR of their linear combination).

Adaptive model for recommendation of news

M. Medo et al. (2009)

Most recommendation systems use a *global* rating system, and only narrow down the centers of interest of the users by categories or keywords – some distinguish between short- and long-term interests; some use implicit ratings (based on access or reading time). The authors use an epidemic-like process to propagate relevant news among users with a similar interest profile; the timeliness of the news is ensured by the exponential spreading of epidemics (if the users find the news relevant) and a continuous time decay.

Financial bubble analysis with a cross-sectional estimator

F. Abergel et al. (2009)

The authors claim that the proportion of stocks with performance beyond some threshold z since “some” reference date (and its asymptotic behaviour $\sim_{z \rightarrow \infty} z^{-\alpha}$) can be used as a bubble indicator – but then, they only check that the cross-sectional variance can be used as a bubble indicator.

Stability analysis with applications of a two-dimensional dynamical system arising from a stochastic model for an asset market

V. Belitsky and A.L. Pereira (2009)

To examine the stability of stock markets, you can build a 2-dimensional dynamical system for the price and the excess demand (for a single asset).

Joint modelling of gas and electricity spot prices

N. Frikha and V. Lemaire (2009)

Gas and electricity prices are important for power plants and energy companies: they represent their costs and revenues. They exhibit the following features: seasonality, trend, spikes, heavy tails, autocorrelation, long-memory, cross-correlation. (After removing the trend and seasonality), they are often mod-

eled by Ornstein processes

$$X(t) = \sum_i Y_i(t)$$

$$dY_i = -\lambda_i Y_i dt + dL_i$$

where the L_i are brownian motions (leading to Ornstein-Uhlenbeck processes) or Lévy processes (to model the spikes – one could also use OU processes with very quick mean reversion); some of those L_i appear in both the gas and electricity models, to account for cross-correlation. The authors replace the Lévy processes by considering OU processes and more general diffusions

$$dY = -\lambda Y dt + \sigma(Y) dW$$

where σ is chosen to give the observed stationary distribution (if you know the drift and the stationary distribution of a diffusion, you can compute its volatility), modeled as a (quasi-saddlepoint approximation of a) normal inverse gaussian (NIG) distribution.

Eroding market stability by proliferation of financial instruments
F. Caccioli et al. (2009)

The proliferation of financial instruments make the markets more efficient, more complete, but it also brings them closer to an unstable state – a phase transition. This comes from the interplay of supply and demand and the price impact of transactions.

The article also contains a concise definition of financial markets (markets that allow intertemporal exchanges of wealth) and a clear description of the 1-period asset pricing framework:

- There are two times, $t = 0$ (today) and $t = 1$ (tomorrow);
- There is a finite set Ω of possible states ω at time $t = 1$, each probabilities p_ω ;
- There are K risky assets, that cost 1 today and pay $r_{k,\omega}$ tomorrow;
- There is one risk-less asset, that costs 1 today and pays 1 tomorrow;
- There is no arbitrage, *i.e.*, there is no portfolio whose return is positive or 0 in all states and positive in at least one state;
- This implies the existence of an *equivalent martingale measure* q such that

$$\forall k \quad E_q[r_k] = \sum_{\omega} q_{\omega} r_{k,\omega} = 0$$

- A contingent claim is a contract that pays f_{ω} in state ω ; if there exists a replicating portfolio θ , *i.e.*, a portfolio θ such that

$$\forall \omega \in \Omega \quad f_{\omega} = f_0 + \sum_k \theta_k r_{k,\omega}$$

the contingent claim is said to be *marketable* and its price is $V_F = E_q[f] = \sum_{\omega} q_{\omega} f_{\omega}$;

- The market is complete if there are at least $\#\Omega$ independent vectors among r_1, \dots, r_K ; then, all claims are marketable and the risk-neutral measure is unique.

A general “bang-bang” principle for predicting the maximum of a random walk
P.C. Allart (2009)

The best predictor (adapted stopping time) of the maximum (on $[0, T]$) of a random walk with drift is obtained with $\tau = 0$ if the drift is negative and $\tau = T$ if it is positive.

Risk concentration and diversification: second-order properties
M. Degen et al. (2009)

First order (I would say zeroth order) approximations of the **risk concentration**

$$C(\alpha) = \frac{\text{VaR}_{\alpha} \sum_i X_i}{\sum_i \text{VaR}_{\alpha} X_i}$$

or the risk diversification $1 - C(\alpha)$, for instance,

$$\frac{F(tx)}{F(t)} \xrightarrow{t \rightarrow \infty} x^{-1/\xi} \implies C(\alpha) \xrightarrow{\alpha \rightarrow 1} n^{\xi-1}$$

are not sufficient: the convergence is too slow. One can devise a second-order (first-order) approximation.

In the case of non-coherent risk measures (such as the value-at-risk), the diversification benefit can even be negative.

```
N <- 1e6
library(actuar)
x <- rburr(N,1,1)
y <- rburr(N,1,1)
f <- function(z) quantile(z,.99)
f(x+y)/(f(x)+f(y)) # > 1...
```

Adaptive model for recommendation of news
M. Medo et al. (2009)

Most recommendation systems use a *global* rating system, and only narrow the centers of interest of the user by categories or keywords – some also distinguish between short- and long-term interests; some use implicit ratings (based on reading time or access). The authors use an epidemics-like process to propagate relevant news among users with a similar rating profile; the timeliness of the news is ensured by the exponential spreading of epidemics (if the users find it relevant) and a continuous time-decay.

A coupled markov chain approach to risk analysis of credit default swap index products
R. Hochreiter and D. Wozabal (2009)

Confusing attempt to add some dependency (sector membership) to the transition matrix generating rating changes:

- Each assets's rating is a Markov chain (with states AAA, AA, etc.) whose transition matrix is known;
- If two assets are in the same sector, their rating are not independent and can be modeled by a Bernoulli mixing model.

***Universal power laws
in the threshold network model:
a theoretical analysis
based on extreme value theory***
A. Fujihara et al. (2009)

Asymptotic analysis of the **threshold network model** – random networks on a set of nodes obtained by randomly assigning a weight to each node (according to a given probability distribution) and linking any two nodes when the sum of their weights exceeds a given threshold.

***Leverage causes fat tails
and clustered volatility***
S. Thurner et al. (2010)

Limits on leverage cause funds to sell in falling markets, amplifying the fall. Limits based on volatility (allow a high leverage when the volatility is low) are even worse. (The article also recall what a *margin call* is: what you have to pay to a lender when the value of your collateral drops below an agreed limit.)

***Atmospheric complexity
or scale by scale simplicity?***
**S. Lovejoy et al.
Geophysical Research Letters (2009)**

The fractal nature of the atmosphere (similar structures are present at different scales) could simplify weather forecast – the article only presents evidence of these fractal structures, but no applications. [This structure can be seen as a form of symmetry, \mathbf{Z} acting by $n : \mathbf{x} \mapsto \lambda^n \mathbf{x}$, which should lead to a conservation law (Noether's theorem), that could simplify the PDEs – or simply allow macroscopic forecasts without looking at the microscopic data.]

***Correlation breakdown,
copula credit default models and arbitrage***
R. Tzani and A.P. Polychronakos (2009)

Complete nonsense: when the market and the model (Gaussian copula for CDSes...) disagree, the market is wrong and the model is right – and you are bankrupt.

A computational view of market efficiency
**J. Hasanhodzic et al.
AlphaSimplex, MIT (2009)**

In a market with periodic returns, modified by the impact of bounded-memory traders, traders with more memory make more profits.

***Market impact and trading profile
of large trading orders in stock markets***
E. Moro et al. (2009)

Market impact of hidden orders (large trading orders, executed incrementally) increases as the square root of the order size; once the order is finished, the impact reverts to half its peak value

The scale of market quakes
T. Bisig et al. (2009)

The multiscale structure of log-price time series can be described by the “term structure of volatility” (volatility of the time series of returns over intervals of size τ , as a function of τ); it is a function, but its values can be combined in some ad hoc way to produce a single numeric “scale of market shocks”. The authors present (somewhat confusingly) a similar measure based on the irregular time series of “directional changes of amplitude greater than λ ”, for various values of λ . This is similar to the term structure of volatility, but measured on *market time*, rather than clock time.

***Modeling scientific citation patterns
and other triangle-rich acyclic networks***
Z.X. Wu and P. Holme (2009)

Empty article presenting a model of network evolution, whose parameters are: the out-degree distribution; the aging of the relevance of papers (nodes); the formation of triangles.

***On the relationship between
trading network and WWW network:
a preferential attachment perspective***
A. Mirzal (2009)

The **page rank** algorithm (the rank of a page depends on the rank of the pages pointing to it, with less weight for pages with too many links),

$$\text{page rank}_i = \sum_{j \rightarrow i} \frac{\text{page rank}_j}{\text{out-degree}_j}$$

is an eigenvalue problem

$$p = p \cdot O^{-1}L$$

p : vector of ranks

O : diagonal matrix of out-degrees

L : incidence matrix

often solved iteratively (after some rescaling to ensure convergence).

The HITS (hypertext-induces topic search) algorithm considers two types of ranks, “hub” and “authority” (you can see this as a hidden fuzzy bipartite structure)

$$\begin{aligned} \text{authority}_i &= \sum_{j \rightarrow i} \text{hub}_j \\ \text{hub}_j &= \sum_{j \rightarrow i} \text{authority}_i \end{aligned}$$

is another eigenvalue problem

$$\begin{aligned}\text{authority} &= \text{hub} \cdot L \\ \text{hub} &= \text{authority} \cdot L\end{aligned}$$

i.e., the vectors of authority and hub scores are eigenvectors of $L'L$ and LL' (to ensure unicity and convergence, it may be necessary to rescale and/or regularize those matrices, as with ridge regression).

The same ideas can be used to study *trading networks*, *i.e.*, networks of buyers, sellers and resellers. [There may be a link between the price discovery process and the convergence of those algorithms.]

A penalized matrix decomposition, with applications to sparse principal components and canonical correlation analysis

D.W. Witten et al.

The first r components of the singular value decomposition of a matrix X ,

$$X = UDV', \quad U'U = 1, \quad V'V = 1, \quad D \geq 0,$$

give its best rank- r approximation (for the Frobenius norm)

$$\sum_{k=1}^r d_k \mathbf{u}_k \mathbf{v}_k' = \underset{Y, \text{rank } Y \leq r}{\text{Argmin}} \|X - Y\|_F^2.$$

This can be generalized by adding a penalty for \mathbf{u} and \mathbf{v} , leading to a penalized rank- r approximation, and a **penalized matrix decomposition** (PMD). The suggested penalty combines the lasso (an L^1 penalty, $\sum_u |u_i|$) with the *fused lasso* ($\sum |u_i - u_{i-1}|$).

The PMD can be used to define **sparse principal components** (other formulations exist, based on regression properties or the variance minimization property of the principal components).

The article also provides (efficient) algorithms to compute those decompositions.

Sparse inverse covariance estimation with the lasso

J. Friedman et al. (2007)

A sparse variance matrix estimator, based on the lasso (L^1 penalty); the sparsity of the matrix gives an undirected (sparse) graph between the variables.

Ant-based clustering and topographic mapping

J. Handl et al.

Ant-based sorting is a topographic mapping algorithm (*i.e.*, an algorithm that maps observations from a high-dimensional space to a plane or some other low-dimensional space, such as multi-dimensional scaling (MDS) or self-organizing maps (SOM)) in which agents (ants) pick up observations (randomly), transport and drop them (randomly) where there are similar observations around. The algorithm can be improved as follows:

- Increase the penalty for dissimilarity, to help separate the clusters;
- Add some short-term memory, so that each ant knows if a newly picked up observation is similar to those around a previous drop point;
- Progressively increase the radius of perception of the ants;
- For a limited time, take into account the number of occupied cells (the density), to help spread out the clusters (only for a limited time, because we want the clusters to be globular, cluster-like);
- The article also suggests some empirical changes to the pickup and drop probabilities, and gives some advice on the choice of the parameters);
- If you want clustering, and not only topographic mapping, apply some clustering algorithm such as agglomerative clustering to the result.

The performance of the algorithm was examined with the F measure (from the ideas of *precision* and *recall* in *information retrieval*)

$$\begin{aligned}G_i &= \text{desired groups} \\ C_i &= \text{clusters produced} \\ p_{ij} &= \frac{\#G_i \cap C_j}{\#C_j} \\ r_{ij} &= \frac{\#G_i \cap C_j}{\#G_i} \\ F_{ij} &= \frac{2p_{ij}r_{ij}}{p_{ij} + r_{ij}} \\ F &= \sum_i \frac{\#G_i}{\#X} \text{Max}_j F_{ij},\end{aligned}$$

the Dunn index

$$D = \text{Min} \frac{\text{inter-cluster distance}}{\text{Max cluster diameter}}$$

and the intra-cluster variance.

For clustering, the algorithm fails to recognize the clusters in presence of a hierarchical structure (it only recognizes the top of the hierarchy), fails to recognize small clusters in general; but scales much better than competing algorithms. For topographic mapping, MDS performs better in low dimensions, SOM in high dimensions.

A hybrid particle swarm ant colony optimization for design of truss structures

A. Kaveh et al. (2008)

(This is just a random article on the subject, among hundreds of others: it does not bring anything new.) **Particle swarm optimization** (PSO) is a population-based optimization algorithm, in which the particles (candidate solutions) move, influenced by

- Their momentum;
- The best solution they have found so far;
- The position and momentum of the particles around them, *i.e.*, (indirectly) the best solution their neighbours have found so far;

- In the **ant colony optimization** (ACO) variant, they are also influenced by (pheromones left around, indicating the momentum of) particles that were there some time ago.

This may not work well in high dimensions, because of the curse of dimensionality, except if, as here, *constraints* drastically reduce the search space.

Choosing colors for Data Visualization **M. Stone (2006)**

- We perceive contrasts of colours in three dimensions: hue, value and chroma; try to use all three.
- Excessive hue variations create clutter: also use contrasts of value and chroma.
- Avoid saturated colours (only use them to highlight).
- To be legible, graphical (or textual) elements should have a contrast of *value* with the background (contrast of hue or chroma is insufficient); smaller sizes require more contrast. Indeed, some artists first “block in the values” and only add colour at a later stage.
- Only use 2 or 3 hues, e.g., analogous or complementary or split-complementary (*i.e.*, one colour and two colours close to its complementary).
- A white background is preferable: it provides a reference for colours (the “white balance” of your digital camera).

Dot Plots: A Useful Alternative to Bar Charts **N.B. Robbins (2006)**

Barcharts can become cluttered when there are many observations (the ink/information ratio is high), when there are several variables (stacked bar charts are almost always a bad idea), or when the zero is not meaningful or too far from the bulk of the data: in those cases, you can use dotplots instead.

Practical rules for using colors in charts **S. Few (2008)**

A list of simple rules, with examples and counterexamples:

- Use a consistent background, to allow a reliable comparison of the colour or value of the plot elements (think of grey squares of the same intensity, on a grey *gradient*);
- The colour of the objects should contrast with the background (counterexample: a heatmap, *i.e.*, a table whose cells are coloured, where the important values sometimes end up in black on a dark background);
- Only use colour with a purpose in mind;
- The differences in colour should be meaningful (the viewer will instinctively try to interpret those differences: at the very least, this would distract him from what he should be looking at; the typical counterexample is a barchart with a different colour for each bar);

- Use neutral colours (greys, browns, pastels) for most information, and bright/dark saturated colours for what requires more attention;
- Do not cover large areas with saturated colours: that looks garish, unsophisticated, unprofessional (the Brewer palettes are fine for large areas);
- Small elements (thin lines, dots in a scatterplot) require brighter/darker and more saturated colours to be easily distinguished; this is the reason why the Brewer palettes (designed for maps) are inadequate for line plots or scatterplots;
- Use a single hue to encode sequential values (or two for diversifying ones, *i.e.*, if there is a clearly defined “zero”);
- Use a dull, hardly visible colour for less important elements (axes and borders could be grey, the background could be white);
- Do not use red and green together, even if they seem widely understood as “traffic light colours”: most colourblind people cannot distinguish them (red and blue is fine);
- Choose a few palettes in advance (and for each, a variant with more saturated colours for scatterplots and lineplots) and keep them at hand;
- Do not use visual effects (3D, reflections, etc.).

Introduction to cycle plots **N.B. Robbins (2008)**

For progressively changing periodic patterns:

```
xyplot( x ~ week | day_of_week )
```

Sequential implementation of Monte Carlo tests with uniformly bounded resampling risk **A. Gandy**

The power of a Monte Carlo test can be improved by replacing the sum

$$\sum_1^n \mathbf{1}_{T_i \geq T}$$

with the whole path of the partial sums

$$\sum_1^k \mathbf{1}_{T_i \geq T}, \quad k \geq 1,$$

and comparing them with boundary paths.

A simple forward selection procedure based on the false discovery rate control **Y. Benjamini and Y. Gavrilov (2009)**

Variable selection, in a regression model, can be seen as a penalized regression with an L^0 penalty; this can be generalized to other penalties, including non-linear ones (a non-linear function of the L^0 or L^1 norm of the coefficients). Variable selection algorithms often perform statistical tests to decide whether to add a new

variable, all with the same threshold for the p -value; instead, one can use the false discovery rate,

$$\text{FDR} = \frac{\#\text{true rejected null hypotheses}}{\text{rejected null hypotheses}}$$

to progressively change this threshold.

***Bayesian methods
for measuring operating risk***
C. Alexander (2002)

If you do not have enough loss data to fit an extreme distribution, add a bayesian prior, in the form of a bayesian network (*i.e.*, more variables, with known dependency relations between them), to incorporate domain knowledge.

***Retrospective exact simulation
of diffusion sample paths with applications***
A. Beskos et al. (2006)

Most algorithms sampling from the paths of a diffusion do not sample from the stochastic process itself, but from a different but hopefully close discrete process. The (confusing) article presents an exact simulation algorithm, based on rejection sampling.

Exact simulation of diffusions
A. Beskos and G.O. Roberts (2006)

Still not understandable, in spite of the examples.

***MCMC methods for multi-response
generalized linear mixed models:
the MCMCglmm R package***
J. Hadfield
Journal of Statistical Software (2006)

The MCMCglmm package fits generalized linear mixed models; it is more restricted than Bugs/Jags, but faster. Presenting the same example in the Bugs language (which is straightforward to understand) would help understand the syntax of the function.

***Exploratory data analysis leading towards
the most interesting binary association rules***
A. Iodice D'Enza et al.

Given a binary dataset, *e.g.*, a basket \times item boolean matrix Z representing the sales of an online shop, **association rules** are pairs of items, $A \implies B$, with a large enough **support** $P(A \cap B)$ and a large enough **confidence** $P(B|A)$ – this can be generalized to tuples. Association rule mining algorithms, such as the *Apriori* algorithm, usually select all pairs with a large enough support, and among them, take those with the largest confidence. The computations can be formulated in linear algebraic terms,

$$\text{Support} = \frac{1}{n} Z'Z$$

$$\text{Confidence} = Z'Z \text{diag}(\text{Support})^{-1}$$

but the matrices are too large. Dimension reduction through **incremental k -means** (add the baskets one by one) can make (those matrices block-diagonal and) the computations amenable.

***Volatility forecasts and the at-the-money
implied volatility: a multi-components ARCH
approach and its relation with market models***
G. Zumbach
Risk Metrics (2007)

A **multiscale ARCH** process is an ARCH(∞) process of the form

$$r_{t+1} = \sigma_t \varepsilon_{t+1}$$

$$\varepsilon_t \sim N(0, 1)$$

$$\sigma_t^2 = \sum_{k=1}^n w_k \sigma_{t, \tau_k}^2$$

$$\sigma_{t, \tau}^2 = e^{-1/\tau} \sigma_{t-1, \tau}^2 + (1 - e^{-1/\tau}) r_t^2$$

i.e., the squared volatility is some linear combination of exponential moving averages, with different time scales, of the squared returns. These factors play a role similar to the risk factors of a risk model. One or two different time scales (say, 3 weeks and 3 years) may suffice. The long-memory ARCH uses a large number of components, but the characteristic times and the weights have simple forms (geometric increasing and logarithmic decreasing),

$$\tau_t / \tau_{k-1} = \rho$$

$$w_k \propto 1 - \frac{\log \tau_k}{\log \tau_0}$$

This can be generalized to a continuous-time model.

***Stability of graph communities
across time scales***
J.-C. Delvenne et al. (2009)

Gauging the quality of a clustering (community structure) in a graph is difficult: here is another measure to consider. Let $(X_t)_t$ be the random walk on the graph and $T_{i,t} = \mathbf{1}_{X_t \in C}$ the boolean variable denoting membership to community C (it is no longer Markov). Its autocorrelation function (plot it with a log-scale for the lag) is a measure of the stability of the community.

Mapping change in large networks
M. Rosvall and C.T. Bergstrom (2009)

You can assess the significance of a clustering or partition of a network (a kind of dimension reduction) by comparing with that of bootstrap samples; the evolution of those clusters can be represented in an **alluvial diagram**. This is exemplified by the emergence of neuroscience from molecular biology, psychology, psychiatry, neurology, medicine.

Random hypergraphs and their applications

G. Ghoshal et al. (2009)

Folksonomies (sets of $\langle \text{user, resource, tag} \rangle$ triplets, in collaborative tagging websites such as flickr, citeU-like, delicious, bibsonomy) or RDF databases (sets of $\langle \text{subject, object, verb} \rangle$ triplets) can be represented by **tripartite hypergraphs**. Some care is needed to extend classical graph-theoretic notions: the degree of a vertex is the number of hyperedges containing it (rather than the number of neighbours of a given colour); there is a degree distribution for each vertex type (colour) and the three are linked (they cannot be chosen independently: they must imply the same number of hyperedges); there are various kinds of projections (onto one or two colours, using vertices of one or two colours). Some properties of hypergraphs can be studied by looking at the generating functions of the three degree distributions: degree distribution of the projections, existence of a giant component, percolation (*i.e.*, proportion of vertices you can remove without breaking the giant component). A random tripartite graph can be defined by specifying the degree distribution (they have to be compatible, *i.e.*, they should all suggest the same number of hyperedges), choosing hyperedge stubs at random for each vertex, and joining them at random. The proportions of those random tripartite hypergraphs do not match those of real-world ones, mainly because they fail to account for multiple tagging (the same user giving different tags to the same resource).

The empirical properties of large covariance matrices

G. Zumbach (2009)

When estimating a covariance matrix from time series, you may want to estimate it on a moving window (or with decaying weights) and consider the evolution of:

- The top eigenvalues (spectrum);
- The distribution of the eigenvalues (spectral density);
- The subspace spanned by the top eigenvalues (it can change, even if the eigenvalues look stable);

In the spectrum, there is no clear separation between noise and non-noise eigenvalues as suggested by random matrix theory (RMT). The dynamics of the covariance and the correlation matrix are very different (some people suggest they have significantly different characteristic time scales and suggest to model correlation and volatility separately, as in the constant correlation GARCH model, with a quickly moving volatility and a slowly changing correlation).

Executing large orders in a microscopic market model

A. Weiss (2009)

Comparison of a microscopic market model (that explicitly models the limit order book, or even a generalized order book, which contains the opinion of a

fair price for all investors, to account for hidden liquidity) and a macroscopic model (that models the limit order book more implicitly, *e.g.*, with two parameters, “shape” and “resilience”): how do **optimal trading strategies** for one model fare in the other? This is an (imperfect) way of measuring the robustness (to model specification) of those strategies.

Computational modeling of collective human behavior: example of financial markets

A. Kirou et al. (2008)

A market model in which traders use information both global and local (from their social network).

Studies of the limit order book around large price changes

B. Toth et al. (2009)

After a large price jump (a single-stock event, not a market crash), all quantities progressively go back to normal, following a power law. This relaxation can be simulated by a multiagent model.

Production copula

H. Iyetomi et al. (2009)

The *production equation*

$$\text{Production} = F(\text{Labour}, \text{Capital})$$

(*e.g.*, the Cobb–Douglas model, $\text{Production} \propto \text{Labour}^\alpha \text{Capital}^\beta$) should be replaced by (a statistical model or, more generally) the probability distribution of

$$(\text{Production}, \text{Labour}, \text{Capital})$$

to account for the heterogeneity of economic agents. The article models the marginal distributions and the copula separately – but their model has fatter tails than the data... Their copula is a **non-exchangeable** (*i.e.*, hierarchical) Gumbel copula.

Smoothing of multivariate data Density estimation and visualization

J. Klemelä

Wiley (2009)

In this multivariate data analysis book, the author uses two types of plots to display information, in very different contexts:

- **Rooted trees**, whose nodes are labeled by numbers, such as the heights of the nodes (for nice plots it should increase as you move away from the root) or the n th coordinate of the point (if it came from the dataset);
- **Volume plots**, built from a rooted tree whose nodes are labeled with two numbers interpreted as the altitude of the node and its width; the tree plot looks like stacked slabs of tree. (It is not uniquely defined: each time there is a branching, you can choose the order of the branches.) This is a 1-dimensional analogue of a treemap;

Here are a few examples.

Plotting the barycenter of each connected component of each level set $[f = \lambda]$ or upper level set $[f \geq \lambda]$ of a density f versus λ gives a tree. Plotting a segment for each connected component of each level set $[f = \lambda]$ (of length the volumes of the level sets, suitably renormalized, e.g., by using the radius of a ball with the same volume), and stacking those segments, gives a **volume plot**: it displays the modes and spreads of the original distribution (the notion of “mode-preserving transformation” or *mode isomorphism* can be formalized). The shape of the peaks gives information about the skewness and the fatness of the tails. The volume plot is actually a 1-dimensional analogue of the treemap.

In a volume plot, you can replace the volume of the levelsets by any interesting function. You can also replace the density by any function built from the data at hand – think of all the functions you use in scagnostics plots. For instance, if you have a shape (say, a single level set), the distance from a reference point gives a foliation, called the *radius transform* of this shape. The corresponding tree, the **shape tree**, formed from the connected components of $S \setminus B(P, r)$ when r varies, shows the **appendages** of the shape. You can change the reference point to hide or reveal more appendages; you can also change the metric. This is called a **tail plot** (or a **radius plot**).

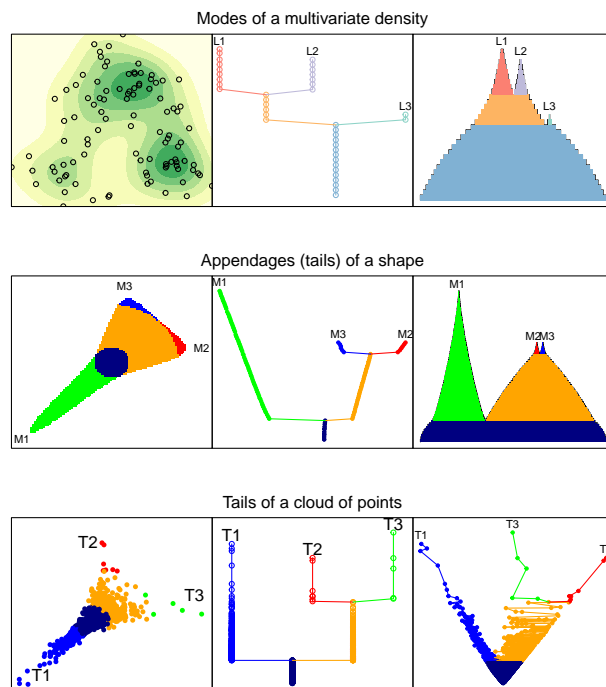

With a cloud of points, you can remove and plot the most central point, and iterate, until the cloud ceases to be δ -connected (a set is δ -connected iif for any two points, there is a chain of points going from one to the other, so that the distance between two consecutive points be less than δ – the problem is that you have to choose δ – instead, you could cluster the remaining observations); you then process the components separately. When plotting this **tail tree** (e.g., using the distance from the center versus the i th coordinate of the last point removed), it is more insightful to use the observations removed rather than the barycenters of the ρ -connected components. This can help guess the number of tails and their shapes: the book provides a large list of examples, in dimension 2, for common copulas. The number of tails concerns me: in dimension d , 2^d tails is not uncommon. Since a tail tree is just a tree structure on a set of points, one could consider other tree structures, such as the minimum spanning tree (MST) or the shortest-path tree (a rooted analogue of the MST).

With a density (or its copula), the tail plots of the level sets can be arranged into a perspective plot.

With a cloud of points, you can estimate the density and look at the mode plot. However, density estimates usually depend on a smoothing parameter: by letting it vary, you have a family of volume plots, that can be represented as a perspective plot.

To visualize the effect of the smoothing parameter, you can also take the modes of the density estimate for different values of the smoothing parameters and arrange

them into a tree

The R code is available in the **denpro** (for the plots, which are very tricky to fine-tune – no ... argument, half-missing contours) and **delt** (for the density estimation algorithms) packages.

The first part of the book also reviews many types of statistical plots and descriptive statistics for high-dimensional datasets. The **depth** of a point (in a cloud of points, or wrt a density) can be defined as $(1 + d)^{-1}$, where d is the Mahalanobis or Euclidian L^2 or L^1 distance to the “center”; as the half-space depth (the minimum proportion of points in a half space containing your point); as the simplicial depth (the probability that your point is inside a simplex whose vertices are random points from the cloud or the distribution); as the convex hull peeling depth (points on the convex hull have depth 1; remove them; points on the convex hull of the remaining points have depth 2; etc.).

Functions or probability densities can be examined by pp-plots, qq-plots, ff-plots; perspective or contour plots (but these are not adequate to visualize tails); slices, projections (marginal densities), or more generally Radon transforms (tomography).

The spread can be examined by looking at the volume of the upper level sets

$$\lambda \sim \text{Volume}(\{x : f(x) \leq \lambda\}).$$

You may want to normalize those volumes (replace them by the radius of a ball of the same volume); you may want to replace the sequence of nested sets $f \leq \lambda$ (the inspiration comes from **Morse theory**) by $[f = \lambda]$ or by depth regions or by minimum volume sets (sets of minimum volume with a given probability).

Multivariate quantiles are defined by replacing $p(X - u)^+ + (1 - p)(X - u)^-$ in the definition of a

quantile by

$$\|X - u\| + p\langle v, X - u \rangle, \quad p \in]0, 1[, v \in \mathbf{S}^d.$$

The book suggests a few plots to examine clusters, but they were not convincing. For instance, you can plot the depth of a point against its i th coordinate, and add edges. In a parallel level plot, you choose the number of clusters and plot the clusters separately in this way, on top of each other – it will always look informative, even if your choice of cluster number is wrong. **Graphical matrices** present the same problem.

The second part of the book is very technical and explains how to prove inequalities and establish convergence results for density estimators.

Among the interesting technicalities are the correlation between a real-value and a vector valued random variable,

$$\text{Cor}(X, \mathbf{Y}) = \max_{\phi} \text{Cor}(Y, \phi' \mathbf{X}),$$

the **mixing coefficient**, $\beta(X, Y) = \frac{1}{2} \int |f_{X,Y} - f_X f_Y|$, can also be computed as

$$\frac{1}{2} \sup_{\mathcal{A}, \mathcal{B}} \sum_{\substack{A \in \mathcal{A} \\ B \in \mathcal{B}}} P(X \in A, Y \in B) - P(X \in A)P(Y \in B)$$

where \mathcal{A}, \mathcal{B} are partitions, which can be used to define asymptotic (or “local”) analogues of the assumptions of “indentically distributed” or “stationary”.

It is always a good idea to preprocess your data, either by sphering it or looking at its copula (it works fine with financial data).

Densities can often be well approximated by simple density classes, such as mixtures, products (as in independent component analysis) or copulas (the tail plots can help choose an adequate family of copulas).

Density estimation algorithms can benefit from efficient data structures, such as those used in the video game industry: for instance, an *evaluation tree* is a binary search tree that represents a setwise constant function, often enhanced by bounding boxes; it can be used to store a density estimate.

The third part of the book presents density estimators. Local averaging estimators include histograms; average shifted histograms (ASH), which approximate a kernel estimator with a triangular kernel; kernel estimators. You can use volume plots to check that the density

estimation is correct – even in high dimensions, when you cannot really “plot” it.

Series estimators include Fourier series, wavelets, projections on a lower-dimensional subspace, including shrinkage estimators, which also tweak the coefficients – the projection is not orthogonal.

Those estimators often minimize some empirical risk (MLE, etc.) and reduce the problem to a finite (combinatorial) one: choose the best density among a finite (huge) set of candidates (δ -net), or a lower-dimensional subspace, or a (countable, infinite) dense set in a lower-dimensional subspace (unless direct computation is possible, these are usually approximated by increasingly finer finite sets)

A greedy **adaptive density estimator** starts with a uniform density on a rectangle, splits it in two in the best possible way (to minimize some measure of empirical risk), and iterates. A **CART histogram** (a histogram is just a locally constant density) proceeds greedily, but also penalize for the complexity of the density, and prunes the result. **Dyadic histograms** only split the rectangles in their middle: they are actually Haar wavelet decompositions. Bootstrap aggregation, *i.e.*, averaging the density estimates on several bootstrap samples, can improve the result.

Stagewise minimization models the data as a mixture, but increases the penalty as more terms are added.

Boosting can be interpreted as a gradient search.

Bayesian methods in finance
S.T. Rachev et al.
Wiley (2008)

(The book is printed on low quality, nose-irritating, dust-mite-friendly paper.)

Clear and detailed introduction to bayesian statistics and its applications to portfolio management – nothing new.

Mean-variance portfolio allocation instability problems can be fixed by robust methods, portfolio resampling or bayesian methods. Bayesian methods take a non-informative or informative prior, mix it with the sample data, and output a posterior distribution of expected returns and variance matrix; in the non-informative prior case, the returns are the sample returns, while in the informative prior case they are shrunk towards the prior; in the non-informative prior case, the variance matrix is scaled *up*; for gaussian returns, the posterior distribution is a Student distribution.

More generally, instead of a gaussian model $N(\mu, \Sigma)$, one can “bayesianize” a regression – in an asset management context, regressions are called **asset pricing models** and the main examples are the CAPM ($r \sim f_1$, where f_1 are the market returns), the Fama-French 3-factor model ($r \sim f_1 + f_2 + f_3$ where the f_i are the market excess returns, the returns difference between large and small caps, and the returns difference between high and low price-to-book stocks), and the arbitrage pricing

ing theory (APT, $r \sim f_1 + \dots + f_n$, where you can freely choose the f_i). You end up with a posterior distribution for the regression coefficients. You can blend several models with bayesian model averaging (BMA).

The **Black-Litterman** framework allows an investor to start with an asset pricing model (e.g., the CAPM, in particular the expected return of all assets is the same) and progressively incorporate more information, in the form of forecasts on the returns of assets or portfolios of assets, each with a confidence level.

A market is said to be **efficient** if one cannot predict future price changes from past prices (weak efficiency), from current public information (semistrong efficiency) or from current public or private information (strong efficiency). In other words, tests of efficiency compare the following models.

$$\begin{aligned}\text{returns}_t &\sim \text{factors}_t \\ \text{returns}_t &\sim \text{factors}_t + \text{information}_{t-1}\end{aligned}$$

Economists often use a 2-step procedure: first estimate the beta of each asset, using time series regressions $r_{i,t} \sim f_t$, then estimate a cross-sectional regression, (*i.e.*, for a single date t) and test if the intercept is zero. In a bayesian setup, you can look at the posterior distribution of this intercept.

But this two 2-step process is incorrect (this is the “error in variables” problem). Instead, one can look for consequences of the efficient market hypothesis (EMH): for instance, under the CAPM, the market portfolio (or your benchmark portfolio) should be efficient (under the APT, some combination of the factor portfolios should be efficient). The tests then consider some measure of inefficiency, such as the difference in returns between the benchmark and the efficient portfolio with the same risk (vertical distance to the efficient frontier), or the difference in risk-adjusted returns μ/σ (Sharpe ratio) between the Benchmark and the tangent portfolio (a kind of “angular distance” to the efficient frontier) or the difference in certainty-equivalent returns (the returns of a risk-free portfolio with the same utility, *i.e.*, the difference in utility converted into returns). In a bayesian context, one can sample from the posterior distribution of the inefficiency measure (it is not tractable: you have to use simulations). Adding constraints (they change the efficient frontier) is straightforward.

One can also directly test for returns predictability,

$$\begin{aligned}\text{return}_t &\sim \text{factor}_{t-t} \\ \text{factor}_t &\sim \text{factor}_{t-1}.\end{aligned}$$

In a bayesian setup, one can estimate the posterior distribution of expected returns, and look at how it changes as the horizon increases: the impact of estimation uncertainty grows, making stocks less and less attractive. [Isn’t this in contradiction with the received wisdom that stocks are good for the long term and bonds better for the short term?]

The *Bayes factor* is not mentioned.

The estimation of **stochastic volatility** (SV) models, contrary to GARCH models, is not straightforward. Approximations, such as the quasi-maximum likelihood, or biased methods, such as the method of moments, are not reliable. The **efficient method of moments** uses an auxiliary, easy-to-fit model, such as the GARCH model:

- You have a complicated model $\mathcal{M}(\theta)$, e.g., a stochastic volatility model;
- You have a less satisfactory but tractable model $\mathcal{M}_0(\zeta)$;
- Estimate the parameter $\hat{\zeta}$ of the tractable model \mathcal{M}_0 on the data;
- For a value θ of the parameters of the complicated model, simulate data and estimate the parameters $\hat{\zeta}_\theta$ of the tractable model on the simulated data;
- Minimize $\|\hat{\zeta} - \hat{\zeta}_\theta\|$ (you can use a maximum-likelihood-based distance instead).

The fact that the sum of the GARCH parameters $\alpha + \beta$ is often almost 1 (it should be less than one for the model to be stationary and anything you do with it meaningful) could be an artefact of a misspecified model, e.g., time-dependent parameters. The linear model with student GARCH noise can be estimated via Gibbs sampling and can easily be generalized to a Markov regime-switching model (MSGARCH), by adding latent variables.

The stochastic volatility models are also latent-variable models: in this case, the number of unknown parameters (the model parameters and the unobserved volatility) is of the same order as the sample. They can be fitted by a Gibbs single-move sampler (*i.e.*, one updates a single parameter or non-observed variable at a time), but this converges very slowly if there are autocorrelations between the latent variables (and there are in the case of time series). This can be remediated by Kalman-filter-based **multimove samplers**.

The models can be extended to allow for jumps: add Bernoulli variables q_t to denote the presence of a jump and log-normal variables j_t for the amplitude of the jump; you can add jumps in the volatility as well: there are then fewer jumps and they are easier to interpret.

The distribution of asset returns are not gaussian: one can model them with a mixture of gaussians, an asymmetric Student T distribution, a stable distribution, an extreme value distribution (EVD), a skew-gaussian distribution (mixture of a gaussian and a truncated gaussian). Copulas are mentioned and the authors are aware of the need for and lack of tools to handle and estimate copulas in high dimensions; they can be used to generalize the Black-Litterman framework (copula opinion pooling). **Coskewness** (third moment between a stock and the market or a benchmark) or alternative measures of risk (expected shortfall (ES), aka conditional value at risk (CVaR)) can be incorporated into portfolio optimization.

A **risk model** is a concise way of describing the dependency between stock returns: it is sometimes written

as a linear model,

$$\mathbf{r} = \boldsymbol{\alpha} + \mathbf{f}\mathbf{e} + \text{noise},$$

where \mathbf{f} are the factor returns, sometimes as a decomposition of the variance matrix of returns V into factor exposures e and factor variance v : $V = \mathbf{e}\mathbf{v}\mathbf{e}'$. Bayesian methods can be used when estimating risk models. The risk or variance of a stock can be decomposed into the contribution of each factor (and their interactions); this can be generalized to other measures of risk.

***Simulation and inference
for stochastic differential equations***
**S.M. Iacus
Springer (2008)**

The first chapter of the book reviews stochastic processes and stochastic differential equations (SDE):

- Random number generation (Mersenne Twister);
- Monte Carlo simulations : the convergence of $\frac{1}{n} \sum g(x_i)$ to $Eg(X)$ is very slow, in \sqrt{n} , but is independent of the smoothness of g ;
- Variance reduction: preferential sampling, antithetic sampling (low discrepancy sequences, *i.e.*, quasi-random numbers, are not covered), control variables (find any relation between the quantity of interest and any other quantity, easier/faster to compute, for instance the call-put parity);
- (Total) variation, quadratic variation

$$[X, X]_t = \limsup_{0=t_0 < \dots < t_N=t} |X(t_{k+1}) - X(t_k)|;$$

- Conditional expectation;
- Martingales;
- Brownian motion, geometric brownian motion, brownian bridge (to simulate a brownian motion);
- The **Karhunen-Loève** expansion of the brownian motion expresses it as a *countable* sum:

$$W(t)(\omega) = \sum_{i=0}^{\infty} Z_i(\omega) \phi_i(t)$$

$$\phi_i(t) = \frac{2\sqrt{2T}}{(2i+1)\pi} \sin \frac{(2i+1)\pi t}{2T}$$

$$Z_i \sim N(0, 1) \text{ iid};$$

- Diffusion processes, *i.e.*, SDEs of the form

$$dX_t = b(t, X_t)dt + \sigma(t, X_t)dW_t,$$

their stationary distribution, infinitesimal generator (only the formula is given, we are not told what it is nor why it is called like that);

- Ito's formula;
- If the diffusion coefficient σ of a SDE only depends on the state variable X_t (and not on t), the **Lamberti transform** turns it, via the Ito formula, into a SDE with unit diffusion coefficient.
- **Girsanov's theorem** is a change-of-measure theorem, that can be used to compute a Radon-Nikodým derivative, *i.e.*, a likelihood ratio.

This chapter ends with a list of (17) useful families of stochastic processes (Ornstein-Uhlenbeck (aka Vasicek), etc.) with unproven formulas (explicit solution, invariant law X_∞ , covariance function $\text{Cov}(X_t, X_s)$, conditional covariance function $\text{Cov}(X_t, X_s | X_0 = x_0)$, conditional law $X_t | X_0 = x_0$, etc.) and properties.

- The **Jacobi diffusion process**

$$dX_t = -\theta \left(X_t - \frac{1}{2} \right) dt + \sqrt{\theta X_t (1 - X_t)} dW_t$$

is reminiscent of copulas: its invariant distribution is uniform $U(0, 1)$; in particular, you can use it to build a process with a prescribed invariant distribution F as $Y_t = F^{-1}(X_t)$.

- Social scientists often consider feedback models (for population dynamics, political polarization, etc.), *i.e.*, models with a drift of the form $b(x) = r(\theta - x)$, whose diffusion coefficient σ^2 is constant, linear or polynomial in x , leading to a gaussian, Gamma or Beta stationary distribution.
- Epidemiologists often consider ordinary differential equations (ODE), to which you can just add a noise term $\sigma(X_t)dW_t$ to get a SDE.

The second chapter examines numerical simulations. The quality of a simulation Y_δ (where δ is the step size) of Y is assessed by looking at how the distance $E|Y_\delta(t) - T(t)|$ changes, for t fixed and δ getting smaller – $O(\delta^{1/2})$ is passable, $O(\delta)$ is better.

The **Euler scheme** is the naive discretization of the SDE: replace the d signs with Δ signs. Note that the discrete paths you get are not discretizations of paths you would get from the SDE itself: except for the brownian motion itself, there is a bias, you are sampling from a distribution of discrete paths close to but different from the desired one. For instance, the paths of the Cox-Ingersoll-Ross model

$$dX_t = (\theta_1 - \theta_2 X_t)dt + \theta_3 \sqrt{X_t} dW_t$$

are (a.s.) positive and therefore well-defined (if $2\theta_1 > \theta_3^2$), but those of the corresponding Euler scheme is not.

The **Milstein scheme** uses a second order Taylor expansion (via Ito's theorem).

$$Y_{i+1} = Y_i + b\Delta t + \sigma\Delta W_t + \frac{1}{2}\sigma\sigma_x((\Delta W_t)^2 - \Delta t)$$

If the diffusion coefficient σ only depends on the state variable X_t (and not on t), you can remove it with the Lamberti transform; things then magically improve: the (simpler) Euler scheme of the transformed process is the Milstein scheme of the initial one; in particular, its order of convergence is 1.

Higher order Taylor expansions (KPS scheme, second Milstein scheme) further improve the convergence; they are comparable to the Runge-Kutta method for ODE.

In some rare cases, the conditional distribution $X_t | X_s$ is known and exact simulation is possible: for the brownian motion, it coincides with the Euler scheme, but

it is also available for the geometric brownian motion (GBM, aka Black-and-Scholes model), the Ornstein-Uhlenbeck (Vasicek) process and the CIR process.

The Euler scheme replaces the SDE by one whose drift and diffusion are constant (this approximation is constant between any two consecutive steps, but it changes at each step): instead, one can approximate the drift by a linear function of X : the **Ozaki** (and Shoji-Ozaki, if the drift also depends on time) method uses such a local linearization.

Diffusion bridges can be simulated for ergodic processes (*i.e.*, those with no “arrow of time”): simulate two paths, one forwards, one backwards, and combine them if/when they intersect.

Exact sampling via rejection sampling is alluded to; it can be extended to diffusion bridges.

The third chapter addresses the estimation problem: you have a discretized sample path from a (time-homogeneous) diffusion process, you know (assume) it belongs to some family of SDEs (e.g., geometric brownian motion), and you want to estimate the corresponding parameters. As often, we will only have asymptotic results, in various setups: large sample (Δ constant, $T \rightarrow \infty$); high frequency ($\Delta \rightarrow 0$, T constant); rapidly increasing ($\Delta \rightarrow 0$, $T \rightarrow \infty$).

In real situations, even though your sample path looks fine (two or three parameters, hundreds of observations, the path looks smooth, sufficiently rich to present (not one but) many “patterns” that numerologists/chartists would be eager to interpret) there is not enough data and the asymptotic results are not valid.

In the ideal ergodic case, if we have a complete (continuous, not discretized) path, we know the invariant distribution; the (parameters intervening in the) diffusion coefficient can be estimated from the quadratic variation

$$\langle X, X \rangle_t = \int_0^t \sigma^2(X_s, \theta) ds;$$

the remaining parameters can be estimated by maximizing the log likelihood (the likelihood ratio is the Radon-Nikodým derivative)

$$\int \frac{b}{\sigma^2} dX_s - \frac{1}{2} \int \frac{b^2}{\sigma^2} ds.$$

In the discrete case, you could discretize those continuous estimators (they are not that efficient).

You can obtain discrete estimators directly, by replacing the integral by a sum – but you have to know the transition probabilities: it works for the Ornstein-Uhlenbeck model, the geometric brownian motion, the CIR model.

If the transition probabilities are not known, use one of the discrete schemes used to simulate trajectories of the SDE (Euler, Milstein, KPS, Ozaki, etc.): their transition probabilities are known. If $\Delta \ll 1$ and $N\Delta \gg 1$, then the Euler scheme is sufficient, if not, then none of those **pseudo likelihoods** is satisfactory.

The likelihood of $x_{t+\Delta}|x_t$ can also be estimated by simulating (with the Euler scheme and a step size δ smaller than Δ) trajectories starting at x_t .

Various expansions (Taylor, Hermite polynomials, etc.) of the likelihood can also be used, leading to **approximated likelihood** estimators.

Bayesian methods (MCMC simulations) can also be used.

Estimating functions (aka moments) are functions f such that $E f(X, 0) = 0$ iff $\theta = \theta_0$. If you choose the function wisely (e.g., apply the **infinitesimal generator** of the diffusion to any function h), this is analytically tractable and often consistent and asymptotically gaussian. You can also use the first and second moments of the transition density: the resulting estimators are consistent and robust to model misspecification.

The **generalized method of moments** is almost identical, but suggests you use more moments than needed: the model is overidentified.

The last chapter examines miscellaneous topics. The AIC (the log-likelihood, corrected for the dimension of the parameter space) could be used to compare models – but beware: it does not work.

Diffusions are amenable to non-parametric estimation. For instance, you can estimate the stationary density (with a usual kernel estimator), estimate the drift parameters (if this part of the process is parametric) and use the Kolmogorov equations, which link stationary distribution, drift and diffusion, to estimate the (non-parametric) diffusion. In a high-frequency setup, you can estimate the drift and diffusion as Nadaraya-Watson kernel regression estimators

$$b(x) = \lim_{t \rightarrow 0} \frac{1}{t} E[X_t - x | X_0 = x]$$

$$\sigma(x)^2 = \lim_{t \rightarrow 0} \frac{1}{t} E[(X_t - x)^2 | X_0 = x].$$

Change-point models can also be estimated with the Euler scheme.

The book is interesting but unpolished:

- Some formulas are wrong (not misleading, just meaningless); others are badly typeset, for instance, the limit in probability is written “ p minus lim”: why not use “plim” or “p-lim” (with a hyphen and consistent typeface) instead?
- The R code, most of which is available in the **sde** package (check the **sde.sim**, **DBridge**, **dcEuler**, **ksmooth**, **cpoint** functions), tends to return invisible objects: invisible objects are useful for functions called for their side effects and whose return values are rarely used, such as plotting functions; but if the return value is just too complicated or long to be printed, it is less misleading for the end-user to implement a **print** method;
- Some theoretical notions are missing or confusing:

the author talks of weak and strong solutions of a SDE but never defined them; the definitions of strong and weak order of convergence look fishy (the weak seems stronger than the strong).

Beautiful Data
T. Segaran et al.
O'Reilly (2009)

Empty.

Recent advances in harmony search
Z.W.Geem et al. (2008)

Harmony search (HS) is a music-inspired optimization algorithm, comparable to genetic algorithms, but it does not assume the genes are 1-dimensional: choose the value of each variable independently (no cross-overs, genes are not linear), either at random or from the *harmony memory*, *i.e.*, the current population (you can end up with more than two parents), and apply some *pitch adjustment* (mutation). This can be refined by putting back some dependency between the variables (ensemble HS (EHS)) and/or progressively changing the parameters (e.g., lower the mutation probability, as in simulated annealing: improved HS (IHS)).

There have been some applications in music (organum composition) and engineering (designing various structures, such as geodesic domes).

*AI methods for algorithmic composition:
a survey, a critical view and future prospects*
G. Papadopoulos and G. Wiggins

The following classes of composition algorithms have been investigated:

- Stochastic processes, such as Mozart's dice game (a musical analogue of R. Queneau's *Cent mille milliards de poèmes*), Markov chains (this requires a corpus, in which melody and rythm are often separated); artificial neural networks, machine learning, stochastic grammars (which try to reflect large structures but fail to account for "ambiguity" or the 2-dimensional structure of music – this is also my main criticism of Haskore: musical structures cannot be represented by a tree, we need a directed (but still acyclic) graph);
- Non-linear systems, iterated functions (but there is no way to evaluate the quality of the result);
- Knowledge-based systems: constraint satisfaction problems (CSP);
- Genetic algorithms (GA) (since it is almost impossible to design a good fitness function, you end up using humans: interactive GA).

Few of those use a geometric model of *pitch space* (pitches can be arranged in a *lattice*, e.g., with thirds in one direction and fifths in the other).

*Frankensteinian methods
for evolutionary music composition*
P.M. Todd and G.M.Werner

One can also consider **coevolutionary algorithms**, with two populations, of composers and critics.

Group Theory and SAGE: a primer
R.A.Beezer (2009)

SAGE is a common interface to several computer algebra systems (CAS) (Gap for group theory, Maxima for symbolic computations, etc.) but fails to follow the evolution of the components – that would be easy if they had an extensive test suite, such as all the computations in one of the many online documentstions.

For finite groups (mainly subgroups of \mathfrak{S}_n for $n \leq 50$), it looked fine, but symbolic computations (Maxima) and plotting (MatPlotLib) are broken (this may be Ubuntu-specific).

*Adventures in group theory:
Rubik's cube, Merlin's machine
and other mathematical toys*
D. Joyner (2008)

Applied group theory with Sage.

To solve the Rubik's cube (many other puzzles are covered): try to find sequences of moves (of the form aba^{-1} (conjugation by internal automorphism), $aba^{-1}b^{-1}$ (commutator), $(ab)^n$) that keep a lot of the facets unchanged; use them to first put the corners in the right places, then the edges, then the corners in the right orientations, then the edges. This can be formalized as a decomposition $g_0 = g_1g_2g_3g_4$ where $g_0 \in G$ is the permutation representing the current configuration;

$$\{1\} = G_4 \subset G_3 \subset G_2 \subset G_1 \subset G;$$

G_1 is the subgroup that fixes the corner positions; G_2 , the subgroup that fixes the corner and edge positions; G_3 , the subgroup that fixes the corner and edge positions, and the corner orientations;

$$\begin{aligned} g_0 &\in g_1G_1 \\ g_1^{-1}g_0 &\in g_2G_2 \\ g_2^{-1}g_1^{-1}g_0 &\in g_3G_3 \\ g_3^{-1}g_2^{-1}g_1^{-1}g_0 &\in g_4G_4. \end{aligned}$$

The Merlin machine (an $n \times m$ array of buttons with lights; pressing a button switches its light and that of its neighbours; your goal is to switch all lights on (or off) from an arbitrary initial position) is a matrix inversion problem: the initial state b is a vector of size nm (with coefficients in $\mathbf{Z}/2\mathbf{Z}$); the possible moves are also vectors of size nm , which can be arranged into a matrix A ; solving the puzzle is equivalent to solving $Ax = b$ (this is not always possible: A need not be invertible).

The **Cayley graph** of a group with prescribed generators $G = \langle g_1, \dots, g_n \rangle$ has the elements of G as vertices

and an edge $x \rightarrow y$ if $y = g_i x$ for some generator g_i . A solution to a puzzle is a path in the Cayley graph of its group. The diameter of the Cayley graph gives (a bound on) the minimum number of moves required to solve the puzzle.

Differential calculus and Sage **W. Granville and D. Joyner**

Sage relies on Maxima, which is woefully unstable (but Maxima is written in Lisp: how can they get a segmentation fault in Lisp?).

Sage notebooks are web-based equivalents of Maple's workbooks: you can use \LaTeX for mathematical expressions; they rely on Twisted for the access from a web browser.

Sage functions can be written in Python (but, of course, Python function cannot be symbolically differentiated).

Here is some sample code (press TAB after the name of a function such as `expand` or `simplify`):

```
x=var('x')
integral(x^2,x,0,1)
n(integral(x^2,x,0,1))
integrate(x^2,x)
a,b,c,d,e,f,x,y=var('a,b,c,d,e,f,x,y')
solve(ax^2+bx+x==0,x)
solve([ax+by+c==0,dx+ey+f==0],x,y)
tan?
diff(sin(x),x,4)
partial_fraction(1/(1-x^2),x)
limit(1/t,t=Infinity)
limit(1/t,t=0,dir="plus")
show(plot(x^2,-2,2))
maxima("sum(3*k+1,k,2,5)")
sum([f(i) for i in range(20)])
```

Sage for Newbies **T. Kosan (2008)**

Integral calculus and Sage **D. Hoffman et al. (2009)**

A calculus book relying on Sage: most of the code is actually Python and the pictures are awful (low resolution, lossily-compressed bitmaps, scaled by a different (random?) and ever changing factor in the horizontal and vertical directions).

Asymptote: the vector graphics language

Asymptote is a variant of Metapost (a language to describe and produce PDF figures to be included in \LaTeX files) with a C++-like syntax: semi-colons, parentheses around function arguments; standard data types (real, triple, vector, matrix, string); standard libraries (operations on strings, arrays, vectors, matrices – including mathematical operations such as matrix inversion or the Fast Fourier Transform (FFT)); plotting li-

braries (any kind of plot with axes, even with logarithmic or broken scales, 3-dimensional plots, diagrams, etc.); ability to include code directly in your \LaTeX files (in the `asy` environment; use the `asy` command to produce the plots). The labels are typeset in \LaTeX , with some Unicode if needed (cyrillic fonts, Asian languages through the old CJK package – no mention of \XeTeX). They seem to have kept all the good features of Metapost, *except* the constraint-solving capabilities – but given the emphasis on “scientific” (*i.e.*, numeric) plots, this may not be an issue.

For an extensive gallery of examples, including many showing that the constraint-solving feature was not that important, check <http://www.piprime.fr/asymptote>.

Primes in P **M. Agrawal et al.**

There exists a polynomial algorithm to determine whether a number is prime. The algorithm is very simple (but not that fast: $O((\log n)^{21/2})$) and based on a generalization of Fermat's little theorem:

$$a \text{ prime} \iff (X + a)^n \equiv X^n + a \pmod{n}$$

for $a \in \mathbf{Z}$, $n \in \mathbf{N}$, $n \geq 2$, $a \wedge n = 1$.

The complexity classes are the following:

- P: there exists a polynomial algorithm to determine if a number is prime
- co-NP: to prove that a number is not prime, it suffices to provide a “non-primality certificate” (the decomposition into a product of prime factors); the verification (product) can be done in polynomial time;
- NP: to prove that a number is prime, it suffices to provide a certificate from which one can check that the number is indeed prime (since Prime is P, the certificate can be empty);
- NP-Complete: a problem is NP-complete if all NP problems can be reduced to it in polynomial time.

A comparison of random forest and its Gini importance with standard chemometric methods for the feature selection and classification of spectral data **B.H. Menze et al** **BMC Bioinformatics (2009)**

Regularized methods can tackle large numbers of predictors, but do not identify and discard irrelevant variables (variables are often called “features”): in chemometry, one often applies them after some feature selection algorithm, *e.g.*, with the *random forest Gini importance* (total change in entropy brought by a given variable or set of variables in a random forest).

Planet: massively parallel learning of tree ensembles with MapReduce **B. Panda et al.**

Classification trees or regression trees (a “common data mining task” at Google) can be parallelized.

***A course in credibility theory
and its applications***

**H. Bühlmann and A. Gisler
Springer Verlag (2005)**

On the use of bayesian models, or more generally hierarchical models, in actuarial science (*i.e.* “insurance”) – they use a different vocabulary: “credibility theory” means “hierarchical model”.

Dynamical bias in the coin toss

Coin tossing is not random: with probability 0.51, the coin lands as it started.

Coin spinning is even worse: depending on the age of the coin, the probability of tails can be as high as 0.9.

***Tag cloud drawing:
algorithms for cloud visualization***
O. Kaser and D. Lemire

Tag clouds, in most websites, are often just an alphabetic list of words of varying sizes, with no attention given to esthetics, ease of use (the alphabetic order is far from optimal) or space usage. Here are a few ideas to improve them:

- Keep the alphabetic order but use a decent (T_EX-like, dynamic-programming-based algorithm (compute the badness b_{ij} of a line containing words i to j) instead of the greedy, Word-like one) line-breaking algorithm; you may want to shuffle the words a dozen times and keep the best layout;
- Sort the tags by decreasing height and add them one by one, greedily, to the first available line; create a new line if needed;
- Take the relations between the tags into account (model them as a weighted graph) and use some heuristic from the *placement problem* in EDA (Electronic Design Automation), e.g., force-directed methods (view the graph edges as springs), simulated annealing, or heuristics for the (NP-hard) *min-cut placement* problem, which recursively cuts the set of tags in two (left/right or top/bottom) so that the cut size (total weight of the edges between the two parts; also add the influence of external edges) be small and the bipartition balanced; the result can be implemented with nested HTML tables (but it looks very tabular).

Using trees to depict a forest

**B. Liu and H.V. Jagadish
VLDB 2009**

When a database query returns too many results, instead of ranking them, present a “representative” subset, obtained by clustering.

Scientific database applications have the following requirements:

- Non-tabular data-types: n -dimensional arrays, ragged arrays, nested arrays, sequences, graphs, meshes;
- **Provenance** tracking, snapshots (“named versions”, *i.e.*, you can modify the data without tampering with other users’ work and without having to copy it), no-override storage manager (just an “update time” dimension);
- Grid storage (because of the volume of data: 100 terabytes);
- Ability to work on data without having to load it (HDF-5, NetCDF file formats);
- Database operations (join, etc.) should account for imprecision, e.g., by adding a “precision” to a column and considering values differing by less than this threshold as equal; more elaborate models could assume the data in a column is gaussian, estimate its mean and variance, and output results with a confidence interval;
- User-defined functions (e.g., in C++).

SciDB does not exist: it is just a wishlist.

***ConvergenceConcepts: an R package to
investigate various modes of convergence***

**P. Lafaye de Micheaux and B. Lique
R Journal (2009)**

If you have a sequence of random variables, or random number generators (or several samples – it may even work with a single path, if it is sufficiently “representative” and “ergodic”), you can study their convergence as follows:

- Plot several samples paths $(X_n)_n$ and check if they leave $[-\varepsilon, \varepsilon]$ for $n > N$: if most do not, then $X_n \rightarrow 0$ a.s.;
- Estimate the proportion of paths that leave this interval,

$$a_N = P[\exists n \geq N : |X_n| > \varepsilon],$$

if it converges towards zero (in most (textbook) examples, it is really clear-cut), the sequence converges almost surely;

- In the plot of the sample paths, instead of the $[N, +\infty[\times [-\varepsilon, \varepsilon]$ infinite rectangle, just consider the narrower $\{n\} \times [-\varepsilon, \varepsilon]$ rectangle: if the proportion of paths outside it

$$p_N = P[|x_N| > \varepsilon]$$

decreases to 0 as N increases, there is convergence in probability;

- For the convergence in law, you can plot the cumulative distribution function (cdf) and check if it moves towards the supposed limit; one could also use an animated quantile-quantile plot (or qqplot, or his-

togram, etc.) or a plot of the $|F_n(x) - F(x)| \sim x + n$ surface;

- For L^p convergence, just compute an estimator of $E|X_n - X|^r$,

$$\hat{e}_n = \frac{1}{|\Omega|} \sum_{\omega} |x_n(\omega) - x(\omega)|^r.$$

The GUI is ugly but interactive.

**Understanding convergence concepts:
a visual-minded and graphical
simulation-based approach**

P. Lafaye de Micheaux and B. Lique
The American Statistician (2009)

**asymptTest: a simple R package
for classical parametric statistical tests
and confidence intervals in large samples**

J.-F. Coeurjolly et al.
R Journal (2009)

Mean comparison tests are robust to non-gaussianity, but variance comparison tests (the 1-sample χ^2 variance test; or the 2-sample Fisher ratio test, `var.test`) are not, even for large samples.

Robust tests and confidence intervals can be obtained by considering asymptotically gaussian quantities such

as

$$\frac{S_n^2 - \sigma^2}{\hat{\sigma}_{S_n^2}}.$$

**copas: An R package
for fitting the Copas selection model**

J. Carpenter et al.
R Journal (2009)

The Copas model accounts for publication bias (more significant or smaller studies (with more extreme results) are more likely to be published) and is used to improve meta-analyses in medical studies.

Use R 2009 Conference

Examples

Year after year, there are fewer and fewer examples that boil down to a simple linear regression: they are replaced by non-linear (sometimes non-parametric) and/or hierarchical linear (or survival, logistic, Markov, spatial, even spatio-temporal multiscale (country/micro-region/region)) penalized models, sometimes with added boosting or a bayesian prior; some presenters use the bootstrap to have more robust confidence intervals.

Examples included

- Non-linear models in biochemistry, to estimate drug interactions, dose-response curves;
- Shape analysis;
- Text mining (for gene names in biology);
- Meta-analysis (aggregating several studies, e.g., with microarray data);
- Time series (building a business cycle (recession) indicator from NBER data: transform and/or filter the data, use non-linear and/or Markov switching (MS) models);
- Forecasting multivariate time series (to optimize a frozen goods supply chain or forecast electricity consumption);
- Multivariate analysis (with **FactoMineR**);
- Design of experiments (DOE), survey design (compute the sample size, in each stratum, for a given desired precision, to estimate fisheries revenues)
- Subject randomization system (subjects for a randomized trial arrive one by one; we then learn in which strata (gender, age, etc.) they are; we decide to give them treatment A or B by flipping a coin; we can hasten the convergence by keeping a running difference $n_A - n_B$ for each stratum and using a biased coin to redress any unbalance).

The large-scale ThomasCook example was interesting:

- They store the data in an SQLite table (modified to hold 30,000 columns – with PL/R, they had ended up writing R code that called PostgreSQL that called R: it was a nightmare to debug);
- They use R for ETL (Extract, Transform, Load), with some Python (BeautifulSoup) for screen-scraping;

- `glmpath` to select variables;
- `randomForest` (on the selected variables) to predict the speed at which the planes will fill;
- The prices are optimized with the random forest model;
- They add a fuzzy inference engine (based on the `sets` package) to prevent cannibalization (you lose clients to yourself) and allow the business to add their input to the model;
- They provide a graphical interface with wx-Python/RPy2 (and `py2exe` to create Windows executables that do not require Python on the clients); R remained on a central server (some call it SaaS: Software as a Service).

Plots

Kaleidoscope plots are those impressive, dense, polar coordinate plots, judiciously using transparent colours, you sometimes see in bioinformatics, often produced by *Circos* (GPL, unrelated to R). There was one on the title page of *Beautiful code*, *Compelling Evidence*, which explains how to use Haskell and OpenGL to produce graphics. The basic idea stems from the graph layout problem: if you are completely clueless about how to plot a graph, just put the vertices in a circle; if the graph is weighted, draw the edges as varying-width ribbons;

finally remark that a contingency table is a (bipartite: rows and columns) weighted graph

and draw it in polar coordinates (pay attention to the order of the segments and the ribbons, label the segments, add axes). Use it if you want artistic plots (that make the user wonder what the plot is about) or if your data is too large to be amenable to more traditional plots.

Two qualitative variables in polar coordinates

Visual analytics are statistical graphics made by artists or good communicators: they should capture the audience's attention and convey the speaker's ideas. The most salient such example is *GapMinder* (a flash-based application to display multivariate time series, as animations) and its narrative power (it helps you efficiently tell a story, but might not be the best tool to *discover* that story). As statisticians, we can try to reduce the information displayed to what is relevant and add model information (distribution, prior, expected values under H_0 , etc., for instance a map of cholera cases can be complemented by well positions and their Voronoi tessellation). R provides graphics for diagnostics, presentation (but no animations or interactivity), and not much for data exploration (*iplot*, *iplot eXtreme*, *ggobi*) – redundant functions do not help (for instance, you can draw a histogram in any of the following ways: `hist`, `truehist`, `histogram`, `qplot(...,geom="histogram")`, `iplot`).

An **information dashboard** (ID) presents all the information needed in a single, easy-to-read page; it can use bargraphs, stacked bargraphs, linegraphs, scatterplots, boxplots, sparklines, treemaps, **bullet graphs** (a thick horizontal line from the origin to represent a single value, with a tick for a reference point (target, last year's value, etc.), and a coloured background to represent how good the value is (3 values, from dark (bad) to light (good) grey; do not rely on colours); do not forget a textual label, with units (smaller), and a scale)

or **horizon plots** (to plot a time series, represent both positive and negative values above the axis, with a different color (blue/red), put the possible values into three bands, of darker colours, and overlay them) – no piecharts.

The `iPlot` package adds **interactive graphics** to R, but cannot be used for large datasets: there is no OpenGL in Java and the data is duplicated between R and the JVM. The soon-to-be-released `iPlot eXtreme`, in C++, should address those problems.

The `PairViz` package uses `graph` and `igraph` to order the variables in a **parallel coordinate plot** using graph-based algorithms (hamiltonian or eulerian path); this can be combined with `scagnostics` if there are many variables.

R can be linked to external visual exploratory analysis tool: `ggobi`, `Visplore` (opensource, but early alpha), etc.

To plot the results of a clustering,

```
bwplot( value ~ variable | cluster )
```

you can add a reference point (the global average of each variable), fine-tune the order of the clusters, of the variables, highlight important variables (or grey out unimportant ones – this will depend on the cluster).

Statistical Tests

Multiple testing often assumes the tests are independent and then controls the *family-wise error rate* (FWER, probability of having at least one wrongly rejected null hypothesis), the *false discovery rate* (FDR, proportion of wrongly rejected null hypotheses) or the *false non-discovery rate* (FNDR, proportion of wrongly non-rejected null hypotheses). If you simulate data similar to yours, you can have an idea of the distribution of the FDR and FNDR and see how it changes as the correlation of the data increases. It is possible to include some knowledge of the correlation structure into the testing procedure: these “factor-adjusted test statistics”, implemented in the `FAMT` package (factor analysis for multiple testing), can improve both FDR and NDR.

When estimating a *p-value* by Monte Carlo simulations (bootstrap, permutations, etc.), some people do not want the *p-value* but are happy with just knowing if $p \leq \alpha$ for some predefined threshold α . Because of this, we can do with slightly less data (than if we wanted p , i.e., all values of α) by looking at the path $(\sum_{1 \leq i \leq n} T_i)_{n \geq 1}$ of partial sums of the test statistic and checking if it remains in or leaves some box- or tunnel-shaped region (sequential Monte Carlo *p-values*).

The `car::Anova` function implements nested **linear tests** (type II tests, i.e., tests of $H_1|H_2$, where $H_1 \implies H_2$) and unconditional linear tests (type III tests) with an *F* statistic.

Matching

When comparing the two models $y \sim x$ and $y \sim \text{treatment} + x$, where the treatment is a binary variable, some people like to have two observations for each possible value of the covariates, one for each value of the treatment. This is usually not the case, but we can instead “fabricate” new observations: **matching** is very similar to regression, but it is not linear (it could be seen as a “non-parametric regression developed by non-statisticians”). This looks like an imputation (or inference with missing data) problem, but it is apparently addressed with ad hoc methods: coarsened exact matching (CEM) is one of them – there are 10 matching packages for R... An application to program evaluation (“program” means sanitation improvement, etc.) was presented.

Penalized Estimators

Penalized estimators (such as non-parametric regression) are good but biased by construction: you can try to estimate and reduce the bias; the `ibr` package implements such an **iterative bias reduction** – but there were too few details in the presentation.

Penalized regression minimizes $\text{RSS} + \sigma^2 k \lambda$, where RSS is a sum of squares, k is the model size, and λ the penalty for complicated models. AIC (Akaike information criterion) uses $\lambda = 2$ but overfits large datasets; BIC (bayesian information criterion) uses $\lambda = \log n$. **Adaptively penalized regression** minimizes $\text{RSS} + \sigma^2 \phi(k, n)$, where ϕ is motivated by the FDR (false discovery rate), i.e., the expected number of wrongly rejected H_0 in a multiple test (it has a higher power than the too conservative FWER (family-wise error rate), which controls the probability of one or more incorrectly rejected H_0 ; with the FDR, you do not have a single *p-value*, but a *sequence* (for the first, second, etc. test): $p/m, 2q/m, 3q/m$).

A full **regularization path** (i.e., a penalized estimator, for all values of λ : lasso, with its L^1 penalty; ridge, with its L^2 penalty; elastic net, with both: $\frac{1}{2}(1 - \alpha) |\beta|^2 + \alpha |\beta|$) can be efficiently computed by **coordinate descent** (discretize the path, estimate one coordinate at a time until convergence, repeat for the next point on the path, etc.). Coordinate descent should work any time your optimization is of the form something + $\lambda \times \text{penalty}$, for instance to build undirected graphical models (it gives you a sequence of graphs) or to complete a matrix (e.g., a movies \times rates matrix, not observed completely).

In **credit rating**, to estimate the probability of default, you can replace the (linear) logit model by a generalized additive model (GAM). (There are (too) many such estimators in R, not only `gam` and `mgcv`; if you hesitate, use `gam` (more stable for small datasets),

unless you have a lot of relatively clean data.)

The **Influence.ME** package provides regression diagnostics (influential observations, etc.) for mixed models; the **merBoot** package uses bootstrap to provide empirical p -values for mixed models.

Non-linear models

The **nlstools** package provides a few functions to help fit non-linear models: **preview** to help you (graphically) choose the starting values; **nls** to fit the data; **overview** as an alternative to **summary**; **plotfit** to display the data and the fitted curve – also check **nlsResiduals**, **test.nlsResiduals**, **nlsContourRSS** (to identify ill-conditioning), **nlsConfRegions**, **nlsJack**, **nlsBoot**.

Univariate data

To estimate the **mode** of unimodal data, you can compute density estimators with wider and wider kernels, look at their local maxima and remember their positions when they disappear: you get a dendrogram-like plot – this can actually be generalized to higher dimensional data (apply some dimension reduction algorithm afterwards, if needed): check the **denpro** and **delt** packages.

The **R2lUniv** package provides graphical summaries of multivariate data, in \LaTeX , but is not as nice and compact as **Hmisc::describe**.

The **DTDA** package provides functions to analyze truncated data (estimator of the cumulated distribution function (cdf), etc.).

The **fitdistrplus** package helps you fit distributions (as **MASS::fitdistr**), but allows for *censored* observations, provides skewness/kurtosis plots (with the dataset, bootstrap replications, and the regions attainable by the models you are considering) and goodness-of-fit tests (Anderson-Darling test to compare the data and the fitted model – it accounts for estimated parameters).

The Tobit model

$$y_1 = \beta x + \varepsilon \\ y = y_1 \cdot \mathbf{1}_{y_1 > 0}$$

can be generalized to **multiple hurdle** models

$$\mathbf{y} = \beta \mathbf{x} + \varepsilon \\ \varepsilon \sim N(\mathbf{0}, V) \\ y = y_1 \cdot \mathbf{1}_{y_1 > 0, y_2 > 0, \dots, y_m > 0}$$

with the **mhurdle** package.

The **mlogit** package fits multinomial logit models (wasn't there already an implementation in **nnet::multinom**?).

Time Series

Markov Switching models can be fitted by expectation maximization (EM): estimate the state at each time; then the parameters in each state; iterate.

You can **mine** a large number of time series by computing a few metrics for each of them (average, volatility, minimum and maximum of the derivative, etc. – use the methods of *functional data analysis* (FDA)) and plot the resulting multivariate dataset (1- or 2-dimensional plots, PCA (principal component analysis), etc.). This is the idea behind **scagnostics**, applied to time series.

In a *threshold autoregressive model* (TAR) model, the autoregression (AR) coefficient depends on the previous value (often, one allows two values depending on the sign; sometimes three values corresponding to “significantly positive”, “significantly negative”, “small”). The idea can be generalized to **threshold cointegration**: two time series are threshold cointegrated if they have a threshold stationary linear combination y , *i.e.*, $y_{t+1} = \alpha(y_t)y_t + \varepsilon_{t+1}$, with $|\alpha(y_t)| < 1$ if $|y_t|$ is large.

The Kalman filter can be robustified to resist to either outliers or regime changes (or even both, but with a delay) with the **rLS** and **ACM** algorithms (not detailed enough).

With the **seewave** package, R can process sound samples (the plots are nice and the PDF presentation even contained an animation) – of course, since R tends to store data in memory, this is only limited to sound *samples*.

Breakpoint models are used in bioinformatics to model the ratio

$$\frac{\text{number of copies of a gene}}{\text{number of copies in the reference}}$$

as a locally constant function of the position on the chromosome; the breakpoints can be estimated with *dynamic programming* – could dynamic programming be applied to other breakpoint problems? I rarely see it outside bioinformatics.

The usual **RMetrics** presentation(s) focused on date arithmetics (the **timeDate** and **timeSeries** packages are aware of weekdays, businessdays, for a given financial center – but I did not really understand their explanation of the **recordIDs** slot) and *portfolio optimization*.

Spatial Models and GIS

The **GeoXp** package provides a few plots for spatial data: *driftmap* (not defined), *angle map*,

$$f(x_1) - f(x_2) \sim \text{angle}(x_2 - x_1),$$

where the angle is with respect to the horizontal axis), *neighbourhood map* (number of neighbours versus distance to the nearest neighbour), *Moran plot* (to check for spatial autocorrelation, plot the value of the variable of interest at a point versus the average value in a neighborhood of this point – you could also use two different variables), outliers (Mahalanobis distance between pairs versus Euclidian distance between pairs); those plots could be linked to a map.

Multivariate Data

To the list of *multidimensional scaling* algorithms, `cmdscale`, `isoMDS`, `sammon`, you can add `isomap`, which tries to find a (non-linear) 2-dimensional submanifold, smooth but close to the data. As always, try all algorithms and try to replace the dissimilarities by their ranks (it does not matter if the matrix is not metric).

The `biclust` package implements many **biclustering** algorithms (for binary, quantitative, ordinal or qualitative variables).

Hierarchical clustering can be performed on principal components (some claim that discarding the last factors of a factor analysis makes the clustering more robust, others claim the opposite); the clusters can be defined by representative individuals (actual data points), variables (as in biclustering) or axes (as in a biplot).

fMRI data can be analyzed through spatial and even (spatio-)temporal ICA (independent component analysis) if you have a sparse description of the singular value decomposition (SVD); also check the `PTAk` package for principal tensor analysis – a similar idea was presented a few years ago at SigGraph.

Canonical correspondance analysis (CCA) and *partial least squares* (PLS) are very similar: the former looks for linear combinations $\alpha'X$ and $\beta'Y$ of X and Y that maximize $\text{Cor}(\alpha'X, \beta'Y)$, the latter maximizes $\text{Cov}(\alpha'X, \beta'Y)$. Both can be regularized: the ridge (replace $(XX')^{-1}$ with $(XX' - \lambda I)^{-1}$) is popular with CCA, the lasso (an L^1 penalty) with PLS.

Data envelopment analysis (DEA, *i.e.*, the construction of *efficient frontiers* in the input \times output or risk \times reward space) can use CCA as a first step, to select the variables to use; beware of outliers: DEA focuses on extremes. DEA can also be applied to medicine.

Distributed quantile estimation (compute a few quantiles on each client, convert them into an estimated cumulated distribution function (cdf), send it to the server which then averages those cdfs) can be generalized to higher dimensions with PCA (only compute the quantiles on the first principal components); this idea can be applied to *monitoring* (e.g., to spot when a coffee machine is about to run out of coffee by listening to it).

Multiple tests and variable selection can be improved by accounting for correlation (with a correlation-adjusted T score). For instance, in genetics, you can group genes in the same pathway (or, if you do not have this information, in the same correlation neighbourhood). For feature selection, you should control the FNDR (false non-discovery rate) rather than the FDR (false discovery rate).

Several presentations focused on **multiple imputation**: exploring/visualizing the structure of missing values with the `VIM` package (there is also a GUI); fixing the separation problem (more variables than observations would remove all the randomness from the impu-

tation procedure) by adding a bayesian prior with the `mi` package; reducing the bias in variance estimates after multiple imputation with a misspecified model with “estimating equations” (no details).

Trees

The `partykit` package unifies the various tree packages (`rpart`, `knnTree`, `Rweka`, `party`, `randomForest`, `gbm`, `mboost`) and should facilitate the implementation of other algorithms; it also provides a PMML interface (PMML is an XML file format to exchange statistical models between applications, mainly used in data mining).

Random forests are not only used for *prediction* or *feature selection*, but also to measure how important each variable is; contrary to univariate measures, they can take interactions into account. The **permutation importance** of X_j is the average decrease in classification accuracy after permuting X_j . This is problematic because a variable can appear important because it is independent from the variable to predict, or just from the other variables. Conditional permutation importance (implemented in the `party` package) can help focus on the former.

The standard benchmark to measure the performance of a tree algorithm is C4.5 – its licence does not allow you to use it, but it has been reimplemented as J4.8 in Weka, available through `Rweka`. Other algorithms include: CART (classification and regression trees) in the `rpart` package; unbiased recursive partitioning (QUEST in the `LohTools` package) and conditional inference trees (CTree in the `party` package). They all perform well, except C4.5/J4.8 without cross validation (cross-validation improves *all* those algorithms and is already included in some of them: if not, do not forget to add it).

Classification trees (CART, in the `rpart` package) can be generalized to a multivariate gaussian outcome (`longRPart`).

After a hierarchical classification, one usually cuts the dendrogram, but you do not have to do it horizontally – *permutation tests* can help you find a good, non-horizontal cut.

Graphs

While the *graphical model* R packages landscape is getting less empty, it remains more heterogeneous than other domains, and is still plagued with external, Windows-only and/or closed source solutions, rarely useable in a professional context: WinBugs, MIM, Genie/Smile (closed-source, but free to use, even commercially), etc. Here are a few examples besides the classical `gR` (actually a combination of several packages) and `gRbase`:

- The `ReBaStaBa` package describes an already constructed bayesian network (*bayesian networks* provide a concise description of a joint distribution);
- The `IdR` (influence diagrams in R) package, can ap-

parently learn the graph structure from the data – too few details in the presentation.

Graph (or link) data abound, from the web (links between Wikipedia articles) to linguistic databases. An **ontology** is a list of words, with links between them; contrary to a taxonomy, those relations are not limited to speciation/generalization but can be arbitrary complicated; polysemy and synonyms are often prohibited (to avoid the mess of gene and protein names); ontologies can be used to represent knowledge and make deductions (an ontology can be seen as a graph theorist’s reinvention of Prolog). OWL (Web Ontology Language) may appear powerful, but is not robust at all; good old RDF (resource description language: it lists triplets (subject, predicate, object), or equivalently (node₁, edge type, node₂), *i.e.*, describes a graph with coloured edges – contrary to OWL, it does not allow for constraints on the predicates such as cardinality, transitivity) is sufficient for most practical purposes.

The **igraph** and **pagerank** packages provide graph-theoretic algorithms; for instance, they can be used to create a **tag cloud** using multidimensional scaling (MDS) for the positions. You may also want to check Wordle (non-free, but free to use), which takes the shape of the words into account, or Many Eyes’s bubble chart (apparently no licence), which uses a circle packing algorithm and amounts to a square root transform.

The **sna** package (social networks) can be combined with the **tm** package (text mining) to analyze mailing lists.

The result of a centroid-based clustering algorithm (*k*-means, PAM (partition around medoids), etc.) can be assessed with:

- The *silhouette plot*, $d(x, c_2(x)) \sim d(x, c_1(x))$, where $c_1(x)$ and $c_2(x)$ are the centroids closest and second closest to observation x ;
- Topology-representing networks (TRN) or *neighbourhood graphs*, weighted graphs with the centroids as vertices and the weight between c_1 and c_2 is the number of points x such that $c_1(x) = c_1$ and $c_2(x) = c_2$ or the average mean average distance.

The **gcExplorer** package relies on **Rgraphviz**, **graph** and **symbols** (to add plots (barplots, etc.) in the graph vertices) to display these, interactively.

Machine Learning

Association rule mining can be seen as a form of “non-symmetric correspondance analysis” for binary data: it can rely on brute force or multiple correspondance analysis (MCA); some algorithms also use exogenous data (e.g., socio-demographic data for a client \times item dataset).

The **set** package provides (finite) set operations, that can easily be generalized to **fuzzy sets** (just replace the topos of truth values $\{0, 1\}$ by the interval $[0, 1]$); applications include relations (order, partial order,

equivalence, etc.) and how to average them (e.g., **voting systems**) – this leads to non trivial optimization problems.

The **TopkLists** package implements algorithms to average **ordinal data**, *i.e.*, rankings, when m raters provide the top k elements in a list of N (more voting systems).

Dynamical Systems

Surprisingly, R is sufficiently fast to simulate dynamical systems (e.g., in ecology), *i.e.*, large systems of differential equations; check the following packages: **desolve** (rather than **odesolve**, which could only tackle small/toy problems) for dynamical systems; **rootSolve** for the steady state solution; **linSolve** for least square solutions (when your linear system is underdetermined, just add $\text{Min } \|x\|^2$ to turn it into a quadratic program); **simecol** for applications in ecology.

High Performance Computing

bigmemory, which uses the Boost C++ interprocess library, paliates the lack of multithreading in R through shared memory or file-based matrices; it also provides iterators to hide (or make implicit) the parallelism provided by **multicore**, **snow**, **nws**. Also check **ff** (matrices limited to $2^{31} - 1$ elements), **ffdf** (as fast as bigmemory), **sqlite** (sufficiently fast), **BufferedMatrix** (inefficient), **filehash** (sufficiently fast).

RCpp allows (eases) the use of C++ and STL containers; conversely, **RInside** allows you to call R from C++; also check **rdyncall** to use C libraries from R.

Several packages provide some parallelism: **multicore**; **snowfall**, **nws**, **Rmpi**; **gridR** (with parallel computations, beware of random number generators: the random numbers on each node should look independent).

Threads (as opposed to parallelism) are needed to process real-time (streaming) data. R will remain mono-threaded for the foreseeable future; in the meantime, use several process (with some C/C++ where needed) and shared memory (with bigmemory) between processes.

R can be used in simple web applications (the user fills in a form and a plot is updated), thanks to the **RApache** module, with some Ajax (Prototype, Scriptaculous, YUI, jQuery, Dojo, Ext), XML or JSON (better than XML for large datasets), and **hwriter** (for static reports, I use **Sweave**).

RdWeb is a (still immature) web interface to parallel computing in R (**RApache** and **Rserve** do not focus on parallelism); it requires a batch system (**at**, openPBS, Torque, etc.)

A **task scheduler** is a hybrid between **make** and **at/crontab**: it automatically executes tasks after a given time, when some conditions (file availability, etc.) are met and allows tasks to be dependent on one another (you can write a quick and dirty task scheduler with **make** and **crontab**: from the crontab, launch **make -k -j 100** in a directory every minute; tasks simply

fail if their starting conditions are not met; track which tasks have run or are currently running by creating empty files with predefined names). The Coalition task manager (in Python, with Twisted Matrix, on Google-Code) handles dependencies, load balancing; it does not seem to provide repeated tasks (“every day”), or tasks starting after a given time. There is nothing specific to R (and there should not be): it just launches executables, which can be R scripts.

A **workflow engine** allows you to write (the equivalent of) Makefiles (*i.e.*, describe dependencies between tasks) graphically and run them on a grid, such as Knime, which focuses on *data pipelines*: it provides all the operations you can want on tables of data, the most common data mining algorithms and plots (Weka), and interfaces with R and BIRT (a J2EE reporting system).

The Nimrod toolkit combines a workflow system (Kepler), a design of experiments framework (DOE, more precisely “computer experiments”, whatever that means – simulations?) and **gaussian processes** (with the **mlegp** package).

Biocep-R is a javaesque application server: huge, exhaustive, unwieldy and fully buzzword-compliant.

The **hive** package uses Hadoop (a distributed computed framework, with a distributed file system, trying to run the computations near the data, initially developed by Yahoo and currently maintained by the Apache foundation) for text mining tasks (with the **tm** package).

Most of those cloud computing frameworks (Amazon EC2, etc.) can generate or use models in the PMML format (designed to exchange statistical models between applications).

GUI

JEdit can be used as an IDE for R (many people advise **Eclipse/StatET**): it interfaces with the **codetools** package (warnings are presented as spelling mistakes would be in a text editor); provides a tree view of the code (based on the R parser), completion popups (for colours or plotting symbols, you have the actual colour or symbol), an object browser, a debugger.

The building blocks for SciViews (an R GUI) are available as individual, reusable packages; some were used to build other GUIs such as Zoo/PhytoImage, an R-based graphical software for image analysis; it also uses the ImageJ image processing Java library (public domain).

Mayday is a visualization platform (in Java, interactive, aware of meta data, with the ability to write plugins) for numeric matrices; it now has an interactive R shell, based on RLink, a replacement (or a layer above) rJava.

Windows

Many mentions of **rcom** and **statconnDOM** (R–C# link) to interface R and Excel (there is even a book on the

subject – frightening) or generate powerpoint files.

R Ecosystem

In many domains, R provides very similar functions in different packages each with its own syntax. Some (well needed but) isolated **unification** works have begun, for instance **Zelig** (statistical models), **partykit** (recursive partitioning algorithms) or **optimx** (for optimization: it provides a single interface and compares the various algorithms, to help the user choose the best for the problem at hand).

Instructional presentations included **sparse matrices** with the **Matrix** package (used for linear mixed models by **lme4**) and spatial autocorrelated (SAR) models; **S4 classes** (the dispatch is based on the type of all arguments, not just the first as with S3 classes); implementing new statistical distributions (the **dpqr** functions, and a few others), as exemplified in the **distr** and **VarianceGamma** packages, with some good general **software engineering** advice.

Provenance tracking tries to answer the question “where does this variable come from? how was it modified?”; it is implemented in CXXR (a C++ reimplementation of R, designed to easily produce experimental versions of the R interpreter): the **pedigree** function is similar to **history**, but the *audit trail* it returns only gives the commands that affected a given object. The Open Provenance model aims at provenance tracking across systems.

Reproducible computing can be easily obtained by recording (“blogging”) everything you type, including outputs and plots, in a way reminiscent of Maple worksheets. Social data networks (Many Eyes, Swivel, the-data.org, etc.) are starting to appear (but they often present pure coincidences as hard evidence).

Multivariate copulas at work

M. Fischer

RMetrics Workshop 2009

While binomial copulas are galore, “higher dimensional” ones (dimension 3 or 4, not the 200 or 2000 I needed a few years ago) used to be rare. The situation is slowly changing:

- Elliptical copulas;
- Archimedian copulas

$$C(x_1, \dots, x_n) = \phi^{-1}(\phi(x_1) + \dots + \phi(x_n))$$

which can be written multiplicatively (set $\theta(x) = \exp -\phi(x)$)

$$C(x_1, \dots, x_n) = \theta^{-1}\left(\prod_i \theta(x_i)\right)$$

- **Generalized archimedian copulas**: use archimedian copulas to group variables two at a time, in a

fully-nested way

or using an arbitrary tree;

- **Generalized multiplicative archimedian copulas:** replace the independent copula \prod by another copula C_0

$$C(x_1, \dots, x_n) = \theta^{-1}(C_0(x_1, \dots, x_n));$$

this can be seen as a $(\mathfrak{S}_n$ -symmetric) deformation of C_0 ;

- **Liebscher copulas** combine several multiplicative archimedian copulas

$$C(x_1, \dots, x_n) = \Psi\left(\frac{1}{m} \sum_j \prod_i \theta_j(u_i)\right);$$

- The **Koehler-Symanowski copulas** are build as follows: take n iid random variables

$$Y_1, \dots, Y_n \sim \text{Exp}(\lambda = 1);$$

choose random variables to model bivariate associations

$$G_{ij} \sim \Gamma(\alpha_{ij}, 1), \quad i < j;$$

(and trivariate associations if you want: $G_{ijk} \sim \Gamma(\alpha_{ijk}, 1)$) and try to put them all in a formula, e.g.,

$$U_i = \left(1 + \frac{Y_i}{\sum_j G_{ij}}\right)^{\sum_j \alpha_{ij}}$$

- Starting from a (graphical model) decomposition

$$f(x_1, x_2, x_3) = f(x_3)f(x_2|x_3)f(x_1|x_2, x_3)$$

one can express a copula as a (complicated) product of bivariate copulas; this is the **pair copula decomposition** (PCD).

A maximum likelihood fit of those on several financial datasets suggests to forget plain archimedian copulas: elliptic (Student) or pair copulas provide a better fit.

Pair-copula constructions of multiple independence

K. Aas et al.

Detailed presentation of pair copulae. The decompositions are not described by a single graphical model but by a (maximal) nested set of (tree) graphical models – a D -vine. Imposing some conditional independence greatly simplifies the model.

Package development in R: Implementing GO-GARCH models

B. Pfaff

RMetrics Workshop 2009

The univariate GARCH model can be extended to a multivariate model by direct generalization (VEC, BEKK, factor models: keep the same formulas, with matrices instead of real numbers, and impose some conditions on them to keep the number of parameters reasonable); by linear combinations of univariate GARCH models (GO-GARCH (generalized orthogonal), latent factor GARCH) or even non-linear combinations (dynamic conditional correlation, general dynamic covariance models).

Consistent return and risk forecasting for portfolio optimization using kernel regressions

J. Hindebrand and T. Poddig

RMetrics Workshop 2009

Separately estimating expected returns and risk model (variance matrix) is suboptimal (when your only source of information is the time series of returns). The authors suggest to estimate both from past returns using *kernel regression* (apparently sometimes called “general regression neural network” (GRNN)) which can be seen as a smoothed k nearest neighbours algorithm. The risk can be estimated “explicitly”, from the residuals

$$\hat{\sigma}^2 = \frac{1}{k} \sum (\hat{y}_i - y_i)^2$$

or “implicitly”

$$\hat{y} = \frac{1}{k} \sum y_i$$

$$\hat{\sigma}_i = \frac{1}{k} \sum (\hat{y} - y_i)^2$$

(the sums are over the k nearest neighbours; for kernel regression, replace those averages by weighted averages).

Financial crises and the exchange rate volatility for Asian economies

T. Oga and W. Polasek

RMetrics Workshop 2009

Markov switching AR-GARCH models are amenable to bayesian MCMC estimation.

Markowitz and two managers

K. Rheinberger

RMetrics Workshop 2009

In many companies, portfolio managers work independently and their strategies or portfolios are combined by higher authorities (*i.e.*, they decide on the capital allocated to each). This is suboptimal: if the asset classes are correlated, the optimal global portfolio need not be obtainable as a combination of efficient subportfolios.

Simple parallel computing in R with Hadoop
RMetrics Workshop 2009

MapReduce (also called **Cloud Computing** or **SAAS** (software as a service)) is a trendy name for “distributed divide and conquer” where the task division step is aware of the location of the data on the *distributed file system* (DFS) to limit network usage. R can use *Hadoop*, a (Java) MapReduce implementation, initially developed by Yahoo and now maintained by the Apache foundation.

**Modeling and evaluation
of insurance risk using actuar**
RMetrics Workshop 2009

The **actuar** package provides some functionalities for actuarial science, which is just “risk management” with a different vocabulary:

- Distributions often used to model losses (on top of the usual dpqr functions, you also have moments $E[X^k]$, limited moments $E[\text{Min}(X, x)^k]$ and moment generating functions $E[e^{tX}]$);
- *Minimum distance estimators* (MDE) for the Cramer-von Mises, modified χ^2 or layer average severity distances (these are not clearly defined);
- Handling (plotting, fitting) of censored data (both sides);
- Various estimators of the distribution of $X_1 + \dots + X_N$ from those of N and the X_i (assumed iid): Panjer algorithm (uses discretized distributions), simulations, normal approximations (these algorithms are not detailed);
- Ruin models, *i.e.*, estimation of

$$P[\exists t > 0 : U(t) < 0]$$

where

$$\begin{aligned} U(t) &: \text{surplus at time } t \\ u &: \text{initial surplus} \\ c_k &: \text{premium collected at time } k \\ N(t) &: \text{number of claims in } [0, t] \\ X_n &: \text{value of the } n\text{th claim} \\ U(t) &= u + \sum_{k \leq t} c_k - \sum_{n \leq N(t)} X_n \end{aligned}$$

- from the distributions of N and X ;
- Simulations of hierarchical models.

An overview of random number generation
C. Dutang
RMetrics Workshop 2009

The default random number generator (RNG) in R (the **runif** function) is the **Mersenne twister** (MT), a linear congruential RNG modified by some bitwise operations. The **randomtoolbox** package implements other RNG (mainly generalized MT: WELL, SFMT) and quasi-random number generators (aka **low discrepancy sequences**):

- For the **Van der Corput** sequence, choose a prime number p , write successive numbers $1, 2, 3, \dots, n$ in base p , $n = \sum_j a_j p^j$ and return $\phi_p(n) = \sum_j a_j / p^{j+1}$; if you choose several prime numbers, you have a multidimensional low discrepancy sequence, the **Halton sequence**; in R, the **halton(n,k)** function returns the first n elements of the k -dimensional Halton sequence;
- The **torus algorithm** (or **Kronecker sequence**) is

$$u_n = (\text{frac } n\sqrt{p_1}, \dots, \text{frac } n\sqrt{p_d})$$

where $\text{frac } x = x - \lfloor x \rfloor$ is the fractional part.

RNGs can be tested by looking at

- The histogram of generated data;
- The autocorrelation function (ACF);
- The order test, which checks in which order x_{i-1} , x_i and x_{i+1} are);
- The Poker test: take d consecutive numbers from your sequence, count how many there are in each $[(k-1)/d, k/d[$ interval ($k \in \llbracket 1, d \rrbracket$), compare with the expected values using a χ^2 test.

Discrepancy can be defined as

$$\begin{aligned} D_n(x, A) &= \frac{1}{n} \# \{ i \in \llbracket 1, n \rrbracket : i \in A \} \\ D_n^\infty(x, \mathcal{P}) &= \sum_{A \in \mathcal{P}} |D_n(x, A)| \end{aligned}$$

for some $\mathcal{P} \subset \mathcal{P}([0, 1]^d)$.

GMM and GEL with R
P. Chaussé
RMetrics Workshop 2009

The *generalized method of moments* (GMM) fits a model to your data by considering several quantities or *moments* (e.g., average, variance, median, quantiles, higher moments, truncated moments, etc.) and fine-tuning the parameters so that the theoretical quantities be as close from the observed ones as possible. More precisely, find several moments $g = (g_1, \dots, g_n)$ so that $E[g(\theta, X)] = 0$ and compute

$$\begin{aligned} \hat{\theta} &= \underset{\theta}{\text{Argmin}} \|\bar{g}(\theta)\|^2 \\ \bar{g}(\theta) &= \frac{1}{T} \sum_t g(\theta, x_t). \end{aligned}$$

Since the moments are not “independent”, the Euclidean distance is not the best choice: you will prefer

$$\hat{\theta} = \underset{\theta}{\text{Argmin}} \bar{g}(\theta)' W \bar{g}(\theta)$$

for some W . The most efficient estimator is obtained with

$$W = \sum_{s \in \mathbf{Z}} \text{Cov}(g(\theta, x_t), g(\theta, x_{t+s}))$$

which can be estimated (with an HAC (heteroscedasticity and autocorrelation consistent) estimator) as

$$\hat{\Omega}(\theta^*) = \sum_{|s| \leq T-1} k_h(s) \hat{\Gamma}_s(\theta^*)$$

$$\hat{\Gamma}_s(\theta^*) = \frac{1}{T} g(\theta^*, x_t) g(\theta^*, x_{t+s})'$$

k_h : some kernel

For instance, one could try any of the following:

- Estimate θ^* with $W = 1$; compute $\hat{\Omega}(\theta^*)$; estimate $\hat{\theta}$;
- Iterate the above until convergence;
- Optimize properly:

$$\hat{\theta} = \underset{\theta}{\text{Argmin}} \bar{g}(\theta)' \hat{\Omega}(\theta) \bar{g}(\theta).$$

The limiting distribution is known.

In finance or economy, you can use the CAPM, the utility function and other meaningful quantities to define moments.

In R, just provide your moments and your data to the `gmm` function.

I did not understand what GEL (generalized empirical likelihood) was.

***A tale of two theories:
Reconciling random matrix theory
and shrinkage estimation
as methods for covariance matrix estimation***
B. Rowe
RMetrics Workshop 2009

Both methods try to remove the noise in the spectrum of the sample covariance matrix: random matrix theory (RMT) violently shrinks the low values to zero; shrinkage smoothly shrinks all values to their mean (or to a predefined value). Combining the two methods turns out to be a bad idea.

***The structure and function
of complex networks***
M.E.J. Newman
arXiv:cond-mat/0303516

Given a network, one can compute the following numeric quantities (invariants):

- Harmonic mean geodesic distance between all pairs (the arithmetic mean would have problems with non-connected vertices);
- Clustering coefficient:

$$C = \frac{1}{n} \sum C_i$$

$$C_i = \frac{\text{Number of triangles connected to vertex } i}{\text{Number of triples centered on vertex } i};$$

- Degree distribution;
- Network resilience: progressively remove vertices, starting with the highest degree ones, and plot of the mean distance between edges versus the fraction of vertices removed;

- **Assortativity** coefficient, to measure **mixing patterns** between vertex types

$$r = \frac{\text{tr } e - \|e^2\|}{1 - \|e^2\|}$$

where e_{ij} is the fraction of edges between vertices of types i and j ; those types can be numeric (e.g., the degree, leading to the **degree correlation**) and even continuous.

Here are a few models of random graphs:

- *Poisson random graphs* (choose the degree of each vertex; join the vertices at random), aka *Erdős–Rényi graphs*;
- Configuration model (replace the Poisson distribution by another one); they fail to account for **transitivity**;
- Exponential random graphs: choose a few numeric properties of graphs, $\varepsilon_1, \dots, \varepsilon_k$, e.g., number of vertices, number of vertices of a given degree, etc.; choose a few numbers β_1, \dots, β_k (inverse temperatures); sample graphs with probability

$$P(G) \propto \exp - \sum_i \beta_i \varepsilon_i(G).$$

These are amenable to (Monte Carlo) simulations, but not analytical derivations, except in the case of **Markov graphs** (the absence/presence of edges are independent unless the edges share a vertex). Unfortunately, they model transitivity in an unnatural way: there are too many complete cliques.

- *Small world model*: put all the vertices on a circle (or any other low-dimensional lattice), connect each vertex to its k nearest neighbours, rewire edges at random with probability p (a variant adds edges with probability p : this can be seen as the average of a lattice and a random graph);
- *The Barabási-Albert model* is a model of network growth, *i.e.*, it tries to explain where the graph properties come from: add vertices one by one, link them to previous nodes, with a higher probability for nodes with a high degree (preferential attachment); the earlier Price model was similar but used directed edges.

Fully mixed epidemiological models, such as SIR (susceptible-infected-recovered: after catching the disease, people (die or) become immune)

$$\dot{S} = -\beta IS$$

$$\dot{I} = \beta IS - \gamma I$$

$$\dot{R} = \gamma I$$

or SIS (reinfections are possible)

$$\dot{S} = -\beta IS + \gamma I$$

$$\dot{I} = \beta IS - \gamma I$$

can be generalized to a network. Other processes on networks include **percolation** and search.

***strucchange: an R package
for testing for structural change
in linear regression models***
A. Zeileis et al.

The **strucchange** package implements tests based on the following **empirical fluctuation processes**:

- OLS-CUSUM: cumulated sum of the residuals (a brownian bridge);
- recursive CUSUM: cumulated sums of the residuals, where the i th residual comes from the model estimated on the first i observations;
- Recursive MOSUM: idem, on a moving window;
- Fluctuations: parameters of the model estimated on an expanding window, suitably renormalized (contrary to the residuals, this is a multidimensional process);
- Moving estimate: idem, on a moving window.

In case of a structural change, these processes “fluctuate more”; they can be compared with boundaries of the form $b(t) = \lambda$ (MOSUM: it is stationary), $b(t) = \lambda\sqrt{t}$ (brownian motion) or $b(t) = \lambda\sqrt{t(1-t)}$. However, the crossing probability is easier to compute for linear boundaries: we lose some power at the beginning and end of the interval.

```
r <- epf(y ~ x, type="fluctuation")
plot(r)
sctest(r)
```

Instead of those *significance tests*, which have no clear alternative hypothesis, you may prefer an F test, which tests against the alternative that there are two different models, one before and one after an (unknown) breakpoint; they compare the sum of squared residuals for the model with and without a breakpoint at observation τ with an F statistic F_τ and aggregate them as $\sup F_\tau$, $\text{Mean } F_\tau$ or $\log \text{Mean exp } F_\tau$.

```
f <- Fstats(y~x)
sctest(f)
```

The package also provides **monitoring**.

***A unified approach
to structural change tests
based on F statistics,
OLS residuals and ML scores***
A. Zeileis

The following classes of structural change tests are actually generalized M -fluctuation tests, built from the empirical fluctuation process (efp):

- CUSUM (the absolute maximum of the cumulative sums of the residuals rescaled by an estimate $\hat{\sigma}^2$ of the error variance – it is not a real test, there is no clear alternative hypothesis, but it is often used as an exploratory tool);
- SupLM = $\sup_{t \in [0,1]} \frac{\|\text{efp}_t\|_2^2}{t(1-t)}$ (in the alternative, the

model parameters have two values, before and after some (unknown) breakpoint);

- The Nyblom-Hansen statistic, where in the alternative H_1 , the parameters follow a random walk, boils down to

$$\frac{1}{n} \sum_{i=1}^n \left\| \text{efp}_{i/n} \right\|_2^2.$$

To detect multiple breakpoints, you may want to use a moving sum (MOSUM) instead of a cumulative sum.

These tests can be extended to a **monitoring** setup, where the observations arrive one by one: estimate the model on $[0, 1]$ and compute the empirical fluctuation process beyond 1; the critical values become a curve $b(t)_{t>1}$ instead of a constant.

Permutation tests for structural change
A. Zeileis and T. Hothorn

The SupF (or SupLM: the test statistic can be transformed to look like an F or a Student T one) tests whether the average of a series of random variables $(X_{k/n})_{k \in \llbracket 1, n \rrbracket}$ is a constant μ against the alternative hypothesis H_π that it is μ_1 before some breakpoint $\tau \in [0, 1]$ and μ_2 after, by considering the statistic

$$\frac{\text{RSS}_\pi}{\text{RSS}_0},$$

suitably renormalized

$$Z_\pi = \sqrt{(n-1) \left(1 - \frac{\text{RSS}_\pi}{\text{RSS}_0} \right)},$$

where RSS_0 and RSS_π are the sums of squared residuals under H_0 and H_π , and aggregating them as

$$D = \text{Max}_\pi Z_\pi.$$

This statistic can be compared with the following distributions:

- \mathcal{D}_∞ : the *unconditional limiting distribution*, i.e., the limiting distribution, for $n \rightarrow \infty$; it is

$$\sup_{\pi \in [0,1]} \pi(1-\pi)B(\pi),$$

where B is a brownian bridge;

- $\mathcal{D}_{\sigma|Y}$: the *conditional distribution*, obtained by randomly permuting the observations (usually computed via simulations; only in very rare cases is it analytically tractable);
- $\mathcal{D}_{\infty|Y}$, the *asymptotical conditional distribution*, which can be computed analytically:

$$Z \sim N(0, \Sigma)$$

$$Z_{\pi, \tau} = \frac{\pi(1-\tau)}{\sqrt{\pi(1-\pi)\tau(1-\tau)}} \quad (\pi \leq \tau)$$

This can be generalized to structural changes in binary variables, multivariate series, stratified observations, parametric models.

Implementing a class of structural change tests: an econometric computing approach
A. Zeileis

Structural change tests can be performed as follows:

- Compute the residuals of your model, $(r_i)_{i \in \llbracket 1, n \rrbracket}$;
- Robustify those residuals, $(\psi(r_i))_{i \in \llbracket 1, n \rrbracket}$, where ψ is an M -estimation scale function; we only want the sum of the robustified residuals to be zero;
- Compute their cumulative sum process $(Z_t)_{t \in [0, 1]}$ (the article is not very clear if we take the cumulative sum of the residuals or build a process from the model coefficients estimated on an expanding window: we cannot get a multidimensional process with just the residuals);
- Estimate the asymptotic covariance matrix of the scores \hat{J} ; we then have

$$\text{Cov}(Z_t, Z_s) = \text{Min}(t, s)\hat{J};$$

you can (should) use an HAC (heteroskedasticity and autocorrelation consistent) estimator for J ;

- Compute the decorrelated fluctuation process

$$\text{efp}_t = \hat{J}^{-1/2} Z_t;$$

it converges to a brownian bridge (since the residuals sum up to zero, we have $Z_0 = Z_1 = 0$); you may choose to use the whole matrix \hat{J} or just its diagonal elements;

- Aggregate this multidimensional process, for instance:
 - Take the maximum of the components at each point in time, then take the maximum accross time (maxBB);
 - Take the L^2 norm of the components at each point in time; then take the average over time (Cramer von Mises statistic);
 - Take the range (*i.e.*, Max – Min) over time, for each component; then take the maximum of those ranges (range test).

This is implemented in the **strucchange** package and will work for any model for which you can compute the residuals (Poisson, logistic, beta regressions, etc.).

Minority games
C.H. Yeung and Y.-C. Zhang
arXiv:0811.1479

A readable review article.

Copula-based non-linear quantile autoregression
X. Chen et al.

A copula-based Markov model (for a stationary time series $(Y_t)_t$) just specifies the copula C of (Y_{t-1}, Y_t) and the marginal distribution of Y_t . This is often estimated by a 2-step procedure: first, estimate the marginal distribution, then, estimate the copula (using either the empirical marginal distribution or the fitted one).

One can look at the τ th quantile of $Y_t | Y_{t-1} = x$:

$$F^{-1}(C(\tau, \cdot)^{-1}(F(x))).$$

The article considers the case of a parametric copula and marginal distribution, but those parameters depend on the quantile τ . This is more robust to model misspecification.

Quantile autoregression
R. Koenker and Z. Xiao (2006)

Quantile autoregression (QAR) is a special case of **random coefficient autoregression** (RCAR)

$$y_t = \theta_0(U_t) + \theta_1(U_t)y_{t-1} + \dots + \theta_p(U_t)y_{t-p}$$

$$U_t \sim U(0, 1).$$

For instance

$$\theta_0(\tau) = \sigma \Phi^{-1}(\tau)$$

$$\theta_1(\tau) = \text{Min}(\gamma_0 + \gamma_1 \tau, 1)$$

leads to a mixture of unit root or explosive behaviour (when $\theta_1 = 1$) and mean-reverting behaviour (when $\theta_1 \in (0, 1)$) – this is actually sufficient to make the process stationary.

Since the functions θ are unknown, this is a non-parametric model. (Most of the theoretical troubles come from the requirement that those functions be monotonic.) You can test for *asymmetric dynamics* by checking if θ_1 depends on τ at all.

March madness, quantile regression bracketology and the Hayek hypothesis
R. Koenker and G.W. Bassett

More details on this example.

Issues on quantile autoregression
J. Fan and Y. Fan

Quantile autoregression (QAR) is related to **functional coefficient autoregression** (FCAR) models

$$y_t = \alpha_0(U_t) + \alpha_1(U_t)Y_{t-1} + \dots + \alpha_p(U_t)Y_{t-p} + \varepsilon_t$$

where U_t is observed. The special case $U_t = Y_{t-d}$ is known as **functional autoregression** (FAR). Identifiability is a real problem, and in case of lack of monotonicity, the estimators are not consistent.

Feature selection in “omics” prediction problems using cat scores and false non-discovery rate control
M. Ahdesmäki and K. Strimmer
arXiv:0903.2003

Linear discriminant analysis (LDA) is a supervised learning algorithm that assumes the data is a mixture of gaussian distributions with the same variance matrix Σ ; the LDA discriminant score of a new observation x for cluster k is

$$d_k(x) = \log P[k|x] = \mu'_k \Sigma^{-1} x - \frac{1}{2} \mu'_k \Sigma^{-1} \mu_k + \log \pi_k$$

where μ_k is the center of cluster k and π_k its weight (or a priori probability). Estimating the inverse Σ^{-1} is problematic: **diagonal discriminant analysis** (DDA, aka naive Bayes classification) assumes it is diagonal. The nearest shrunken centroids (NSC, aka PAM, partitioning around medoids) algorithm is a regularized version of it.

The article suggests a regularized LDA (regularize the variances (shrink to the median) and the correlation matrix (ridge regularization) separately) to account for correlations, *i.e.*, for non-spherical clusters.

Monitoring networked applications with incremental quantile estimation

J.M. Chambers et al.
arXiv:0708.0302

Sequential quantile estimation algorithms compute quantiles in a “cumulative” (online) way, as data arrives:

- Exact algorithm exist (e.g., based on the quick sort) to track a single quantile, but they have to keep a potentially large buffer of data; they can be modified to track a set of quantiles;
- Stochastic approximation is similar, but assumes the data has a continuous distribution to approximate between the quantiles.

Incremental quantile (IQ) estimation is a quick-and-dirty algorithm that allows both online quantile estimation and *aggregation* of quantiles from distributed agents; it uses cumulative distribution functions (CDF), which are easy to aggregate, rather than quantiles:

- On each agent, wait until you have enough data; turn it into a cumulative distribution function (CDF); blend it with the previous CDF estimate;
- From time to time, send it to the server, and start the computation afresh;
- On the server, aggregate the CDFs received from the agents and compute the desired quantiles.

The CDFs can be stored and sent as a set of quantiles (for increased precision, we may want more quantiles than the final users actually receive).

This can be useful in distributed QoS (quality of service) measurement.

Text mining infrastructure in R

I. Feinerer et al.
Journal of statistical software (2008)

The **tm** package provides a framework to manage collections of texts (with their metadata; to avoid memory problems, you can just keep the metadata in memory and leave the texts on disk) and relies on other packages for stemming (**Rstem**, **snowball** (Weka)), synonym substitution (**wordnet**), part-of-speech tagging (**openNLP**), term-document matrix computation (**Matrix**, for sparse matrices), machine learning algorithms (for unsupervised learning (document clus-

tering): hierarchical clustering, k -means; supervised learning (document classification): k -nearest neighbours (kNN), support vector machines (SVM); or more text-specific tasks: information retrieval, keyword extraction), string kernels (**kernlab**).

The **string kernel** of two strings x and y is the scalar product $[\Phi(x), \Phi(y)]$ of their embeddings in some high-dimensional space: knowing this scalar product is sufficient for most linear-algebra-based algorithms, the actual coordinates are not needed. Examples include:

- $k(x, y) = \sum_{s \sqsubseteq x, y} \mathbf{1}_{s_0=s_{|s|}} =$ (bag of words)
- $k(x, y) = \sum_{s \sqsubseteq x, y} \mathbf{1}_{|s| \leq n}$ (full string kernel)
- $k(x, y) = \sum_{s \sqsubseteq x, y} \mathbf{1}_{|s|=n}$ (string kernel)
- $k(x, y) = \sum_{s \sqsubseteq x, y} \lambda^{|s|}$ (substring kernel).

Forecasting the term structure of government bond yields

F.X. Diebold and C. Li (2003)

The forward rate can be approximated as

$$f_t(\tau) = \alpha_t + \beta_t e^{-\lambda_t \tau} + \gamma_t \lambda_t e^{-\lambda_t \tau}$$

where the three time series α (level), β (slope) and γ (curvature) can be estimated with an AR model (why did λ disappear?).

Comparing smooth transition and Markov switching autoregressive models of US unemployment

P.J. Deschamps (2007)

Comparison of a Markov switching autoregressive model (MSAR) and a logistic smooth transition autoregressive model (LSTAR)

$$y_{t+1} = (\alpha_0 + \alpha_1 y_t) + G_t(\beta_0 + \beta_1 y_t) + \varepsilon_t$$

$$G_t = \frac{1}{1 + e^{-(a s_t + b)}}$$

where s_t is *observed*, e.g., $s_t = y_t - y_{t-12}$. There are variants with other shapes for the transition function G (it need not be symmetric) and/or more than two states.

Two-dimensional correlation optimized warping algorithm for aligning GC×GC-MS data

D. Zhang et al.

Two-dimensional time warping can be applied to spectrometry.

Fast text mining using kernels in R

I. Feinerer and A. Karatzoglou

String kernels

$$k(x, x') = \sum_{s \in A^*} \text{num}_s(x) \text{num}_s(y) \lambda_s$$

usually require $O((|x| + |y|)^2)$ operations, but they can be computed from the **suffix tree** of the texts in linear time; using a **suffix array** (not defined), as implemented in the **kernlab** package is (still linear but) more efficient.

Spectral clustering is just a complicated name for clustering (using traditional techniques) after PCA-dimension reduction using the kernel trick.

Invariant coordinate selection

D.E. Tyler et al.

Most multivariate data analysis methods are based on the variance matrix, or more generally *one* measure of dispersion. **Invariant coordinate selection** (ICS) uses *two* measures of dispersion, V_1 and V_2 , and looks at the eigenvalues and eigenvectors of one wrt the other, *i.e.*, looks for $p \in \mathbf{R}$ and $h \neq 0$ such that $V_2 h = \rho V_1 h$; these are also the eigenvalues of $V_1^{-1/2} V_2 V_1^{-1/2}$. For elliptical data, any two measures of dispersion are proportional $V_2 = \lambda V_1$: ICS highlights departure from gaussianity.

Examples of scatter (or dispersion) matrices include:

- The variance matrix;
- The weighted variance (the weights could depend on the Mahalanobis distance);
- M -estimates of the variance, *i.e.*, an adaptively-weighted variance;
- Higher breakdown robust scatter matrices: MVE, MCD, S -estimates, τ -estimates, etc. (they are computationally expensive);
- A dispersion matrix wrt to the origin (*i.e.*, the location estimator is constant);
- A dispersion matrix of the pairwise differences, $\text{Disp}(x_i - x_j)_{i,j}$
- Fourth central moments;
- Tyler's shape matrix.

Outliers are often spotted by looking at the Mahalanobis distance for one measure of dispersion: besides (before) a plot of the first eigencoordinates, a scatterplot of those distances for several measures of dispersion may also be helpful.

Tools for exploring multivariate data: the package ICS

K. Nordhausen et al.

Journal of Statistical Software (2008)

A more application-oriented presentation of invariant coordinate selection (ICS). The ICS transformation can be described as:

- Whiten the data wrt the first measure of dispersion: $x \mapsto (x - 1'\bar{x})\text{Disp}^{-1/2}$ (stopping after that step is not satisfactory: the square root is not unique and the whitening transformation is not affine-equivariant);
- Perform a principal component analysis (PCA) on the whitened data, wrt the second measure of dispersion.

Scala by Example

M. Odersky

Scala is a functional and object-oriented language, with static typing and type inference (somewhat inferior to Haskell), whose main advantages are:

- It is a script-like language, easy to write and read;
- It runs on the **Java Virtual Machine** (JVM) and can therefore leverage all existing Java libraries and the Java infrastructure and knowledge you may already have;
- It provides a rather exhaustive implementation of parallelism patterns: Erlang's **actors**, lazy variables, explicit parallelism, Java threads, etc.;
- Method names can contain weird characters (*:, etc.), facilitating the creation of libraries that look like domain-specific languages (DSL).

Its main drawbacks are:

- The type inference is not as good as Haskell's (e.g., you have to provide the return type of recursive functions);
- Function types can be unreadable, with the name of the variable (function) in the middle of the type, as in C;
- There are still too many parentheses.

Here is a summary of the syntax.

When you define a variable, it can be left unevaluated (**def**, this is useful for functions, which are just blocks), immutable (**val**), mutable (**var**), lazy (**lazy val**) or evaluated in the background (**var x = future(f(1))**).

```
def f(
  g : Int => Int, // Function argument
  a : Int,
  b : => Int, // Not evaluated immediately
): Int = { ... }
class Foo(a:Int, b:Int) {...} // private members
class Bar(...) Extends Foo {
  ...
  override def toString ...
}
val x = new Foo(1,2);
```

A **trait** is a Java interface, designed to be added to a class, *i.e.*, designed for multiple inheritance; abstract classes are designed for single inheritance.

Case classes provide implicit constructors, implicit getter methods and pattern matching, *i.e.*, implicit tests on the type of objects – this is just syntactic sugar, but it increases code readability.

```
abstract class A
case class A1(n:Int) extends A
case class A2(n:Int, m:Int) extends A
...
e match { case A1(n) => n
          case A2(n,m) => n+m }
```

Type parameters (aka templates or generic types)

can also specify lower and upper bounds on types.

```
class Set[A]
// A implements the Ordered trait:
class Set[A <: Ordered[A]]
// A can be converted into
// something that implements Ordered
class Set[A <% Ordered[A]]
```

Inheritance relations can be automatically **lifted** to generic types, so that if $A <: B$, then $\text{Stack}[A] <: \text{Stack}[B]$. In some cases, this mapping is not covariant but contravariant: e.g., if $A <: B$, then $\text{Fun}[B, C] <: \text{Fun}[A, C]$.

```
class Stack[+A]
class Fun[-A, +B]
```

Functions are just objects with an **apply** method; $f(x)$ is just a shorthand for $f.\text{apply}(x)$; arrays implement the same interface and use the same syntax.

Tuples, written (a, b) , are just a shorthand for the $\text{Tuple2}[A, B]$ type.

Besides **Array** (Java's mutable arrays), Scala provides a **List** type (homogeneous, immutable, unsuitable for random access), as in Lisp, with the usual **map**, **foreach**, **forall**, **exists** (called **all** and **any** in some other languages) methods. The **for** comprehension is a shorthand for those list operations.

```
for(x <- xs if f(x)) yield g(x)
```

Streams are lazy (potentially infinite) lists; they have (almost) the same methods. Iterators, *i.e.*, classes with **hasNext** and **next** methods, are an imperative analogue of streams; prefer them to streams if you know previous values can be discarded.

Methods can have implicit arguments (actually, even the method name can be implicit: these are implicit conversions (casts)), but this does not look as useful the named and implicit arguments of most scripting languages.

Detailed examples include an auction service (actors), type inference, electric circuit simulation, N -queen problem (list comprehensions), building **N**, Newton's method and more general fixed point problems, stacks (type parameters).

This introduction does not mention some important features of Scala, such as the ability to include XML directly in the code (not as strings), with the $\langle \rangle$ delimiters, in the same way most languages allow you to enter strings directly (not as arrays of characters), with the `"` delimiter.

Regularized discriminant analysis
J.K. Friedman
Journal of the American Statistical
Association (1989)

Your data comes from a mixture of distributions, $\sum_k \lambda_k f_k(x)$, and you want to find from which class k a given observation x comes from. If you knew the prior probabilities λ_k and the conditional distributions f_k , you would just use the Bayes rule. If those conditional distributions are multivariate gaussian with identical (resp. different) variance matrices, obtained from the plug-in (aka sample) estimators, this is linear discriminant analysis (LDA) (resp. quadratic discriminant analysis (QDA)). Some people also use diagonal discriminant analysis (DDA).

You can use a regularized estimator of those variance matrices.

Partial least squares: a versatile tool for the analysis of high-dimensional genomic data
A.-L. Boulesteix and K. Strimmer (2006)

Should you want formulas to compute partial least squares (PLS) yourself, here they are. Let X be the predictive variables (one observation per row, few rows, many columns) and Y the variable to predict. The data is assumed to come from latent components T ,

$$X = TP' + \text{noise}$$

$$Y = TQ' + \text{noise}$$

Once you have those latent components T , you can estimate \hat{Y} by least squares. The latent components are of the form $T = XW$, where W is defined by some iterative optimization procedure (there are many of them: PLS1, PLS2, NIPALS, Kernel-PLS, SIMPLS, etc.) such as

$$\begin{aligned} \forall i \quad & \text{Maximize } w_i' X' Y Y' X w_i \\ & \text{such that } w_i' w_i = 1 \\ & \text{and } \forall j < i \quad w_i' X' X w_j = 0. \end{aligned}$$

In R, check the **pls**, **pls.pcr**, **plsgenomics**, **gpls** packages.

Multi-objective optimization using genetic algorithms: a tutorial
A. Konak et al.
Reliability engineering and system safety
(2006)

Multiobjective optimization do not lead to a *single* but to a *set* of solutions (the Pareto set, aka efficient frontier) – transforming the problem into a single-objective one is rarely satisfactory: it involves arbitrary choices (weights, utility function) that often have a huge (and badly understood) effect on the solution.

Genetic algorithms (GA) naturally produce a population of solutions, but care should be taken: the solutions found should

- be uniformly distributed (genetic algorithms tend to produce clusters (genetic drift): to prevent this, you can try to decrease the fitness of densely populated areas)

- explore the whole spectrum of the efficient frontier (genetic algorithms tend to focus on the middle and miss the extremities – you may want to store non-dominated solutions in a separate list, to avoid losing them).

There is a very large number of multi-objective genetic algorithms: the authors provide a comparison table (check PAES, NSGA-II, SPEA-2).

Multi-objective generic algorithms: problem difficulties and construction of test problems

K. Deb

A set of test problems for multi-objective genetic algorithms.

Spectral graph theory and its applications

D.A. Spielman (2004)

An interesting applied linear algebra course, that explains how to read the properties of a graph from the eigenvalues and vectors of its incidence matrix or Laplacian matrix. The Laplacian of an edge is $\begin{pmatrix} 1 & -1 \\ -1 & 1 \end{pmatrix}$ and the Laplacian of a graph is the sum of those of its edges. Applications include graph colouring, error correcting codes, random matrices and random graphs, graph approximation (find a sparser graph whose Laplacian matrix is close, in spectral norm – this can be used to speed up linear system solving).

Maximum overhang

M. Paterson et al.

arXiv:0909.0093, arXiv:0910.2357

An evaluation of mathematics competitions using item response theory

J. Gleason

Notices of the AMS (2008)

An introduction to item response theory (IRT).

Little B: Biological modeling

Little B is a Lisp-like biological simulation language – basically, to define large systems of ordinary differential equations (ODE) from simple blocks. Only have a look if you think Lisp has too few parentheses...

OpenModelica Users Guide

P. Fritzson et al.

Modelica is a Pascal-like, object-oriented, equation-based, domain-specific language (DSL), targeted at physical (event-based) simulations, probably similar to Matlab' Simulink; there are interfaces to/from Matlab or Maple. OpenModelica is a free implementation with an Eclipse-based IDE (integrated development environment).

WaveScript User Manual

A (functional) language to describe (and run) data flow graphs. The compiler is written in Scheme and converts the code to C or MLtron (there is also an unsupported C++ backend through XStream).

It is not a “higher order data flow language”: the graph does not change at runtime.

Scale theory, serial theory and voice leading

D. Tymoczko (2007)

When turning a harmonic progression into a set of melodies (*i.e.*, you have a chord voicing, often spread over several octaves, you have chosen the next chord, but you still have to decide on the voicing), composers try to use *efficient voice leading*, *i.e.*, try to limit how far each voice moves; this facilitates the perception of independent musical lines (in addition, you may want those voice leadings to avoid crossings and be bijective). The number of voice leadings may look daunting (especially for large chords, *e.g.*, hexachords), but the problem is not.

Freer than Max – porting FTM to Pure Data

I. m Zmölzig (2007)

The FTM library, that provides complex data structures to data flow languages, is now available for Pure Data – it is an alternative to Pure Data's “graphical data structures” and the PDCContainer (C++ STL) library.

Analytical features

to extract harmonic or rhythmic information

G. Cabral et al.

Description of an automated musical feature (note, chord, rythm, timbre) extraction tool; it just combines known algorithms:

- Time-based pitch recognition algorithms compare (by looking at the correlation or just the distance) the signal with its lags; it works better for low frequency signals;
- Frequency-based pitch recognition algorithms (*e.g.*, the harmonic product spectrum (HPS)) try to find a frequency f for which the spectrum has peaks at $2f$, $3f$, $4f$, etc. (I expect this to fail for lamellophones); the cepstrum is mentionned but not defined;
- For better pitch recognition, you can combine several algorithms;
- Chord recognition algorithms split the spectrum into regions, compute the energy in each, assign it to the 12 notes, normalize the resulting vectorm and apply some machine-learning algorithm.

Can the Red Queen help catch the Snark?

A co-evolutionary waveform transformation approach

M. Caetano et al.

SBCM 2007

One can generate constantly changing sounds with optimization algorithms such as genetic algorithms: those algorithms tend to converge, but you can use them to model two populations, predators and preys, and have them *coevolve*.

***Applications of group theory
on granular synthesis***
R. Fabbri and A. Maia
SBMC 2007

Granular synthesis is an extreme case of additive synthesis: create a sound by combining (adding) hundreds or thousands of sound particles, defined as small areas or clouds in the time×frequency space (with a gaussian envelope and a width of 10 ms to 20 ms). The evolution of those grains with time is often defined by stochastic methods or finite automata. The article suggests to use group theory instead, with the symmetric group or some of its subgroups (alternating, dihedral and cyclic groups). The group action is not clearly defined; it could be:

- The action of the symmetric group on the set of all sound particles, not just those currently used;
- Some action on the parameters of the particles (frequency, duration, amplitude).

At each step, a random element from the group is selected to transform the set of particles.

The implementation relies on Sage, NumPy, PyAudiolib, Matplotlib, wxPython.

***Methods for evaluating clustering algorithms
for gene expression data
using a reference set of functional classes***
S. Datta and S. Datta
BMC Bioinformatics (2006)

How good are the results of your hierarchical clustering? In a biological context, you can use gene ontology (GO) databases to compute a biological homogeneity index and a biological stability index.

This could be generalized to a non-biological setup:

- For the homogeneity index, find another source of data and check if the clusters are consistent with it;
- For the stability, just resample and compare.

Also check the `pvclust` package.

Phantom probability
Y. Izhakian and Z. Izhakian
arXiv:0901.0902

To model the fact that the probability of an event, $P(A) \in [0, 1]$, is not known precisely, you can try to replace $[0, 1]$ by something else. I would have tried the ring of probability distributions on $[0, 1]$, but you can follow the lead of synthetic geometry, or algebraic geometry and its dual numbers, which adds a nilpotent element ε to the real line $\mathbf{R}[\varepsilon]/\langle \varepsilon^2 \rangle$, and add an idempotent (phantom) element \wp : $\mathbf{R}[\wp]/\langle \wp^2 = \wp \rangle$. Intuitively, use $a + b\wp$ to mean “I estimated the probability

as $a + \wp b$, where \wp is the probability of some other event on which I know nothing”. This can be generalized to

$$\frac{\mathbf{R}[\wp_1, \dots, \wp_n, \dots]}{\langle \wp_i \wp_j = \wp_{\text{Max}(i,j)} \rangle}$$

where the \wp_i are more and more hidden – you could have made them independent, $\mathbf{R}[\wp_1, \dots]/\langle \wp_i^2 = \wp_i \rangle$. Almost everything in probability theory (limit theorems, etc.) can be generalized to probabilities with values in a phantom ring.

Synthetic differential geometry
M. Schulman (2006)

Decision making in phantom spaces
Y. Izhakian and Z. Izhakian

Classical decision theory assumes that the probabilities of all events are known: it addresses risk (we do not know which event will be realized) but not uncertainty. With phantom probability theory, this can be generalized to situations where some but not all probabilities are known (each unknown probability is a nilpotent phantom probability). Plots of the efficient frontier have one more dimension for each phantom dimension.

***A survey of product-integration with a view
toward application in survival analysis***
R.D. Gill and S. Johansen
The annals of statistics (1990)

If X is a real (*i.e.*, the matrix coefficients are signed measures) matrix-valued measure on $(0, t]$, then its **product integral** is

$$Y(t) = \mathcal{P}_{s \in (0, t]} (\mathbf{1} + X(ds))$$

$$= \lim_{\substack{0=t_0 < t_1 < \dots < t_n=t \\ \text{Max}|t_i - t_{i-1}| \rightarrow 0}} \prod \left(\mathbf{1} + X((t_i, t_{i-1}]) \right)$$

It could also be defined by the Volterra equation (aka Kolmogorov forward equation)

$$Y(t) = \mathbf{1} + \int_{s \in (0, t]} Y(s^-) X(ds).$$

Here are some applications:

- Link between survival and hazard functions:

T : positive random variable (survival time)
 $S(t) = P[T > t]$ (survival function)

$$\lambda(t) = -\frac{d \log S(t)}{dt} \text{ (hazard rate)}$$

$$\Lambda(A) = \int_A \lambda(u) du \text{ (survival measure)}$$

$$S(t) = \mathcal{P}_{(0, t]} (\mathbf{1} - d\Lambda)$$

- In a censored context, the product-limit (Kaplan-Meier) estimator is the product integral of the empirical commulative hazard function (Nelson-Aalen estimator): this formulation can help derive properties of those estimators;

- For multivariate censored data, there is no classical estimator (the naive one would depend on a choice of coordinates) but the product-integral can provide a (complicated but) well-defined one;
- All this can be generalized to Markov processes (the survival analysis model uses 3 states: alive, censored, dead) by using matrices of size the number of states – it even works for countable state space Markov chains (e.g., Markov branching processes).

Current State of Java for HPC
B. Amedro et al.
Inria (2008)

Java is useable for high performance computing (HPC), e.g., with the ProActive library (LGPL, developed at the Inria) as an MPI replacement, but the performance greatly depends on the virtual machine (JVM) used and communications can be a bottleneck.

Versatile and declarative dynamic programming using pair algebras
P. Steffen and R. Giegerich
BMC Bioinformatics (2005)

When you need to implement several dynamic programming algorithms (they are everywhere in bioinformatics), you may want to factor out the algorithm into an algebraic dynamic programming (ADP) algorithm; what remains is then almost purely declarative:

- The alphabet used by the input sequence;
- The set of candidate solutions: they can be expressed as a set of trees, described by a *grammar*;
- A way to compute the score of a candidate tree (recursively).

Least angle regression
B. Efron et al. (2003)

An introduction to the Kalman filter
G. Welch and G. Bishop (2001)

Portfolio optimization in R
R in Finance 2009

Most portfolio optimization problems can be solved within R:

- For mean-variance optimization with no constraints (except perhaps a long-only one), use the `portfolio.optim` function in the `tseries` package;
- For the whole efficient frontier, call the function inside a loop;
- For the maximum Sharpe ratio portfolio, search on that efficient frontier;
- For mean-variance optimization with linear constraints (linear transaction costs, maximum weights, sectors or countries, etc.), use `solve.QP` in the `quadprog` package;
- Expected shortfall (ES, aka conditional value at risk, CVaR) optimization, is only a linear problem (but

beware: it is a *scenario-based* optimization) is just a linear problem: you can use the `Rglpk_solve_LP` function in the `Rglpk` package (it can also do mixed integer linear programming (MILP), but not quadratic programming);

- For more general constraints and/or performance/risk measures, such as

$$\Omega(r) = \frac{\int_r^\infty (1 - F(u)) du}{\int_{-\infty}^r F(u) du}$$

the drawdown (which can be plotted as an **underwater graph**, with the `chart.Drawdown` function), the **Rachev ratio** $R = \text{CVar}_\alpha^+ / \text{CVar}_\alpha^-$, you can check the `DEoptim` package.

A few remarks:

- Drawdown optimization looks very good in-sample, but it is a scenario-based optimization: how does it perform out-of-sample?
- There is no mention of constraints on the number of assets or of mixed integer quadratic programming (MIQP): what about `Rsymphony` (it is open-source)?
- There is no mention of stochastic programming – but it is not reasonable (yet?) for more than 2 or 3 assets.

Working with xts and quantmod
R in Finance 2009

The `xts` package relies on `zoo` to provide *time-based indexing*:

```
x <- xts(rnorm(N, Sys.Date()-1:N))
x["2009-01-01"]
x[index(x) >= Sys.Date()-5]
x["2009-01-01/2009-01-05"] # Interval
x["2009-01"] # One month of data
```

You may also want to check the `to.period` (convert to OHLC (open-high-low-close)), `endpoints` (to extract weekly, monthly, etc. data), `period.apply` functions.

The `quantmod` package abstracts data access, from local (RData, CSV, SQLite, MySQL) or public sources (Google, Yahoo, Oanda, FRED). The `getSymbols` functions assigns to local variables of the same name.

```
getSymbols("AAPL;IBM")
getSymbols("USD/EUR", src="oanda")
```

You may also want to check: `getDividends`, `getQuote`, `getSplits`, `getFX`, `getMetals`, `getOptionChain`.

There are also a few plotting functions.

```
candleChart(
  GSPC, subset="2009-01-01",
  theme="white", TA=NULL
)
chartSeries(IBM)
addBands()
?newTA # to add your own TA indicators
```

```
AddMACD(32,50,12)
reChart(
  subset="2009",
  theme="white", type="candles"
)
?chartSeries3d # For yield curves, etc.
```

Data can be loaded on-demand (lazily) and cached in memory or in a file.

```
attachSymbols(
  DB=DDB_Yahoo(),
  pos=2, prefix="E."
)
search()
str(ls("DDB:Yahoo"))
```

For more, check TTR, blotter, PerformanceAnalytics.

Statistics for Financial Engineering: Some R Examples R in Finance 2009

After clearly explaining the difference between linear, non-linear and non-parametric regression, the author presents three applications of statistics in finance.

The **probability of default** (PD) is often modeled as

$$P[\text{default} | \text{rating}] = \exp(\beta_0 + \beta_1 \text{rating});$$

which can be transformed via a **Box-Cox transformation** $p \mapsto (\kappa + p)^\lambda$ (unless the problem dictates another family of transformations); you cannot naively take the logarithm, because the probability can be zero (many textbooks do this, and have to throw observations away, resulting in a biased estimator). Whatever transformation you choose, do not forget the **residual analysis**. (The presenter wrote a book about transformations.)

Most stylized facts about an interest rate time series $(R_t)_t$ are visible in the following plots:

$$R_t \sim t, \quad \Delta R_t \sim t, \quad \Delta R_t \sim R_{t-1} \quad (\Delta t)^2 \sim R_{t-1}.$$

They can be modeled as a **diffusion process**

$$\Delta t = \mu(R_{t-1}) + \sigma(R_{t-1})\varepsilon_t$$

where the drift μ and the volatility σ can be non-linear (e.g., $\sigma(r) = \beta_0 r_1^\beta$) or **non-parametric**. With 50 years of data, non-parametric regression (e.g., with the **SemiPar** package – the presenter wrote a book on non-parametric estimation with the package author), non-parametric regression performs better: the parametric model will be outside the confidence interval of the non-parametric one. In this case, the residuals look GARCH

```
garch(x=res^2, order=c(1,1))
```

but the GARCH residuals still have some AR(1) noise

```
garchFit(
  formula = ~arma(1,0)+garch(1,1),
  data = res
)
```

and are far from Gaussian

```
garchFit(
  formula = ~arma(1,0)+garch(1,1),
  data = res,
  cond.dist = "std"
)
```

This 2-step process may be suboptimal.

The last example tries to predict future returns (starting with the worst):

- The average of the previous returns;
- The CAPM, forecast = $\beta \cdot$ previous returns;
- Bayesian shrinkage:

$$\text{forecast} = \lambda \cdot \text{previous returns} + (1-\lambda) \cdot \text{market returns}$$

- The previous market returns (this is the best forecast, but all stocks end up with the same forecast).

The **bayesian shrinkage** can be implemented with WinBUGS/R2WinBUGS (OpenBugs/BRugs is no longer on CRAN, and OpenBugs was written in a obscure, commercial, non-textual, Pascal-like language (the source file is a binary file); JAGS is not mentioned):

$$\mu_i \sim N(\alpha, \sigma_1^2) \\ r_{i,t} \sim N(\mu_i, \sigma_2^2);$$

this is a data-driven shrinkage: the amount of shrinkage is σ_1^2/σ_2^2 .

Risk Capital for Interacting Market and Credit Risk: VEC and GVAR models R in Finance 2009

International financial regulations (Basel II) assume that market and credit risk are independent and consider that assumption conservative: actually, the interaction between market and credit risk can be benign or malign. For small fluctuations, this can be seen from a Taylor expansion: let x be the risk factors (market, credit); let $f(x)$ be the value of your portfolio, then

$$f(x + \varepsilon) = f(x) + f'(x) \cdot \varepsilon + f''(x) \cdot \varepsilon \cdot \varepsilon + o(|\varepsilon|^2),$$

where the bilinear form $f''(x)$ can be positive, negative, or neither. This shows the problem for small fluctuations: we would like a decomposition

$$f(x + \varepsilon) = f(x) + g_{\text{market}}(x, \varepsilon_{\text{market}}) + g_{\text{credit}}(x, \varepsilon_{\text{credit}})$$

for large fluctuations as well – this works iff the portfolio is *separable*, i.e., $f(x) = f_{\text{market}}(x) + f_{\text{credit}}(x)$.

The rest of the presentation is a confusing example (the GVAR in the title is apparently a vector autoregression (VAR) with fewer parameters).

ICA for multivariate financial time series R in Finance 2009

Since independent component analysis (ICA) is an optimization problem, you can easily add constraints; you could define a **constrained PCA** in the same way.

This presentation also tries to give technical details on how ICA is estimated (but it quickly becomes a list of formulas with no explanations) and how a time dimension can be added (but their “time-varying mixing matrix” looks like a moving window estimator).

Random portfolios: Practice and Theory R in Finance 2009

Random portfolios can be seen as a kind of bootstrap or permutation test.

The basic idea is the following: since we add so many constraints, many things only depend on the constraints; random portfolios can measure the performance or risk coming from the constraints and isolate the value added by the portfolio manager.

Random portfolios (and matched portfolios) can replace a benchmark or a peer group: they will be less biased and lead to tests with a higher **power**; they can also incorporate more information, such as the position at the beginning of the period and the turnover constraint.

Random portfolios can also help measure the (sometimes unwanted) impact of constraints: you can compare the performance and risk of random portfolios for several sets of constraints (e.g., loose or tight constraints on sector weights). [This was new.]

Generating random portfolios is problematic. [This is also new.]

- A rejection strategy is not reasonable (there are too few portfolios satisfying the constraints);
- Algorithms to sample inside a polytope do not apply if there are non-linear constraints;
- You can compute an optimal portfolio for random returns, but this may be biased;
- You can use a random search: start with a random, unconstrained portfolio and minimize a penalty for broken constraints; however, you will be close to a binding constraint (this does not worry me: we are in high dimension, everything is close to the boundary) and the sampling will not be uniform (this is not very worrying: this is almost exactly what a portfolio manager does, except that he starts with non-random returns).

Matching portfolios D. Kane R in Finance 2009

To measure the performance of a portfolio, one may look at the average capitalization, the momentum, and the book market value of its constituents and compare with the corresponding quintile portfolio: but you have a single portfolio and the more factors you add,

the emptier those quintile portfolios become. *Matching* views those portfolio characteristics (except those in which the portfolio manager claims expertise) as constraints and build a portfolio matching those constraints.

I do not see the difference with *random portfolios*.

Quantile regression in R R in Finance 2009

The definition of a quantile can be formulated as a linear optimization problem and this generalizes readily to a regression setup

$$\alpha_t = \underset{\alpha \in \mathbf{R}}{\operatorname{Argmin}} \sum_{i=0}^n \rho_{\tau}(y_i - \alpha)$$
$$\rho_{\tau}(u) = (\tau - \mathbf{1}_{u < 0})u.$$

Even with a linear model, quantile regression can highlight non-linear features, such as the conditional distribution of the data (this is not as general as the distribution of $y|x$, but almost: there is a model, which assumes a linear relation between the quantiles of x and (a linear combination of) y , but that relation can depend on the quantile; in particular, we can end up with non-gaussian, and even multimodal, distributions) or the dependence of the regression coefficients on the quantile (for an additive gaussian model, we would expect the intercept to be the inverse cumulative distribution function of the quantile and the other coefficients to be constant).

Two plots: conditional densities (this is similar to a violin plot, but with an underlying linear model); coef \sim quantile.

In a time series setup, you can use quantile regression to estimate a **quantile autoregression** (QAR): it will be non-gaussian, but still partly parametric.

Quantile regression is actually equivalent to CVaR (conditional value at risk) portfolio optimization; by approximating the weight function of a spectral risk measure by a locally constant function, quantile regression can be used to optimize portfolios for any “pessimistic” risk measure (this has nothing to do with quantile regression: it applies to linear programming in general).

The presentation ends up with a non-gaussian regression

$$\text{score} \sim \text{team 1} + \text{team 2} + \text{home advantage}$$

(all the predictors are qualitative variables, the variable to predict is a count variable: this would classically be estimated by a Poisson model – but we would have to check this distributional assumption). With quantile regression, we keep the linearity of the model, but remove any distributional assumption; the model can be estimated as a (not unreasonably) large but sparse linear program and one can *sample* from the distribution of scores, in a half-bayesian fashion.

Quantile regression can be seen as a prior-less bayesian regression with no distributional assumptions.

Using R for hedge fund of funds management
E. Zivot
R in Finance 2009

When faced with non-gaussian data, use the Cornish-Fisher expansion to compute the value at risk (VaR) or the expected shortfall (ES, CVaR).

If the time series of returns do not have the same length: select the best risk factors; compute the exposure of the funds to those factors; simulate the missing returns; use those simulated returns to estimate the marginal contribution to risk (MCTR) or risk attribution for VaR or ES. This is available in the **PerformanceMetrics** package.

This reminds me of the problem of estimating a variance matrix $\text{Var}(x_1, \dots, x_n)$ when there are many missing values: the maximum-likelihood estimator can be computed explicitly (this is “just” linear algebra, albeit horrible), but an MCMC simulation is easier to implement (and less likely to be buggy). However, even for toy examples, the convergence is horribly slow.

The presentation mentions but does not tackle the following problems:

- Biases (survivorship, reporting, backfill);
- Serial correlation (performance smoothing; illiquid positions).

Particle learning
R in Finance 2009

Not understandable. None of the articles they refer to are available.

Performance Analysis in R
R in Finance 2009

Clear presentation of what the **PerformanceAnalytics** package can do: measure, compare, decompose the performance or risk of portfolios.

Market Microstructure Tutorial
R in Finance 2009

Market microstructure is the study of why markets are not efficient and how to profit from it (or, equivalently, help make them more efficient); this includes behavioural effects.

The *Glosten-Milgrom model* considers two traders: one (informed) always buys (or sells, this is fixed at the beginning); the other (non-informed) buys or sells with probability 1/2 (they just buy or sell, the model does not consider the need to find a counterparty); only one trader (selected at random) trades at each point in time. We define the *bid* (respectively, *ask*) as the probability that the informed trader is buying (resp. selling) given that the last trade was a buy (resp. sell). The bid and ask converge towards the true price (0

or 1) (*i.e.*, the market goes where the informed trader wants: market manipulation is indistinguishable from price discovery).

The *Kyle model* considers a market maker facing informed and non-informed traders and sets the price to the expected true price given the total order size he sees; the informed trader chooses the order size to maximize profit. There again, information leaks very quickly.

Event study: a change-point model approach
R in Finance 2009

Hidden variable (aka latent variable, or regime switching if that variable is discrete) models can be estimated via Monte Carlo simulations. In this example, we consider spells of iid gaussian random variables

[[PLOT]]

and estimate the model by Gibbs sampling, with a bayesian prior:

- Estimate the state at each point in time;
- Estimate the parameters in each spell;
- Estimate the transition probabilities;
- Iterate.

(At each step, we consider the whole time series.) This can be repeated with a different number of regimes, and the best model can be selected by looking at the *Bayes factor*.

In a financial setting, breakpoints need not coincide with announcements: they can occur before.

Detecting structural breaks in tail behavior
W.H. Liu
R in Finance 2009

The *Hills estimator* of the tail index (and the tail index itself) only makes sense for power law tails and, even in that case, is known to be very noisy. Replacing the power law by a general extreme value (GEV) distribution does not solve those problems: tests for structural breaks (I do not know them: SupLN, OLS-based CUSUM, Nyblom-Hansen, generalized M-fluctuation) return a surprisingly high number of potential regime changes.

For risk management purposes, estimators of GEV models are as problematic as the Hills estimator.

Portfolio Optimization with R/RMetrics
R in Finance 2009

Quick overview of what is available in **RMetrics** for portfolio optimization – there is an ebook with the same title (it excludes: quadratic (non-linear) constraints, integer constraints, non-linear objectives, Black-Litterman copula pooling (BLCP), quadratic lower partial moments (QLPM), copula tail risk: these will be covered in a second volume). The list of packages looks exhaustive: **Rglpk**, **Rsymphony**, **Rlpsolve**, **quadprog**, **Ripop**, **Rsocp**, **Rdonlp2**, **Rnlminb**.

Econometrics and practice: mind the gap!
Y. Chalabi and D. Würtz
R in Finance 2009

There is an unreasonable number of variants of the GARCH model, but fitting them poses many practical issues (bugs, parameter initialization, optimization schemes, etc.).

The presentation slides contain some sample code: it is surprisingly straightforward (it would be trickier to estimate a stochastic volatility model, *i.e.*, a model with two sources of randomness: you would need to consider a time series of (hidden) innovations).

The stationary assumption is often violated.

We might be tempted to use *robust* methods to throw outliers away, but we cannot afford it: we would underestimate risk. Instead, you can include them in the model, either as isolated points or as a different regime: **MS-GARCH** (Markow-Switching GARCH) is one such example.

Indirect inference can help fit a difficult-to-fit model g by using an (easier-to-fit) model f :

- Estimate the auxiliary model f in the data y : $\hat{\theta}$;
- For all possible values of the parameters ρ of the model g , generate a sample \tilde{y} , and estimate the auxiliary model f on it: $\tilde{\theta}(\rho)$.
- Find the parameters ρ that minimize the distance $\|\hat{\theta} - \tilde{\theta}(\rho)\|$.

Introduction to high-performance computing with R
D. Eddelbuettel
R in Finance 2009

You can profile your code with the `system.time`, `Rprof`, `Rprofmen`, `tracemem` functions; the `profr` and `proftools` package; the `prof2dot.pl`, `valgrind`, `kcachegrind`, `sprof`, `oprofile`, Google PerfTools tools.

Vectorization, with the `*apply` or `outer` functions, or just-in-time compilation with Ra (a set of patches for R, available for Debian/Ubuntu – a very search-engine-unfriendly name) and the `jit` package, can speed things up.

For the best performance, you can rewrite the most time-consuming parts of the code in C/C++: with `.C`, the C function uses C types; with `.Call`, it uses R types (`SEXP`); with `Rcpp`, the conversion between R and C++ types (templates) is transparent. The `inline` package and the `cfunction` function allow you to put the C code (with `.Call` or `.C` conventions) directly inside the R code – as with Perl's `Inline::C` module.

In the other direction, `RInside` allows you to evaluation R code from a C/C++ program.

Other high-performace topics were not mentionned:

- Parallel computing: `MPI`, `nws`, `snow`;
- Out-of-memory computations: `biglm`, `ff`, `big-`

- `matrix9`;
- Scripting and automation.

A latent-variable approach to validate credit rating systems with R
B. Grün et al.
R in Finance 2009

Credit rating of several firms (obligors) by several raters (banks, rating agencies) can be modeled as a mixed model: let the observed score $S_{i,j}$ be the probit of the announced probability of default for obligor i according to rater j :

$$S_{i,j} = S_i + \mu_j + \sigma_j Z_{i,j},$$

where S_i is the latent (consensus) rating and μ_j the bias of rater j .

This can be generalized into a dynamic model by assuming the latent probability is AR(1) and examined, by Gibbs sampling, with the `rjags` and `coda` packages. In particular, you can look at: bias and variance of raters, consensus rating; and the residuals can be further analyzed.

In practice, you have to map the ordinal rating of the rating agencies (AAA, etc.) into probabilities: this hides the bias.

RMeCab

MeCab is a Japanese morphological analyzer, *i.e.*, a tool to cut sentences into words (there are no spaces between words in Japanese). It looks more robust than its competitors (ChaSen, CaboCha) and can now be used from R.

After installing R, MeCab, MeCab-ipadic (beware, they apparently only provide a *binary* package, even for Linux):

```
install.packages(
  "RMecab.tar.gz",
  destdir=".", repos=NULL
)
library(RMecab)
```

To split a sentence into words, and get the POS (part-of-speech) of those words:

```
RMecabC("猫が鼠を食べた。")
```

The default output of the command-line tool (word, POS0, POS1, POS2, POS3 (more and more detailed), conjugated form (?), dictionary form, pronunciation, pronunciation (yes, twice)):

```
RMecabText("text.txt")
```

The frequency dataframe, with primary key word-POS0-POS1 (sort it before use):

```
RMecabFreq("text.txt")
```

The term-document matrix:

```
docMatrix("corpus/")
d <- docMatrix(
  "corpus/",
  pos=c("名詞", "形容詞"))
cor(d)
```

N-grams:

```
Ngram("text.txt", N=4)
```

However, my current (NLP) interest is lexicography and I am skeptical about the ability of R/MeCab to handle very large datasets (say, all of Wikipedia).

I still have to read the book, *Rによるテキストマイニング入門* (石田基広, 2008).

Pessimistic Portfolio Allocation and Choquet Expected Utility

Details on the relation between

- Choquet expected utility (very similar to *cumulated prospect theory*: when computing the expected utility, we give more or less importance (we distort the probability of) favourable or unfavourable events);
- coherent (or spectral, or pessimistic) risk measures.

Estimation and decomposition of downside risk for portfolios with non-normal returns

K. Boudt et al (2007)

Some people are apparently still using gaussian parametric value at risk (VaR) estimators...

After recalling the Edgeworth expansion of a cumulative distribution function (around the Gaussian)

$$G(z) = \Phi(z) + \sum_{i=1}^r P_i(z)$$

and the Cornish-Fisher (CF) expansion of the corresponding quantile function

$$G^{-1}(\alpha) = z_\alpha + \phi(z_\alpha) \sum_{i=1}^r P_i^*(z_\alpha)$$

$$z_\alpha = \Phi^{-1}(\alpha)$$

the authors compute the **modified VaR** (mVaR) and the **modified expected shortfall** (mES), corresponding to the second order Cornish-Fisher expansion, *i.e.*, a Gaussian distribution modified to have non-trivial skew and kurtosis.

By differentiating the mVaR or mES with respect to portfolio weights, one can compute risk attribution.

Since the estimation of higher moments is noisy, the authors suggest to clean the data before computing skewness and kurtosis: they do not remove or truncate outliers, but just *shrink* them (the cleaning threshold should be beyond the desired VaR threshold).

SemiPar, an R package for semiparametric regression

M.P Wand et al. (2005)

The main R functions for semiparametric regression are `gam::gam`, `SemiPar::spm`, `mgcv::gam`; you may also want to check the `lmeSplines` and `fields` packages. `SemiPar` is younger than `gam`, but allows for bivariate terms and better plots.

```
r <- spm( y ~ f(x) )
```

```
plot(r)
points(x, y)
plot(r, drv=1) # First derivative
```

You can impose the smoothing parameter (e.g., `spar=3`), the number of degrees of freedom (`df` for a single term, `adf` (approximate degrees of freedom) if there are several terms) or the basis (e.g., `basis="trunc.poly"`, `degree=5` – by default, cubic radial basis functions).

```
u ~ x + f(y)      # semi-parametric
u ~ f(x) + f(y)    # additive model
u ~ f(x,y)         # bivariate smoothing
```

For bivariate smoothing (used in spatial statistics, you may want to check and/or alter the nodes: there may be too few or too many). For higher dimensions, you can use a *geoadditive* model

```
u ~ f(x,y) + f(z)
```

The function also accepts binary data (`family="binomial"`), count data (`family="poisson"`), or mixed models (with the usual horrible syntax).

Unit root quantile autoregression inference

R. Koenker and Z. Xiao

Financial time series are often autoregressive with a root near unity: for quantile auto-regression, this changes the asymptotic distributions, but the correct tests are more powerful (for non-gaussian innovations) than tests based on a gaussian model.

Conditional quantiles of volatility in equity index and foreign exchange data

J.W. Galbraith (2001)

Quantile regression $r_t \sim r_{t-1} + \sigma_t$ can highlight asymmetric behaviour in time series of foreign exchange returns.

VAR, SVAR and SVEC Model: Implementation within R package vars

B. Pfaff

Journal of Statistical Software (2008)

The `vars` package estimates vector autoregressive (VAR) models

$$y_t = A_1 y_{t-1} + \dots + A_p y_{t-p} + u_t$$

or structural VAR (SVAR) models

$$A y_t = A_1^* y_{t-1} + \dots + A_p^* y_{t-p} + B \varepsilon_t$$

(for the model to be identifiable, you have to add restrictions (prior knowledge) on A and/or B) or structural vector error correction (SVER) models (not explained clearly). The package should be used in conjunction with the `urca` package, whose author systematically refuses to output p -values and only provides test statistics and a couple of critical values.

***Generalized linear mixed model analysis
via sequential Monte Carlo sampling***
Y. Fan et al. (2007)

Generalized linear mixed models (GLMM) are notoriously more complicated to estimate than linear mixed models or generalized linear models. **Sequential Monte Carlo** (SMC) sampling is an alternative to Monte Carlo Markov Chain (MCMC) sampling: it is a *static analogue of particle filters*. You have to add a time dimension to the problem, for instance, by adding the observations one by one (the time-indexed family of posterior distributions is more and more precise) or by sampling from the family of posterior distributions $(\pi_0^{1-t}\pi^t)_{t \in [0,1]}$, where π is the desired posterior and π_0 the prior or a gaussian distribution centered on an approximate fit.

***Parsimonious classification
via generalized mixed models***
G. Kauermann et al. (2007)

Supervised classification can be performed via a generalized additive logistic model (logistic GAM)

$$P(Y = 1) = f_1(x_1) + \dots + f_p(x_p)$$

where the unknown functions f_i are estimated as generalized splines or, equivalently, as a mixed model

$$f_i(x) = \sum_j u_{i,j} b_j(x)$$

$$u_{ij} \sim \text{some prior}$$

where the b_j are the basis functions and the u_j their coefficients.

See also the `gam.step` function for a similar approach.

***Anomalous returns
in a neural network equity-ranking predictor***
J.B. Satinover and D. Sornette (2008)

A nonlinear AR(10) model fitted on quarterly retruns with a neural returns can beat the S&P 500 (or would have, in the 1990s), even if you include trading costs (but with a much higher volatility).

***Detecting speculative bubbles
created in experiments
via decoupling in agent-based models***
M. Roszcynska et al. (2008)

Bubbles are periods when everyone makes the same investment decisions (one could argue that short-selling helps prevent bubbles, by allowing people to make opposite investment decisions).

Decomposition of proper scores
J. Bröcker (2008)
arXiv:0806.0813

Scores are a way of measuring the quality of estimators of probabilities (or estimators of probability distributions).

An estimator \hat{p} of the probability of a binary random variable Y is *reliable* if

$$\forall p \quad P[Y = 1 \mid \hat{p} = p] = p.$$

Given an observation $y \in [0, 1]$ of Y , the **Brier score** of \hat{p} is $(y - \hat{p})^2$; with several observations and forecasts, you would take the average of those quantities. This sum of squares is used in decision theory.

This can be generalized to non-binary (discrete or continuous) random variables (the article is not always clear); some properties of the Brier score lead to its decomposition into *reliability* and *sharpness* (information content).

Model of information diffusion
D.V. Lande

Cellular automata (the game of life) on a 2-dimensional grid can be used to model information diffusion. (I am skeptical about the lack of influence of the graph structure: a 2-dimensional graph and a small-world graph are very different – physicists are already used to seeing differences between 2- and 3-dimensional phenomena...)

***“Bubbles in society”
The example of the United States
Apollo program***
M. Gisler and D. Sornette

Bubbles, *i.e.*, collective over-enthusiasm, are (unavoidable and) beneficial: they foster innovation and allow the development of new technologies; examples include wars, cold wars, space programs, etc.

***The w-index:
a significant improvement on the h-index***
Q. Wu (2008)

One can reduce the number of citations papers of a researcher get (or any finite sequence of positive numbers) to a single index,

$$\sup\{w : \text{he has } w \text{ papers cited at most 10 times}\}.$$

If you plot the number of citations against the paper number w (after ranking the papers in decreasing citation order), this is the intersection of the curve with the $n = 10w$ line. Of course, this “10” is arbitrary...

***Probing the improbable:
methodological challenges for risks
with low probabilities and high stakes***
T. Ord et al.

When estimating very low probabilities (e.g., asteroid impact), you should consider that the argument could be incorrect, for many reasons:

- Theory (e.g., choice of Newtonian mechanics or general relativity);

- Model: is it broad/detailed enough (which celestial bodies to include, influence of their shape or structure, etc.); retraction rates of academic papers suggests that the proportion of inadequate models is at least 10^{-3} ;
- Calculations: intentional simplification (if a physicist is doing the computations) or errors: the probability of computational errors varies between 1% (drug doses in hospitals) and 90% (if you use spreadsheets).

(The problem is sometimes obvious in the conclusion: claims that something “is impossible” are almost always wrong.)

The estimate can be improved by providing several models.

Contrary to what the title suggests, the article only focuses on the probabilities, not on the stakes: there can be unpleasant situations where $\int \text{Stake } dP = \infty$.

Nonlinear dimension reduction with kernel sliced inverse regression

Y.-R. Yeh et al. (2007)

The sliced inverse regression (SIR), a linear dimension reduction technique (not explained clearly: in a regression setup $y \sim x$, look for $y = f(\beta x)$, where βx has much fewer columns than x and f is a linear or non-linear function, by looking at $\Sigma_{x|y}$ and Σ_x) can be extended with the “kernel trick”.

The Fast- τ estimator for regression

M. Salibian et al.

A τ -estimator is defined as

$$\hat{\beta} = \underset{\beta}{\text{Argmin}} s^2(\beta) \frac{1}{n} \sum_i \rho_2 \left(\frac{y_i - \beta x_i}{s(\beta)} \right)$$

$$\frac{1}{n} \sum_i \rho_1 \left(\frac{y_i - \beta x_i}{s(\beta)} \right) = 1.$$

(The second equation defines s .) If $\rho_1 = \rho_2$, it is an S -estimator (and the first equation simplifies to $\hat{\beta} = \underset{\beta}{\text{Argmin}} s(\beta)$). The *breakdown* is determined by ρ_1 ; the *efficiency* by ρ_2 .

Contrary to common belief, τ -estimators can be efficiently implemented.

Robust performance testing with the Sharpe ratio

O. Ledoit and M. Wolf

Journal of empirical finance (2008)

The tests traditionally used to compare Sharpe ratios are not robust to fat tails, autocorrelation or volatility clustering. One can use the same test statistics, but “assume” that their limiting distribution is $N(0, \Psi)$, with Ψ unknown (instead of known) and estimated with an HAC (heteroskedasticity and autocorrelation robust) estimator. The resulting p -values are higher, *i.e.*, apparent differences are less significant.

Correlation, hierarchies and networks in financial markets

M. Tumminello et al.

arXiv:0809.4615

Hierarchical clustering from a correlation matrix (minimum spanning tree (MST), average linkage MST, etc. – try several algorithms) can also be used to *filter* the correlation matrix: if C_1 and C_2 are two separate subtrees joined by an edge (or an internal node),

$$\exists c \quad \forall i \in C_1 \quad \forall j \in C_2 \quad \text{Cor}(i, j) = c$$

(as a result, there are as many (potentially) different values in the correlation matrix as internal nodes: $n - 1$). The structure of the filtered correlation matrix can replace the traditional factor model $V = \text{eve}'$. This **hierarchical nested factor model** has one factor for each internal node, but a *bootstrap* will often suggest that only a few are significant: fuse the non-needed nodes with their parent.

To check the goodness-of-fit of this hierarchical nested factor model, compare the Kullback–Leibler distance between the filtered matrix and the (raw) observed one with what you would expect of the observed matrix if the filtered matrix was the right one (with a multivariate Gaussian or Student distribution).

To check the stability of the filtering algorithm, check the average Kullback–Leibler distance between filtered bootstrapped matrices: random matrix theory (RMT) is bad, shrinkage and hierarchical nested factor models are good.

Stock market volatility:

an approach based on the Tsallis entropy

S.R. Bentes et al.

arXiv:0809.4570

Entropy is often used in a cross-sectional way, on the distribution of prices (or market capitalizations) of stocks at a given date, but you can also use it in a time series fashion, on the distribution of the returns of a single stock, as yet another measure of volatility.

They authors fail to properly define and motivate the Tsallis entropy

$$S_q(p) = \frac{1 - \int p^q}{q - 1}$$

they prefer over the Shannon entropy

$$H(p) = \int -p \ln p.$$

Smile dynamics:

a theory of implied leverage effect

S. Ciliberti et al. (2008)

arXiv:0809.3375

The volatility surface, if you only want a Taylor expansion around the money, can be studied without a complete model of the returns of the underlying (*e.g.*,

local volatility (the volatility is a deterministic function of the price), stochastic volatility, GARCH, jumps and Lévy processes, multiscale fractals, SABR, etc.): the *term structure* of the skewness (and higher moments) suffices

$$\Sigma(K, T) = \sigma \left(1 + \frac{\zeta(T)}{6} M + \frac{\kappa(T)}{24} (M^2 - 1) + O(M^3) \right)$$

$$M = \frac{1}{\sigma\sqrt{T}} \left(\frac{K e^{-rT}}{S} - 1 \right)$$

where K is the strike, T the maturity, M the money-ness, $\zeta(T)$ the skewness (of the returns of the underlying over intervals of size T), $\kappa(T)$ the kurtosis. The *term structure* of the skewness

$$\zeta(T) = \frac{\zeta(1)}{\sqrt{T}} + \frac{3}{\sqrt{T}} \sum_{t=1}^T \left(1 - \frac{t}{T} \right) \rho_{\text{leverage}}(T)$$

can be computed from the *leverage correlation function* (that quantifies the *leverage effect*, *i.e.*, the correlation between past returns and future squared returns)

$$\rho_{\text{leverage}}(t) = \frac{E[r_i r_{i+t}^2]}{\sigma^3}$$

which can be approximated as

$$\rho_{\text{leverage}}(t) = -A e^{-t/\tau}.$$

The *dynamics* of the implied volatility are between those suggested by the *sticky strike* ($\Sigma = \Sigma(K, T)$ (does not change as time passes), an upper bound, correct for short maturities) and the *sticky delta* ($\Sigma = \Sigma(M, T)$, lower bound, good approximation for longer maturities).

In the same way a 1-factor model of the returns of a stocks allows the volatility to be decomposed into a market volatility and an idiosyncratic volatility, it also allows for the decomposition of the skewness (into three terms).

Similarly, long-range volatility clustering would induce a non-trivial term structure on the kurtosis.

***An extensive set of scaling laws
and the FX coastline***
J.B. Glattfelder et al.
arXiv:0809.1040

The laws are all of the form something $\propto (\Delta x)^k$ or something $\propto (\Delta t)^k$ where Δx is the price change (that could be interpreted as an “intrinsic time”), Δt a time interval and “something” is the L^p average ($p \in \{1, 2\}$) of:

- Absolute returns in Δt ;
- Number of ticks in Δt , or Δx ;
- Number of direction changes in Δt , or Δx ;
- Maximum price move (drawdown) in Δt ;
- Waiting time for a price move of Δx (in absolute value or not);
- Total variation in Δt , or Δx ,

***Solvable stochastic dealer models
for financial markets***
K. Yamada et al.
arXiv:0807.0481

Yet another agent-based model, whose agents have different horizons and try to predict future prices with moving averages.

***Bayesian analysis of value-at-risk
with product partition models***
G. Bormetti et al.
arXiv:0809.0241

Empty article suggesting to use gaussian mixtures (instead of a gaussian model) to estimate value-at-risk (VaR). (“Product partition” is the physicaese word for “gaussian mixture”).

***Minimal agent based model
for financial markets I:
origin and self-organization of stylized facts***
V. Alfi et al.
arXiv:0808.3562

Stylized facts could be a *finite size effect*: they could disappear as the number of agents grow.

The authors build their (uninteresting) model on:

- Short-horizon investors;
- Herding
- The only available information is the price time series, ie, everyone is a chartist, with either a long or short horizon, and looks at what others are doing.

***Towards a common framework
for statistical analysis and development***
K. Imai et al.
**Journal of computational and graphical
statistics (2008)**

What about “refactoring statistical analysis” (or, equivalently, on “ontology of statistical analysis”) in the way you refactor (statistical) software? The article advocates the **zelig** package (a unified interface to models implemented in other packages), explains how R’s formulas can be generalized to accomodate constants and more complex models, presents Zelig’s dynamically-generated GUI and the *dataverse network* (a data-sharing/publishing platform).

***Efficient emulators for multivariate
deterministic functions***
J. Rougier (2007)

Climate models can be seen as (deterministic) functions $f : \mathbf{R}^N \rightarrow \mathbf{R}^M$, $x \mapsto y = f(x)$ with N very large. Since they are expensive to evaluate, they are often replaced by statistical approximations or *emulators*, *i.e.*, regressions $y \sim x$ from a small number of evaluations, where both x and y are vectors and have a spatial dependency structure modeled by a gaussian process.

In case the output is a vector and you are more familiar with scalar outputs, you can:

- Forecast the coordinates independently
- Perform a principal component analysis (PCA) or, better, a canonical correlation analysis (CCA) on the output space;
- uncurrify the function to be evaluated, *i.e.*, replace $x \mapsto (y_1, \dots, y_n)$ by $(x, i) \mapsto y_i$ (this assumes that the y_i are commensurate);
- Replace $x \mapsto f(x)$ by $x \mapsto N(\hat{f}(x), V(x))$ where $\hat{f}(x)$ is the predicted value and $V(x)$ its precision.

The article explains how to use linear algebra to approximate and speed up the estimation of this gaussian process.

Residual-based shadings for visualizing (conditional) independence
A. Zeileis et al.

Mosaic plots (that display contingency tables) and *association plots* (that display the Pearson residuals of a log-linear model $r_{ij} = (n_{ij} - \hat{n}_{ij})/\sqrt{n_{ij}}$) can be augmented by shadings or colours to display the significance of (*i.e.*, the p -value of a statistical test for) departure from independence:

- The usual χ^2 of independence, $\chi^2 = \sum_{ij} r_{ij}^2$ can be replaced by $M = \text{Max}_{ij} |r_{ij}|$, so that the whole test is significant iff a cell is significant;
- The critical values of this test (used to decide whether to colour or not) are data-dependent: they can be computed by *permutation tests*;
- The traditional colourings rely on the HSV (hue, saturation, value) *colour space* (a cone, whose vertex is black, whose base has a fully saturated rim and a white center) and can be misleading (saturation is not uniform accross hues); it can be replaced by the HCL (hue, chroma, luminance) space (a double cone, with a white vertex on one side and a black vertex on the other, and a fully saturated rim in the middle – that rim is slightly broken: admissible chroma and luminance values depen on the hue);
- Instead of changing just the saturation, you can also change both chroma and luminance;
- When there is nothing significant, use a medium grey (not white); as significance increases, increase the range of hues (a more colorful picture looks more significant).

Those ideas are implemented in R in the `vcd` package: check the `mosaic`, `assoc` and `cotabplot` functions.

Singular value decomposition and its visualization
L. Zhang et al. (2005)

To study a periodic signal (of known periodicity, *e.g.*, for hourly data you would expect a daily pattern), you can put the data in a matrix (dates in rows, time in columns – you can already plot this matrix as a surface to see intraday and interday patterns) and perform a singular value decomposition (SVD): it expresses the

matrix as a sum of rank-1 matrices. Plotting the data corresponding to matrices 1, 1+2, 1+2+3, etc. can highlight patterns in the data. Potential applications are similar to those of functional data analysis (FDA).

Delineation of irregularly shaped disease clusters through multiobjective optimization
L. Duczmal et al.
Journal of computational and graphical statistics (2008)

To detect a spatial cluster, in epidemiology, compute the *Kulldorff scan statistic*

$$\frac{\text{incidence inside}^{\text{cases inside}}}{\text{incidence outside}^{\text{cases outside}}}$$

for each (connected) potential cluster and select the one with the highest values (for circular clusters, this statistic is well approximated by a *Gumbel distribution*). This will select non-significant tree-like “clusters”: you can add a penalty, such as the *compactness*

$$\frac{\text{Area}}{\text{Parameter}^2}$$

and maximize

$$\left(\frac{\text{incidence inside}^{\text{cases inside}}}{\text{incidence outside}^{\text{cases outside}}} \right) \left(\frac{\text{Area}}{\text{Parameter}^2} \right)^\alpha$$

for some value of α (higher values favour circular shapes, while the actual cluster may be around a road, river, shore or plume or air pollution).

Instead, one can use a genetic algorithm to find clusters in the scan statistic vs compactness *Pareto set* (*i.e.*, efficient frontier). (Most machine learning algorithms can be generalized to multi-objective optimization.)

Modeling spatial-temporal binary data using Markov random fields
J. Zhu et al.

The spatial linear model

$$x_{i,j} \sim y + x_{i+1,j} + x_{i-1,j} + x_{i,j-1} + x_{i,j+1}$$

can be generalized for spatio-temporal data

$$x_{i,j,t} \sim y + x_{i+1,j,t} + x_{i-1,j,t} + x_{i,j-1,t} + x_{i,j+1,t} + x_{i,j,t-1}$$

The article does this in the context of a binary (autologistic) model (infected or not) and suggests to estimate it properly (previous attempts were estimating the spatial and temporal components separately), via Gibbs sampling.

Autologistic regression analysis of spatial-temporal binary data via Monte Carlo maximum likelihood
J. Zhu et al. (2008)

Terser but illustrated article on the spatio-temporal autologistic model

Hierarchical structure and the prediction of missing links in networks

A. Clauset et al.
arXiv:0811.0484

A **hierarchical random graph** is build from a dendrogram with a probability assigned to each internal node, by linking two vertices with the probability coming from their closest common ancestor.

Conversely, one can use a maximum likelihood (MCMC) approach to find the hierarchical random graph closest to a given network.

Once found, this hierarchical organization can also be used to predict missing connections.

Statistical properties of information flow in financial time series

C. Eom et al.
arXiv:0811.0448

The information flow between stocks can be studied by looking at

- the Granger causality within all pairs of stock retruns.
- the minimum spanning tree of the correlation matrix of their returns.

Serial corelation and heterogeneous volatility in financial markets: beyond the LeBaron effect

S. Bianco et al.
0810.4912

The *LeBaron effect*, *i.e.*, the negative correlation between volatility and autocorrelation,

$$\langle x_t^3 x_{t-1} \rangle < 0,$$

exists in high-frequency data.

Look-ahead benchmark bias in portfolio performance evaluation

G. Daniel et al.
arXiv:0810.1922

If you are assuming that the composition of your benchmark (often, an index) is constant and use the constituents from the end of the test period, you have a textbook example of a *look-ahead bias* and/or *survivor bias* (many indices are defined as the top N stocks in some market). The authors measure that bias: it can be as large as 8% per annum for the S&P 500.

Volatility effects on the escape time in financial market models

B. Spagnolo and S. Valenti
arXiv:0810.1625

One can use the *probability distribution of escape times* to analyze (or build a more formal statistical test of) the goodness of fit of a financial time series model.

Scale free effects in world currency network

A.Z. Górski et al.
arXiv:0810.1215

Yet another article on the minimum spanning tree of the correlation matrix of exchange rates; this one also looks at what happens if one changes the reference currency.

From time series to complex networks: the visibility graph

L. Lacasa et al.
arXiv:0810.0920

Here is an algorithm to turn a time series into a graph (feel free to imagine yours and check if/how time series properties translate into graph properties): one vertex for each observation, two vertices are linked if one can “see” the other in the flatland world `plot(.,type='h')`. A periodic time series becomes a random graph; a fractal time series becomes a scale-free network.

Portfolio optimization under habit formation

R. Naryshkin and M. Davidson
arXiv:0810.0678

The classical 1-period portfolio optimization problem

$$\text{Maximize } E[U(W_T)]$$

(maximize the expected utility of final wealth) can be replaced by the (also classical) multiperiod (or continuous time) optimal investment/consumption/bequest problem

$$E \int_0^T e^{-\rho t} U(C_t) dt + e^{-\rho T} B(W_T)$$

(maximize the discounted utility of consumption and utility of bequest, where T is the terminal time, C_t the consumption, W_t the wealth, U the utility of consumption, B the utility of bequest). This model has several drawbacks: the utility of consumption remains constant (or predefined). it should actually depend on the previous consumption

$$\bar{C}_t = \frac{1}{t} \int_0^t C_u du$$

to account for habit formation or intolerance to a decline in the standard of living.

The article suggests a utility of the form

$$U = T \left(\frac{C_t}{C_0 + \beta \bar{C}_t} \right),$$

for which the solution can be approximated with a discrete stochastic programming method (for two assets, it is $O(n^3)$, but it is exponential in the number of assets).

Distributed multilevel modeling
D. Afshartous and G. Michailidis

Because of confidentiality reasons or storage limitations, you may want to estimate a multilinear model on distributed data (one database for each group) without exchanging too much data between the nodes. This is possible; it is not an approximation. The article also contains a terse refresher on multilevel models, with formulas for all the estimators you may want.

Introduction to statistical learning theory
O. Bousquet et al.

Good tutorial about the *theory* of supervised classifiers and the general *inequalities* you use to study them (these are inequalities with few assumptions: you are already familiar with the Markov and Chebychev ones, but there are many others).

No fishy arguments to sell you some magical algorithm as in some other articles on the subject.

Should risk managers rely on maximum likelihood estimation method while quantifying operational risk?
B. Ergashev (2007)

Operational risk is usually estimated with a loss distribution approach (LDA): for each risk cell C (line of business, event type, etc.), estimate the distribution of the severity of losses and the frequency of losses (exponential, log-normal, log-normal-gamma, log-logistic, Weibull, generalized Pareto, g -and- h , log-???; Poisson, binomial, negative binomial); these are then aggregated to produce the distribution of the total loss. To complicate things, the data we are given are often stripped of “small” losses (say, under USD 10,000); some risk cells are almost empty; and the model need not be specified properly.

The model can be estimated using a maximum likelihood estimator (MLE) or some kind of “distance” between distributions (between the empirical distribution of the data and that of the model) such as the **Cramer von Mises statistic**

$$\text{CvM}(F, G) = \int [G(x) - F(x)]^2 f(x) dx$$

or the **Anderson–Darling statistic**, almost identical, but with more weight on the tails

$$\text{AD}(F, G) = \int \frac{[G(x) - F(x)]^2}{F(x)[1 - F(x)]} f(x) dx$$

or a quantile-based distance

$$\text{QD}(F, G) = \sum_p [F^{-1}(p) - G^{-1}(p)]^2$$

where the sum is over a set of quantiles $p \in [0, 1]$, such as R’s `ppoints(N)` or the author’s “equally spaced” (sic)

$$p = \frac{1 - \varepsilon}{k}, \quad k \in \llbracket 1, N \rrbracket.$$

The estimation procedure should be robust to local extrema, e.g., simulated annealing (SA). The distance-based methods estimate the severity of losses distribution and the frequency of losses separately, while the MLE approach can estimate the joint model. The article finds the quantile distance estimation superior, with a log- T /Poisson model, simulated data in an ideal situation, simulated data with insufficient data in some cells, simulated data from a mixture of log-gaussians (I am not sure the data from such mixtures is bad enough).

You may also look at other metrics:

- Kolmogorov: $d_K(F, G) = \sum |F(x) - G(x)|$
- Lévy: $d_L(F, G) = \inf\{\varepsilon > 0 : \forall x F(x - \varepsilon) \leq G(x) \leq F(x + \varepsilon)\}$
- Total variation: $d_{TV}(F, G) = \frac{1}{2} \int |f(x) - g(x)| dx$
- Kullback–Leibler (aka entropy divergence)

$$K(F, G) = - \int \log(g/f) f(x) dx$$

- Hellinger distance: $H(F, G) = \sqrt{\int (\sqrt{f} - \sqrt{g})^2 dx}$
- Fisher information:

$$I(F||G) = \int \|\nabla \log f - \nabla \log g\|^2 f(x) dx.$$

Activity spectrum from waiting-time distribution
M. Politi and E. Scalas
arXiv:08013043

Waiting times in high-frequency financial data do not follow an exponential distribution, but can be modeled by a continuous mixture of exponentials

$$\psi(\tau) = \int_0^\infty g(\lambda) \lambda e^{-\lambda \tau} d\lambda.$$

Finding the **activity spectrum** $g(\lambda)$ from the density of durations ψ or the more directly accessible survival function (an inverse Laplace transform) is a numerically unstable task and can be tackled by a regularization method such as Tikhonov’s (this could be another name for *ridge regression*).

Personal recommendation via modified collaborative filtering
R.-R. Liu et al.
arXiv:0801.1333

An application of bipartite networks.

Voter models on heterogeneous networks

V. Sood et al.

arXiv:0712.4288

Two examples of dynamical systems on **heterogeneous graphs** (*i.e.*, graphs whose node degree distribution is “broad” – the results can be qualitatively different from those obtained on a lattice):

- Voter model: each node has a state (0 or 1), a randomly-chosen node imports its new state from a randomly chosen neighbour;
- Invasion model: idem, but replace “import” by “export”.

Critical comparison of several order-book models for stock-market fluctuations

F. Slanina

arXiv:0801.0631

There are many order book models but none reproduces the features of empirical data: return distribution, absolute return autocorrelation, Hurst exponent:

- Stigler: limit orders (buy, sell) arrive at random times and are executed if possible, or stay;
- BPS: buy and sell particles are introduced from both ends of the allowed price interval $[p_1, p_2]$, diffuse (follow a random walk), and annihilate when they meet.

Those models can be augmented with cancellations (evaporation); the other models mentioned (Genoa, Maslov) are more promising but not detailed.

Fluctuating epidemics on adaptive networks

L.B. Shaw and I.B. Schwartz

arXiv:0801.0606

Classical epidemic models (SIR, SIRS) can be studied on a fixed network or on a network changing to avoid contagion.

Asymptotic theory of statistics and probability

A. DasGupta (Springer, 2008)

A reference book, but a readable one (the style is lively and you can open it at any chapter, the author will not assume you have already read the previous 500 pages), covering everything you may want to know about convergence or limits in probability and statistics.

I only read the two chapters available on the publisher’s website.

Chapter 2 presents various **metrics** on the space of probability distributions (Kolmogorov, Lévy, total variation, Kullback–Leibler (*minimum distance estimation* is a synonym for KL estimation), Hellinger, etc.); reviews the various notions of convergence and the relations between them; recalls the *Poisson approximation* (*i.e.*, convergence to a Poisson distribution); explains that gaussian distributions are extremal (if you fix the variance) for the maximum entropy and the minimum Fisher information problems.

Chapter 29 explains what “the bootstrap works” means, and reminds us that it could fail (infinite variance, non-differentiable functions, support of F_θ that depends on θ , $\theta \in \partial\Theta$, tangency problems, etc.) – in that case, the m/n bootstrap may still work. For time series prefer fixed block sizes (there is an optimal block size that depends on the spectrum of the series); the bootstrap will not work for long-memory time series.

Comparison of volatility measures: a risk management perspective

C.T. Brownlees and G.M. Gallo (2008)

<http://ssrn.com/abstract=107321>

Volatility refers to any estimator that converges to the *integrated variance*

$$\lim_{\tau \rightarrow 0} E \left[\frac{1}{\tau} \int_T^{T+\tau} (r_t - \bar{r})^2 dt \right].$$

This assumes that you have an underlying *continuous* model of stock prices. Ideally, the estimator should be robust to the misspecification of this model.

Volatility estimators can be assessed by comparing them with a reference volatility, an implied volatility (VIX) and by checking the value at risk (VaR) and the expected shortfall (ES).

The authors find that the *daily range* is preferable to the realized volatility (which does not look at the overnight returns – the article lists several realized volatility estimators), which is better than a GARCH model.

Modern Multivariate Statistical Techniques

A.J. Izenman (Springer, 2008)

The sample chapter looked empty.

Statistical Design

G. Castella (2008)

Not understandable.

Multifractal analysis of Chinese stock volatilities based on partition function approach

Z.-Q. Jiang and Z.-X. Zhou

arXiv:0801.1710

The **multifractal analysis** of a positive time series (the realized volatility) can be carried out as follows:

- Put the time series into boxes of size s ;
- Sum the volatilities in each box;
- Normalize, *i.e.*, divide by the sum of all boxes;
- Compute:

$$\chi_q(s) = \sum_{\text{boxes}} (\text{normalized volatility})^q$$

$$\chi_q(s) \sim s^{\tau(q)}$$

$$\alpha = \frac{d\tau}{dq}$$

$$f(\alpha) = q\alpha - \tau(q).$$

***Effect of Asian currency crisis
on multifractal spectra***

**G. Oh et al.
arXiv:0801.1475**

The multifractal detrended fluctuation analysis (MF-DFA) of a time series (or returns) is performed as follows:

- Make sure the mean is 0;
- For each s , divide the data into boxes of size s ; remove a linear (or polynomial of degree m , or spline) trend; compute the average of the squared residuals; take the L^p average $F_p(s)$ of the value in each box;
- Fit $F_p(s) \sim s^{h(q)}$.

***Bayesian core: a practical approach
to computational bayesian statistics***

**J.M. Marin and C.P. Robert
Springer (2008)**

Interesting.

***Generalizing Swendsen-Wang
for image analysis***

A. Barbu and S.-C. Zhu

To sample from probability distributions on graphs (graph colourings), the Gibbs sampler performs poorly if the variables are linked (e.g., if they form a grid, as in image analysis). The Swendsen-Wang (SW) method paliates this by clustering the nodes at random (turn all the edges between nodes of different colours off, turn some of the remaining edges off at random, take the connected components – you have a different clustering each time) and changing the colour of whole clusters at a time. However, since there is no Metropolis-Hastings (MH) rule, it only works for the Ising-Potts model. It can be seen as a *data-augmentation* procedure: we actually sample from the joint distribution

Potts model \times Random Cluster Model

by moving, à la Gibbs, in only one marginal chain at a time.

This can be improved as follows:

- Use the data to get an a priori probability that two adjacent nodes have the same colour (say, a measure of pixel intensity similarity, if you are trying to segment an image) and use that probability when deciding which edges to turn off; this gives more meaningful clusters (if the probabilities are completely wrong, no real harm is done: the constant probability of the SW model is wrong as well);
- Allow the number of colours to increase or decrease: the new colour of the cluster can be a new one or an existing one.
- Use a Metropolis-Hastings (MH) acceptance probability.

The algorithm can be applied to *image segmentation* (identify the various elements of an image: car, sky, building, tree, lion, etc.).

Large graphs can be handled as follows:

- Multigrid clustering: only apply the algorithm to a subset of the data (e.g., a slice of a cube, a single image in a video, etc.);
- Multilevel clustering (for instance, in motion segmentation, this would give you a hierarchy of clustering: pixels, pixels moving in the same way (cheetah limbs), actual objects (cheetah)).

***Maximum spanning trees, asset graphs and
random matrix denoising in the analysis
of dynamics of financial networks***

**T. Heimo
arXiv:0806.4714**

You might want to denoise your correlation matrix using random matrix theory (RMT) before computing a minimum spanning tree (MST) (useful but notoriously unstable). This is actually a bad idea: the denoised matrices are even less stable and have lost most of the clustering information.

***Global recessions as a cascade phenomenon
with heterogeneous, interacting agents***

P. Ormerod (2008)

Which countries are in recession can be modeled on a (small world) graph: each node will go in recession the next year with probability α , will go out of recession with probability β , and will also go in recession if sufficiently many of its neighbours go in recession. As usual, the physicist's intuition that the shape of the network is irrelevant and can be assumed a lattice breaks down for small world graphs.

***How to quantify the influence of correlations
on investment diversification***

**M. Medo et al.
arXiv:0805.3397**

A definition of the **effective portfolio size** of a basket: the number of stocks, with iid returns (and therefore equal expected returns and risk) for which the minimum variance portfolio has the same risk. You can use the tangential portfolio instead.

***Evolutionary Monte Carlo methods
for clustering***

**G. Goswami et al.
Journal of computational and graphical
statistics (2007)**

Clustering algorithms either try to solve an optimization problem, more or less greedily. For instance, k -means tends to get stuck in a local optimum; you can compensate for this by running them several times and choosing the best solution; and/or you can start with a partition coming from a hierarchical clustering. MClust is similar to k -means but uses a mixture of gaussians and the BIC (bayesian information criterion) to choose the number of clusters.

You can avoid that local optimum problem altogether by sampling from some posterior distribution.

This article suggests an improvement over MCMC sampling based on **parallel tempering** (PT) (you have several MCMC chains, each with its temperature, sampling from distributions of the form $g(z) \propto \exp(-H(z)/T)$, and we want to sample from the coldest) by adding the following operators:

- Crossover: select two chains (parent 1 and 2), consider the intersection of the clusterings

choose two clusters A and B in each parent and exchange the intersection $A_1 \cap A_2$ and $B_1 \cap B_2$

- Crossover (idem, but only select one cluster in the first parent – which remains unchanged)

- Crossover (idem, but do not reallocate the whole intersections, but only part of them (chosen at random))

- random exchange: swap two adjacent tempered chains.

In all cases, use the Metropolis-Hastings probability of the set of all tempered chains to decide whether to keep the clusterings.

This evolutionary Monte Carlo clustering (EMCC) algorithm can be used with a “Dirichlet process prior” (not defined), with an energy function $H(z)$ coming from an objective function to optimize (k -means) or a log-likelihood (mixture of gaussians, as in MClust); it can also be used for *variable selection* (just cluster the variables).

Time series decomposition and analysis in a study of oxygen isotope records M. West (1995)

The *bayesian periodogram*, *i.e.*, the posterior distribution of ω in a simple model

$$x_t = a \cos \omega t + b \sin \omega t + \varepsilon_t,$$

can help identify quasi-cyclical components. Being a whole distribution, it has a finer resolution than the classical, discrete (FFT (Fast Fourier Transform)) periodogram, which can miss frequencies between the Fourier frequencies.

The author suggests to fit an $AR(p)$ model (or an autoregressive state space model, *i.e.*, an $AR(p)$ model observed with noise) to the data, in a bayesian way: you can look at the distribution of the roots of the characteristic polynomial to test whether the data is stationary (the roots are in the $\{|z| < 1\}$ disc), you can also identify noise (roots with a small real part, *i.e.*, an argument close to $\pm\pi/2$); after somehow sorting those roots, you can look at the distribution of the arguments of the first ones: they correspond to the frequency of the *quasi-cyclical component* of the dataset (it is not extremely clear if they directly look at the roots or at the bayesian periodogram of the fitted $AR(p)$).

In a bayesian context, you can use a mixture distribution to account for or model outliers with a *contamination model*: replace $\varepsilon \sim N(0, v_0)$ by

$$\varepsilon \sim (1 - \pi)N(0, v_0) + \pi N(0, v_1)$$

with π small and $v_1 > v_0$.

Regime switching can be studied in a non-bayesian setting: cut the data in 2 or 3.

An appendix explains how to sample from (simulate) the posterior distribution of an $AR(p)$ model or a more general state space model (SSM).

Stock price jumps: news and volume play a minor role A. Joulin et al. arXiv:0803.1769

Empirical observations suggest that price jumps are not cause by news (they are followed by increased volatility while news are followed by a lower volatility) or large transaction volumes, but rather by very small-scale *liquidity squeezes* – market microstructure is a nonlinear system with feedback and has a non-mean-reverting effect.

Feasibility of portfolio optimization under coherent risk measures I. Kondor and I. Varga-Haszonits arXiv:0803.2283

The authors remark that (unconstrained) optimization of coherent risk measures (expected shortfall (ES), etc.) is sometimes unfeasible, the risk measure not being bounded below.

Shouldn't the conclusion be that constraints are necessary? The article has a more worrying shortcoming: the authors assume that the returns are elliptical (fine) and use a naive estimator of the dispersion matrix – unifying risk model estimation and optimization is good unless you botch the first step and end up with a singular matrix...

To their defense, they correctly identify the cause of the problem: if you rely on the *empirical* returns distribution, an asset will *strongly dominate* the others with non-zero probability.

***Log-normal continuous cascades:
aggregation properties and estimation.
Application to financial time series***

A. Bacry et al.
arXiv:9894.0185

The article is not understandable, but the introduction gives a definition of *multifractality* as a generalization of the “square root of time rule” to non trivial term structures:

- Square root of time: $E[X_t^2] \propto t^{1/2}$;
- Scaling behaviour: $E|X_t^q| \propto t^{\zeta q}$;
- Multifractal: $E|X_t^q| \propto t^{\zeta(q)}$, where ζ is concave but not linear.

***How much random a random network is:
a random matrix analysis***

S. Jalan and N. Bandyopadhyay
arXiv:0805.4343

To quantitatively measure the randomness of a network, one can compare the distribution of the eigenvalues of its adjacency matrix with those of a random matrix, e.g., using the Δ_3 statistic (approximately, the sum of square residuals of a linear fit of the cumulated distribution function (a staircase function) of the (empirical) distribution of the eigenvalues).

The article does not explain why we should expect the adjacency matrix of a random network to look like a random matrix.

***Bayesian approach to clustering real value,
hypergraph an bipartite graph data:
solution via variational methods***

A. Vasquez
arXiv:0805.2689

A physicist remarks that mixture models (or rather bayesian model averaging (BMA) of mixture models, since you rarely know the number of clusters) can be generalized to biclustering, *i.e.*, simultaneous clustering among both subjects and variables.

***Note on two-phase phenomena
in financial markets***

S.M. Jiang et al.
arXiv:0801:0108

Looking for a regime change (a “bifurcation”) from a unimodal to a multimodal distribution in 1-minute index returns: the authors find that this is linked to the return tails – this looks like an artefact of the way they are modeling those distributions.

***A brief history of generative models
for power law and lognormal distributions***

M. Mitzenmacher

Power law distributions, aka fat tail distributions, *i.e.*, $P[X \geq x] \sim_{x \rightarrow \infty} cx^{-\alpha}$, *i.e.*, $\log P[X \geq 0]$ is well approximated by an affine function in $\log x$ for large x , are very similar to log-normal distributions

$$\log f(x) = -\frac{(\log x)^2}{2\sigma^2} + \left(\frac{\mu}{\sigma^2} \log x\right) - \log \sqrt{2\pi}\sigma - \frac{\mu^2}{2\sigma^2}$$

(especially if σ is large) and can be used interchangeably.

Power laws can be generated by *preferential attachment*:

- Start with a 1-mode graph;
- Add a new node, link it to a uniformly-chosen node with probability α or, with probability $1 - \alpha$ to a node chosen randomly and proportionally to its degree.

This can describe the world wide web or, say, the distribution of species (degrees) among genera (nodes).

The relation between word frequency and word length can stem from an optimization problem (Huffman coding) – but simpler models, using randomness without optimization, yield similar power law distributions.

Multiplicative processes lead to log-normal distributions (e.g., Black-Scholes), but if X_t is a geometric random walk and T an exponential random variable, then X_T follows a power law.

***Topological structures
in the equities market network***

G. Leibon et al.
arXiv:0805.3470

A *multiresolution clustering* of N time series (think: stock returns) can be obtained as follows:

- Cluster the time series, using your preferred clustering algorithm (the article suggests “hierarchical spectral clustering” but assumes the reader already understands what it is);
- Compute the average time series in each cluster (think: sector returns);
- Project the time series on the subspace spanned by those average time series (this allows each time series to be considered as a member of several clusters, with weights);
- Start again with the residuals: if you are lucky, the next step can be interpreted (think: countries);
- Iterate until the eigenvalues of the correlation matrix of the residuals look like those of a random matrix, *i.e.*, until the residuals are indistinguishable from the Gaussian ensemble.

The introduction of the article contains ideas that could be developed further. For instance, random matrix theory (RMT) studies the distribution of the eigenvalues of the correlation matrix of gaussian iid variables: in statistical terms, this can be seen as the null

hypothesis of a test. One could use the same ideas with another null hypothesis: a given correlation matrix, e.g., coming from a clustering (this could be used to *test* if sectors are sufficient to explain return correlations).

Comparison of detrending methods for fluctuation analysis

A. Bashan et al.
arXiv:0805.4081

Short-range correlation in a time series is characterised by the exponential decay of the autocorrelation function

$$\rho(s) \sim \exp(-s/\tau),$$

where the decay time τ can be obtained as

$$\tau = \int_0^\infty \rho(s) ds \quad (?).$$

When this integral diverges, there are *long-term correlations*; quite often, the decay can be approximated by a power law

$$\rho(s) \sim s^{-\gamma}, \quad \gamma \in (0, 1).$$

The estimation of this exponent γ directly from the autocorrelation function ρ is very noisy: one can do better.

One can study the *scaling behaviour* (in finance, this could be called the “term structure of volatility”), *i.e.*, how the properties of the time series (e.g., the standard deviation) change with the sampling frequency (e.g., whether the economist’s “square root of time” rule is valid). More specifically:

- Somehow detrend the time series;
- Compute the *fluctuation function* $F(s)$ on scale s , *i.e.*, the standard deviation of the time series resampled at period s ;
- Try to estimate α such that

$$F(s) \sim_{s \rightarrow \infty} s^\alpha;$$

this is linked to the power law decay in the autocorrelation function by $\alpha = 1 - \gamma/2$; when $\alpha = \frac{1}{2}$, there is no long-range dependency; when $\alpha \in (\frac{1}{2}, 1)$, there is; when $\alpha \in (0, \frac{1}{2})$, there is *negative* long-range dependency; when $\alpha \geq 1$, the series is not stationary.

There are many ways of detrending the time series:

- Do not do anything: this is (almost) Hurst’s R/S ;
- Subtract the moving average on a window of size s ; always check that your chosen detrending method does not introduce bias: here, use a centered window;
- Fit a linear function on a moving window of size s and take the residuals; people often take non-overlapping windows and then worry about the discontinuities this introduces;
- Fit a polynomial of degree d on a moving window of size s and take the residuals; this is the *detrended fluctuation analysis* (DFA)

- Use a local (linear or polynomial) regression;
- Use Fourier analysis to remove known frequencies; this is limited to periodic, regular, known trends;
- Embed the time series in a higher-dimensional vector space, perform some kind of dimension reduction to identify the “trend” and take the residuals;
- Apply digital high-pass filters (Butterworth, Chebyshev, elliptical filters (?)).

Agents for traffic simulation

A. Kesting et al.
arXiv:0300

Funny article on simulating road traffic with heterogeneous agents operating in a shared environment; some of the visualization methods are... interesting – for instance, the coffee-meter to measure the driving comfort.

Efficient navigation in scale-free networks embedded in hyperbolic metric spaces

D. Krioukov et al.
arXiv:0805.1266

Routing algorithms on a graph (e.g., the internet) usually work by laborious information exchanges between neighbouring nodes – but if the graph is embedded in a metric space, if each node knows its “coordinates”, those of its neighbours and those of the target (strictly speaking, there are no coordinates in a metric space: each node only needs to know the distance between each of its neighbours and the target), one can use a *greedy* routing strategy: send packets to the neighbour closest to the destination. This could explain the *Milgram experiment* (sending letters to unknown persons, identified by name, location and job, by sending it to the friend “closest” to the target, leading to the “six degrees of separation”).

Real-world network suggest a *negatively curved* space.

However, determining the metric embedding will likely require laborious information exchanges

Accurate estimator of correlations between asynchronous signals

B. Toth and J. Kertesz
arXiv:0805.2310

Asynchronicity biases the naive correlation estimator towards zero. Just model the asynchronicity, for instance x_t and y_t could be AR(1) processes with missing values, or Ornstein-Uhlenbeck (OU) processes (not random walks: we want stationary processes) observed at discrete (different) times and try to manufacture an estimator from the cross-correlation of $\text{locf}(x)$ and $\text{locf}(y)$.

Power law in customer’s expenditures in convenience stores

T. Mizuno
arXiv:0802.0105

Yet another example of a power law distribution, in point-of-sale (POS) databases.

The structural role of weak and strong links in a financial market

A. Garas et al.
arXiv:0805.2477

Apparently, one can cluster (or apply modern/trendy tools of graph theory: scaling theory, percolation, fractal analysis, community detection (this one is not mentioned), etc.) using the correlation or their daily returns. Removing the 99% links with the largest correlation keeps the network connected.

New approach to community detection in networks

A.D. Medus and C.O. Dorso
arXiv:0808.0375

Community detection (this is the graph-theoretical word for clustering, a *community* being a subgraph “whose nodes are more connected between themselves than to external nodes”; it is often easier to look for non-overlapping clusters, *i.e.*, partitions; it can be used for “dimension” (graph size) reduction) algorithms usually try to maximize some *merit factor* such as the *modularity* of a partition of the graph

$$\sum_{\text{subgraphs}} \frac{\# \text{ external links}}{E[\# \text{ external links} | \text{degrees}]}$$

This is an NP-complete problem, mainly because the modularity is a *non-local* merit factor; furthermore, evidence suggests that modularity cannot find clusters smaller than a certain size.

There are local alternatives: a *strong community* is a subgraph C such that

$$\forall i \in C \quad k_i^{\text{in}} > k_i^{\text{out}}$$

(where k_i^{in} is the number of edges between node i and other nodes in C , and k_i^{out} is the number of edges between node i and nodes outside C); a *weak community* is a subgraph C such that

$$\sum_{i \in C} k_i^{\text{in}} > \sum_{i \in C} k_i^{\text{out}}.$$

One can find a partition into communities by maximizing

$$\sum_C \frac{\sum_{i \in C} k_i^{\text{in}} - k_i^{\text{out}}}{\sum_{i \in C} k_i}$$

under the constraints

$$\forall C \quad \forall i \in C \quad k_i^{\text{in}} > k_i^{\text{out}}$$

or

$$\forall C \quad \sum_{i \in C} k_i^{\text{in}} > \sum_{i \in C} k_i^{\text{out}}.$$

You may want to replace the strict inequalities $>$ by \leq .

Multifactor analysis of multiscaling in volatility return intervals

F. Wang et al.
arXiv:0808.3200

Many articles study the distribution of *return intervals*

$$\inf\{t : \text{Volatility}_t > q\}.$$

This one is empty.

The distribution of first-passage times and durations in FOREX and future markets

N. Sazuka et al.
arXiv:0808.0372

The distribution of the first passage time

$$T_p = \inf\{t : \text{Price}_t \geq p\}$$

is well approximated by a Weibull distribution with a power law tail.

Since inter-trade durations are not exponentially-distributed, we cannot use Lévy processes to model tick data.

A model for interevent times with long tails and multifractality in human communications: an application to financial trading

J. Perello et al.
arXiv:0805.1353

Interevent times are not Poisson; they can be modeled by mixture distributions (Poisson and something else).

Higher-order potential forces observed in bubbles and crashes in financial markets

K. Watanabe et al.
arXiv:0808.3339

Bubbles and crashes can be identified from a non-linear AR(1) model

$$y_{t+1} = f(y_t) + \text{noise}$$

where f moves from \forall through \nexists to \nexists .

Improved subset autoregression

A.I. McLeod and Y. Zhang
Journal of Statistical Software (2008)

Some time series, e.g., those with periodic features, have a complicated autoregression structure: for instance, only the first, second and eleventh partial autocorrelations are significantly non-zero (an AR(2) process with 11-year periodic patterns). You can fit this model more parsimoniously than an AR(11) with the FitAR package.

Power law distributions in empirical data

A. Clauset et al. (2007)

arXiv:0706.1062

Some interesting and clear remarks about power law estimators:

- Whether the data is continuous or discrete does matter: when using estimators for continuous data with discrete data (because you do not like zeta functions), beware of the bias they introduce;
- With fat-tailed data, least-squares-based estimators such as the classical histogram regression

$$\log p(x) = \alpha \log x + \beta,$$

should be avoided; prefer maximum likelihood estimators such as the *Hills estimator*;

- To find the cutoff beyond which your data follows a power law, you can compare the data with the corresponding quantiles (with a *Kolmogorov–Smirnov test*): if the threshold is too low, they do not match, if it is too high, they do not match either because there is too much noise; use the bootstrap if you want a confidence interval on this threshold.

Boom and bust in continuous time evolving economic model

L. Mitchell and G.J. Ackland (2008)

Economic systems (modelled here by companies competing on prices – lower prices mean higher sales but lower margins) need not converge to an equilibrium, but can exhibit *cycles*; this is similar to the Lotke–Volterra oscillations in ecology.

Heavy-tailed statistics in short-message communications

W. Hong et al. (2008)

Not all event patterns are Poisson.

Fat tails, long memory, maturity and ageing in open-source software projects

D. Challet and S. Valverde

arXiv:0802.3170

You can do a lot of interesting data analysis from a version control system (CVS, SVN, etc.) log, e.g., look at the distribution of the number of lines changed, or inter-commit time, for a given file, a given developer or the whole project; look at the cross-correlation between changeset size and intercommit time. This highlights different periods in the lifecycle of the project – if you manage programmers, you can use this idea to monitor your employees.

CVS's deficiencies (no tracking of file moves or re-names) create visible artefacts in some of the plots.

The log-periodic-AR(1)-GARCH(1,1) model for financial crashes

L. Gazola et al.

The oscillations before a crash, with slow rises and faster drops, accelerating before the singularity, can be modeled as

$$p_t = A + (t_c - t)^\beta (B + C \cos(w \log(t_c - t) + \phi)) + u_t.$$

The article suggests to use an AR(1) model with GARCH innovations for the noise term u_t .

A non-parametric investigation of risk premia

C. Peroni

Simplistic credit risk models, of the form

$$\text{corporate rate} = \text{government rate} + \text{risk premium}$$

i.e., corporate spread = risk premium are not confirmed by historical data: there are too few defaults to account for such a high risk premium. *Affine multifactor models*,

$$\text{corporate spread} \sim \text{government term structure},$$

(you can use some form of dimension reduction on the term structure: principal component analysis (PCA), factor analysis, kernel PCA, etc.) can be improved by

- allowing non-linearities (use a generalized additive model (GAM) on the (discrete) time structure);
- adding macroeconomic variables (inflation).

Stochastic volatilities and correlations, extreme values and modeling the macroeconomic environment under which Brazilian banks operate

T. Barnhill and M. Souto (IMF)

Most estimators of volatility and correlation perform equally poorly – stick to the simplest one, the exponentially weighted moving average (EWMA).

When estimating how well those estimators perform, do not compare their immediate results (volatility forecasts) but their P&L impact, as they are used in portfolio management.

Credit derivatives and risk management

M.S. Gibson (2007)

Empty article, stressing that credit derivatives do not eliminate risk; the following risk sources remain and may be tricky to quantify:

- credit risk;
- counterparty risk;
- model risk;
- rating agency risk;
- settlement risk.

Financial Modeling under non-gaussian distributions

E. Jondeau et al.

Springer Finance (2007)

This is a reference book (if you want details about any statistical *test* useful (or misleading, misused) in finance, it should be there), but not a very good one: it

emphasizes the value of the statistic of the tests rather than the p -value; the plots are often uninformative (for instance, the differences between a gaussian density and a non-gaussian density are invisible unless you use a logarithmic scale on the vertical axis) and lack axis names and units; it compares the log-likelihood of non-nested models with a different number of parameters (better use the BIC instead); etc.

Financial returns present the following *stylized facts*:

- Fat tails;
- Asymmetry (negative skew);
- Aggregated normality;
- Absence of serial correlation;
- Volatility clustering (all measures of volatility are serially correlated);
- Time-varying cross-correlation.

There are tests for all of those (but beware: some are only asymptotic; others assume that the mean and variance are known, not estimated).

Those stylized facts can be explained by the *microstructure* of financial markets (the book only considers *order-driven markets*), leading to either:

- Stable distributions (amenable to computations, through their *characteristic function* – the density can then be approximated via numeric integration);
- *Subordinated* processes, *i.e.*, the prices are geometric random walks in *market time* (aka event time or theta time), reflecting intermittent information arrival (this could be an interview question: if X_t is a brownian motion and the market time I_t has log-normal increments, what is the distribution of X_{I_t} ?)
- Mixture of distributions (estimated via the generalized method of moments (GMM), with the corresponding χ^2 test);

Current models of the *order book* (there is a detailed description of the *EKO model* of the quote arrival process) are not satisfactory.

GARCH models, and their generalizations, for instance, those based on *duration* between trades, such as ACD (autoregressive conditional duration) model (?) or CAR (compound autoregressive) model (?) can model some of the stylized facts.

GARCH models have an *aggregation* problem: if daily returns are GARCH, then weekly returns need not be GARCH; if stock returns are GARCH, then portfolio returns need not be GARCH. You can get both temporal and cross-sectional (portfolio) aggregation by enlarging the class of GARCH processes to *weakly GARCH* processes (which includes GARCH-like process with ARMA, non-gaussian innovations).

The GARCH model is over-simplified: it uses a single source of randomness, for the returns;

$$\begin{aligned}\varepsilon_t &= \sigma_t z_t \\ \sigma_t^2 &= \omega + \alpha \varepsilon_{t-1}^2 + \beta \sigma_{t-1}^2;\end{aligned}$$

stochastic volatility models have another one, for the

volatility;

$$\begin{aligned}\varepsilon_t &= \sigma_t z_t \\ \sigma_t^2 &= \exp h_t \\ h_t &= \omega + \beta \sigma_{t-1}^2 + v_t;\end{aligned}$$

they can be estimated with a *Kalman filter*.

Realized volatility, *i.e.*, volatility estimated from high-frequency data, is a discrete analogue of the *quadratic variation* (which leads to some more tests).

You can also test for the presence of jumps in the data.

Time-varying volatility is not sufficient to explain fat tails: the innovations seem to be genuinely non-gaussian.

You can still use GARCH estimators that assume the innovations are gaussian, even if they are not, and plug in estimates of the first two moments; these *quasi-maximum likelihood estimators* (QMLE) are often consistent but the resulting tests have to be robustified.

Not all values of skewness and kurtosis are attainable (the (wrongly stated) condition is simple: a set of determinants have to be positive); if you want a distribution inside some amenable family, the range of possible values is even smaller.

Beyond a few ad hoc non-gaussian distributions (say, the skewed Student T distribution), you can easily get one by a series expansions around the gaussian distribution: multiply the gaussian probability distribution function ϕ by a polynomial – if you are not careful, you end up with a non-positive “density”. Common choices are the *Gram-Charlier expansion*

$$1 + \frac{a}{6}H_3(x) + \frac{b}{24}H_4(x)$$

and the *Edgeworth expansion*

$$1 + \frac{a}{6}H_3(x) + \frac{b}{24}H_4(x) + \frac{a^2}{72}H_6(x)$$

where the *Hermite polynomials* are

$$H_i(x) = (-1)^i \frac{1}{\phi(x)} \frac{\partial^i \phi}{\partial x^i}.$$

The probability distribution function (pdf) g of a skewed version of a distribution with pdf f and cumulative distribution function (cdf) F can be obtained by *hidden truncation*,

$$g(z) = 2f(z)F(\xi z).$$

The *entropy distribution* is that with the lowest entropy among the distributions with the desired moments; if you only specify mean and variance, you get a gaussian distribution, *i.e.*, $p(x) \propto \exp P(x)$ for a degree 2 polynomial P ; if you ask for the first k moments, P just becomes a polynomial of degree (at most) p . Entropy distributions tend to be multimodal.

You can build gaussianity or goodness of fit tests from the moments, the whole density function or its restriction on some intervals.

GARCH models can be generalized by considering several time-varying moments – but beware, not all possible values of those higher moments come from an actual density function (but the GARCH-like specification of the time dependency of the higher moments can still be used to *test* for their time-dependence). More generally, you can consider *autoregressive conditional density* (ARCD) models.

There are several multivariate GARCH models, such as:

- the *vech* model, where each element of the covariance matrix V_t is a linear combination of the previous squared residuals $\varepsilon_{i,t-k}\varepsilon_{j,t-k}$ and the elements of the previous covariance matrices $V_{t-\ell}$
- the *diagonal vec model* is the special case where $V_{i,j,t}$ only depends on $\varepsilon_{i,t-k}\varepsilon_{j,t-k}$ and $V_{i,j,t-\ell}$;
- the *BEKK* model ensures that V_t is positive definite (add more time lags if you want):

$$V_{t+1} = \Omega + A'\varepsilon_t\varepsilon_t'A + B'V_tB;$$

- In higher dimensions, you can use an *orthogonal GARCH* (PCA-GARCH) model, a *factor GARCH* model, or a *flexible GARCH model* (?).

It is often easier to model the correlations and the volatilities separately (most of the previous models do not guarantee that the variance matrix remains positive definite):

- The *constant conditional correlation* (CCC) model: the correlation matrix is constant, only the volatilities are time-dependent;
- The *dynamic conditional correlation* (DCC) model,

$$\begin{aligned} u_t &= \left(\frac{\varepsilon_{it}}{\sigma_{it}} \right)_{i \in \llbracket 1, n \rrbracket} \\ \text{Cor}_t &= (\text{diag } Q_t)^{-1/2} Q_t (\text{diag } Q_t)^{-1/2} \\ Q_t &= (1 - \delta_1 - \delta_2) \bar{Q} + \delta_1 u_{t-1} u_{t-1}' + \delta_2 Q_{t-1} \\ \bar{Q} &= \text{Cov } u \end{aligned}$$

- The ARMA-like *time-varying correlation* (TVC) model,

$$R_t = (1 - \theta_1 - \theta_2)R + \theta_1 R_{t-1} + \theta_2 \Psi_{t-1}$$

where Φ_t is the sample correlation matrix of the normalized residuals;

- The *general dynamic covariance* (GDC) model (which nests most of the above).

Many 1-dimensional distributions do not have a natural multivariate generalization (the gaussian, Student or more generally elliptical distributions are exceptions); there are (several) skewed generalizations of the multivariate gaussian or Student distributions.

Choosing a copula family imposes restrictions on the various measures of concordance (Kendall's tau, Spearman's rho, etc.); for instance, many popular copulas only allow for positive dependence.

Here are a few copulas:

- Gaussian;
- Student;
- Frank, *i.e.*, archimedian with

$$\phi(t) = \log \frac{e^{-\theta} - 1}{e^{-\theta t} - 1};$$

- Clayton, *i.e.*, archimedian with

$$\phi(t) = (t^{-\theta} - 1)/\theta;$$

- Gumbel, *i.e.*, archimedian with

$$\phi(t) = (-\log t)^\theta;$$

- Plackett;
- Marshall-Olkin.

Margins and copula can be estimated together or separately and you can mix parametric and non-parametric models.

You can test the goodness of fit of a copula.

You can build a GARCH-like model by replacing the variance by the parameter(s) of the family of copulas you have chosen.

With copulas, moment computations often become analytically intractable.

There are two approaches of *extreme value theory* (EVT), that lead to estimators of the same quantities: you can focus on the distribution of maxima over subsamples, or on the tail (or *peaks over thresholds* (POT)), *i.e.*, the distribution of exceedances over a threshold.

If the (rescaled) maximum of X_1, \dots, X_n converges, then it converges to a *generalized extreme value distribution* (it encompasses the Frechet (fat tails), Gumbel (thin tails) and Weibull distributions)

$$H_\xi(x) = \exp(-(1 + \xi y)^{-1/\xi})$$

(for $\xi = 0$, take the limit). The parameter ξ is the *tail index*; its inverse $1/\xi$ is the *shape index*. You can graphically estimate this parameter with a *quantile-quantile plot* and formalize this with a regression.

If the distribution of X is in the domain of attraction of the extreme value distribution H_ξ , then the extreme distribution function

$$F_u(x) - P[X - u \leq y | X > u]$$

can be approximated by the *generalized Pareto distribution*

$$G_{\xi, \psi}(x) = 1 - \left(1 + \frac{\xi}{\psi}\right)^{-1/\xi}$$

You can also plot the *mean excess function*,

$$e(u) = E[X - u | X > u].$$

The tail index can be estimated with the *Pickands estimator*, the *Hills estimator* (popular, but it assumes we are in the domain of attraction of the Frechet distribution) or the Deckers–Einhorn–de Haan (DEdH)

estimator (a variant of the Hills estimator, that corrects for this problem, and appears more stable).

There is no satisfactory way of determining “where” the tail starts for those estimations.

For (non-iid, stationary) time series (under mild conditions), H_ξ gets replaced by H_ξ^θ (for the same ξ), where $\theta \in [0, 1]$ is called the *extremal index*.

On the other hand, the subsample maxima approach is (asymptotically) unaffected by the dependence structure.

High quantiles can be estimated from the extrema or the tail approach.

Most of the results only hold for 1-dimensional variables: the EVT limit theorems (analogues of the central limit theorem) only hold in one dimension...

With several (say, two) variables, if you get the copula wrong (and you sure will), the tail distribution will be wrong. There are three ingredients to the tail:

- The tail of the margins;
- The *asymptotic dependence*, which is unrelated to the dependence of the bulk of the data; it can be measured by

$$\chi = \lim_{u \rightarrow 1} P[V > u | U > u]$$

$$\bar{\chi} = \lim_{u \rightarrow 1} \frac{2 \log P[U > u]}{\log P[U > u, V > u]} - 1$$

(and can be estimated from (1-dimensional) tail index estimators);

- The time dependency.

To plot the tail of a bivariate random variable, consider the *Frechet transformation*

$$S = -\frac{1}{\log F_X(X)}.$$

Prefer *expected shortfall* (ES) to value at risk (VaR) (not coherent, *i.e.*, does not recognize that diversification reduces risks; ignores extreme risks) or variance (symmetric, ignores extreme risks).

VaR can be computed from a “historical simulation”, with moving window artefacts (the VaR estimates jump); the expected shortfall does not erase those artefacts. EVT-based estimators do not have this problem.

The *GARCH-EVT* model separates the conditional volatility and the tail distribution (compute the GARCH residuals via quasi-maximum likelihood (QML), *i.e.*, assuming gaussian innovations (this is consistent even if they are not gaussian); estimate the tail of the residuals; filter (?) the initial data).

The book mentions *quantile regression*, purportedly to define the conditional autoregressive value at risk (CAViaR), but their presentation is confusing and further clouded by typos.

RiskMetrics estimates volatility by an exponential (autoregressive) moving average of squared returns.

Computing the VaR of a portfolio can be tricky; if you have derivatives, you should take into account the non-linearity of those instruments.

In portfolio construction, you can approximate the investor’s utility with mean, variance and higher moments; you can also add downside risk (VaR, ES) constraints.

There are several approaches to option pricing:

- Binomial lattice;
- Replicating portfolio;
- No-arbitrage: build a risk-free portfolio with the option and the underlying; since it is risk-free and there is no arbitrage, its dynamics, *i.e.*, a stochastic differential equation (SDE), are known; since we also know the dynamics (SDE) of the underlying, we get that of the option; this eventually leads to a partial differential equation (PDE) which can be solved with the *Feynmann–Kac formula* (?);
- Martingales, *i.e.*, *risk-neutral density* (this can be seen as a “change of base”, performed to simplify the computations – and indeed, some parameters, such as the investor’s preferences and the growth of the stock even disappear);
- Pricing kernel (?).

The risk-neutral density (RND) can be estimated from the option prices. This is a non-parametric approach: there is no model of the underlying prices evolution. The authors have apparently never heard of *functional data analysis* (FDA) and happily present estimates of a density function with negative values; mixtures of distributions; Edgeworth expansions (this is the second time they explain this, but it became abominously confusing); *maximum entropy* (good to estimate density functions); splines (FDA), kernel (local) regression can give acceptable results, though, but not in the tails.

The book also explains the relation between risk-neutral and objective density: the latter incorporates the investor’s preferences and the trend (?).

The last chapter presents option pricing in a stochastic volatility model, *i.e.*, with time-dependent volatility, and the volatility, modeled by a *square root process*, comes from a second source of randomness; and in jump models (Lévy processes are often amenable if you use the characteristic function).

I have not read the appendices on stochastic calculus.

***Music constraint programming* T. Anders (2007)**

Computer aided composition (CAC) is often based on stochastic processes such as Markov chains, automata, grammars (cellular automata, fractals, L-systems, etc.) or on *constraint programming* – the topic of these presentations.

Music theory studies structures inside musical pieces, such as

- melody (how notes follow one another, in time);

- harmony (how notes can be combined, at the same time, to form a “chord”, and how chords follow one another);
- counterpoint (how melodic lines fit together);
- harmonic counterpoint (counterpoint on an underlying harmonic progression)
- musical form (macrostructure)
- orchestration (choice of instruments)

Musical representation is inherently bidimensional: a musical piece can be seen as a set of melodies, played at the same time; a set of chords, played in succession; a set of measures, played in succession; etc. List-based (or tree-based) representations (e.g., Haskore) will choose one of those representations and accessing the others will be extremely clumsy. Instead, those inclusion relations can be represented by an acyclic graph: an event (note) is both in a melody and a chord, the chords and bits of melodies are in measures, melodies and measures are in the piece.

Constraint programming can be used to compose music; traditional programming concepts (abstract data types, object-oriented programming) come in handy, and even functional programming becomes useful: the constraints (rules) are functions returning a boolean value, and you may want to transform them, *i.e.*, to specify (dynamically) where to apply them.

The *constraint store* is the set of possible values of the variables, often expressed as a cartesian product of their domains. The search algorithm progressively reduces it:

- *Propagate* the constraints, while keeping the set of potential solutions a box, *i.e.*, $\mathbf{x} \in \prod [a_i, b_i]$; for instance, given $x_1 = 3$, $x_2 \in [1, 10]$ and $x_1 \geq x_2$, the search space can be reduced to $\{3\} \times [1, 3]$;
- *Distribute* the constraints: when you can no longer propagate any constraint, choose a variable, and split its domain: for instance, $x_1 \in [1, 10]$ can be decomposed into $x_1 = 1$ and $x_1 \in [2, 10]$, or $x_1 \in [1, 5]$ and $x_1 \in [6, 10]$; the algorithm then proceeds recursively, on each branch of this tree.

When distributing the constraints, you have to choose which variable to distribute (*variable ordering*)

- *First-fail principle*: start with the variables that are the most likely to fail (if the search in a branch has to fail, it had better fail early), e.g., variables with a small domain or with a lot of constraints;
- left-to-right variable ordering: earlier notes first, longer notes first – variable ordering is used in manual composition: you classically write the harmonic progression before the actual pitches, the melody before the accompaniment;

and how to distribute it (*value ordering*)

- take the first (lowest) value;
- take a value at random (for musical purposes, this is better: the result will be more “varied”);
- use some domain-specific heuristic.

Some rules might be too complicated to be evalu-

ated with the information currently available (e.g., harmonic constraints when the rhythm is still undetermined): their *context* is *inaccessible* and should be resolved as early as possible.

Constraint programming is easy to parallelize.

Should you want to play with constraint programming in general, you can have a look at Mozart (an implementation of the Oz multi-paradigm programming language) or Gecode (C++).

Check the author’s thesis for more details on Strasheela.

Concepts, techniques and models of computer programming **P. Van Roy and S. Haridi (2003)**

This book about programming languages paradigms, more recent than Finkel’s, is based on Oz (and its implementation Mozart/Oz), a *multi-paradigm* programming language – or rather, Oz was designed to illustrate all the paradigms presented in the book – it is more a pedagogical language than a real-world one. This multiplicity is apparent in the variety of “equal” operators: `==` (test), `=` (binding), `:=` (assignment), `=:` (constraint propagation). But if you want a language with more rarely-present features, such as *dataflow variables* or *constraint programming*, it might be a good choice.

A word of caution: Mozart/Oz is not portable – it only runs on 32-bit machines.

The book is based on a series of *kernel languages*, the basic features of Oz, plus the topic of the current chapter, without any form of syntactic sugar or *linguistic abstraction* (loops, etc.): these are simpler to reason with.

The book also contains some Fortran-bashing (replacing a comma by a dot created another valid program that contributed to the loss of a satellite) and some shared-state concurrency bashing (because of a race condition in its stateful concurrent software, a medical radiation machine actually killed people).

Declarative computation model

The various scoping, typing, evaluation policies are presented:

- static (or lexical) scoping (a function, or *closure*, can use variables from the environment in which it was defined – this can be used to hide implementation details, since that environment is often no longer directly accessible);
- dynamic scoping (a function can use variables from the environment from which it is called, e.g., Vision’s special (carret) variables);
- weakly typed (you cannot get type errors: the computer will silently convert everything – even if you are trying to compare, say, a real number with a list of strings);
- strongly typed (you can get type errors);

- dynamically typed (some type checks are made at runtime, you may get type errors during the execution even though the program compiled fine);
- statically typed (the type checks are made at compile time, you cannot get type errors at run-time; Alice is apparently a variant of Oz with static typing; also note that statically typed languages need not be *explicitly typed*: some let the compiler infer the type of each variable);
- *eager* (supply-driven) evaluation (execute code thoroughly, when it appears);
- *lazy* (demand-driven) evaluation (only execute code when and if it is needed – this allows infinite data structures, such as “the list of all integers”, because they will never be evaluated completely; in Oz, define lazy functions with `fun lazy` instead of `fun`); the authors suggest that languages should be eager by default and allow some functions to be lazy;
- *non-strict* evaluation may perform more operations than lazy evaluation (which is guaranteed not to do any non-needed work) in the hope that they will be needed later (Haskell is not lazy but non-strict).

Kernel language semantics: interesting discussion on how the environment store can be implemented.

Variables can only be assigned once; they are then *bound* to a value; before that, they are *unbound*, or bound to other (unbound) variables. This is the *single-assignment store*.

As a result, there is no difference between input and output variables in a procedure: a procedure just adds information (bindings) to the store; variables that were unbound and become bound can be seen as outputs, while variables that were already bound can be seen as inputs. Functions are mere syntactic sugar: `x=f(y,z)` is equivalent to `f(?x,y,z)` (the question mark is an indication for the programmer: it is ignored by the compiler).

Declarative programming techniques

A (superficial) chapter is devoted to declarative programming techniques:

- difference between recursive computation and *iterative computation* (it looks recursive, but it uses a *bounded stack*);
- state transformations, such as *accumulators*, to turn recursive computations into iterative ones – this can be seen as a functional programming design pattern, that becomes invisible when the language provides it (states or mutable variables);
- currying;
- `foldl`, `foldr`, `map`, `filter`;
- *difference lists*;
- complexity and amortized complexity, with the *banker’s method* (put “credits” aside, for each operation, use them, if available, when needed, to perform costly operations) and the *physicist’s method* (use a *potential function* to measure how good the current state is and whose differences represent the cost of the cleaning operations,

e.g., the number of operations required to rebalance a tree, or $\Theta(1)$ thereof);

- Serialization (pickling).

For instance, most of the description of a graphical user interface (GUI) should be declarative (see a later chapter).

A *functor* is a parametrized module, that depends on some “interfaces” (aka *abstract data types* or ADT – there is apparently nothing in Oz to define types: they will only be in the programmer’s mind, as C++’s traits), for which the user will have to choose concrete implementations. A *module* is an instance of a functor. More generally, a functor is a function that returns a module – no language extension is needed, but Oz provides a linguistic abstraction.

An *open program* is a program that interacts with other programs (or humans), only known at run time; its execution is therefore not deterministic.

Declarative concurrency

Because of single-assignment, Oz’s threads (similar to a shell’s background processes) do not lead to observable non-determinism or race conditions. The *causal order* is the partial order between the execution steps. Threads can be *ready* or *suspended*; a *scheduler* decides which to run, trying not to *starve* them.

If you add *exceptions* to the concurrent model, it is no longer declarative, because the state “before the exception was thrown” is execution-dependent.

Dataflow variables can be used to communicate between threads: synchronization is implicit (no locks, etc.), dependencies can be dynamic (dictated by the data, not hardcoded), they also allow computations with partial values. A dataflow variable can be seen as both stateful (it can change state, *i.e.*, become bound – but only once) and stateless (its binding is monotonic: information can be added but neither removed nor altered).

Single-assignment variables are related to *futures* (an unbound object whose contents are being computed in separate thread) and *I-structures* (arrays of single-assignment variables).

Instead, you can use *streams* (analogue to Unix pipes). They can be demand-driven (lazy), supply-driven (eager, but if you generate data faster than you can consume it, you will run out of memory) or with a bounded buffer.

This chapter details applications such as logic gates (*lift* boolean operators to streams) and *coroutines*.

Mozart/oZ has a parser generator tool, `gump`, to extend the language with linguistic abstractions.

To accommodate demand-driven concurrency, the kernel language is augmented with a *trigger store* and a `ByNeed` primitive (that asks for its argument to be computed). (There is a problem, though: in `X==Y`, if neither `X` or `Y` is bounded or needed, they both remain unbound and unneeded; this may be a deadlock.)

Declarative concurrency can be used to let the computer determine the order of the computations, in a data-dependent way – for instance, to draw a tree, you can let the computer compute the coordinates of the points, without bothering exploring the tree yourself; or to solve the *Hamming problem*, *i.e.*, to enumerate all integers of the form $2^a 3^b 5^c$, `H=1|{Merge3{Times 2 H}{Times 3 H}{Times 5 H}}`.

Logic programming generalizes this: the constraint propagation is no longer local and the constraints are no longer equalities.

Laziness can have beneficial effects on complexity: it can turn an $O(f(n))$ *average* complexity algorithm (say, a queue implementation, which is problematic for (pure) functional languages) into a *worst-case* $O(f(n))$ complexity.

There is however a mismatch between computers (optimized to modify data) and the declarative model (which does not modify data). You can overcome some of those efficiency problems with *state*, *memoization* (but this changes the signature of the function – think Haskell *monads* – it looks awkward because it is), *instrumentation* (counting function calls – this sounds like *aspect oriented programming* (AOP)). Furthermore, the stateful model is more expressive: complex algorithms are simpler – in particular, for graph algorithms – my big problem with Haskell...

Interaction with the outside/real world brings observable nondeterminism: communicating with (independent) clients; displaying a video stream, skipping frames when needed; interacting with stateful components (hardware, libraries, UI); implementing specifications, protocols expressed in terms of state.

Impedence matching suggests to mix several computation models, for instance:

- a sequential component in a concurrent model (you need a “thread-safety enhancing” layer);
- a declarative component in a stateful model;
- a centralized component in a distributed system;
- a non-security-conscious component in a security-conscious environment (you need a “protector” – sandbox, jail, chroot, etc.);
- a non-failure-safe component in a failure-safe system (you need a fault-tolerance layer).

Message passing concurrency

Message-passing concurrency can be obtained by adding *ports* to the kernel language; they generalize streams: several threads can send messages to a port, a stream knows where the data is coming from.

Message passing can be used to implement RMI (remote method invocation – this can probably be seen as a synonym of message passing) and multi-agent systems (MAS, such as lift control systems – also used for hard disk heads). The message passed can be a *continuation*, *i.e.*, a block of code or an indication of the computations to run after the message has been processed – the recipient of the message is responsible for

the next steps of the program.

This chapter also contains an introduction to Erlang/OTP (Erlang is the language, OTP is the implementation or, rather, a set of libraries) – if you need that in a mainstream language, check the POE (Perl) and Twisted (Python) frameworks.

Here are a few concurrent message-passing patterns: several ports within a single thread (but you have to do the scheduler’s job); a queue (two ports, clients can send data to it, or retrieve data, in a FIFO manner); thread and subthread termination detection.

The *non-deterministic concurrent* model (aka concurrent logic programming) is between the declarative concurrent and the message passing one: it allows you to merge two streams (if you want more, it becomes awkward and inefficient; you would expect compiler to have been developed to make this efficient, but you would be wrong).

A port can be seen as a state: it is a list of values, which can be generated and used anywhere (contrary to a stream); if you only look at the latest value available, it behaves like a (stateful) variable. *Cells* implement the same idea, without concurrency: the model remains *sequential*.

Explicit State

State can be implicit (only present in the programmer’s mind, as with accumulators) or explicit: the kernel language can be extended with *cells*, that can be written to. Thus, Oz ends up with three equality operators: `==` (equality test), `=` (mathematical equality, binding), `:=` (assignment). Also beware of the difference between equality between cells (`X==Y`) and their contents (`@X==@Y`).

The authors try to motivate the need for states by encapsulation and compositionality – unconvincingly. *Invariants* (and encapsulation) can help reason with stateful programs (or components).

Component-based programming (encapsulation): procedures (functions and blocks of code); functors (compilation units, modules); threads; object-oriented programming adds another way of composing components: inheritance (but it adds unwanted dependencies; design patterns are the art of avoiding the resulting problems).

An *abstract data type* (ADT) can be:

- open (its structure is visible and tweakable);
- secure (encapsulated; security can be obtained through unforgeable tokens provided by the compiler or the VM, or just with lexical scoping)
- declarative (immutable, but you quickly end up creating a large number of instances; those instances have to be passed around)
- stateful (single instance; it can be a state in the scope of the procedures that need it and need not be passed around)
- unbundled (the data and the operations on the data

are stored separately – the compiler and/or virtual machine (VM) can ensure that the ADT remains secure, if needed);

- bundled.

Declarative languages (Scheme, Prolog) tend to provide open, declarative, unbundled ADTs; object-oriented ones (Java, Smalltalk) tend to provide secure, stateful, bundled ADTs.

You can use state to implement *revocable capabilities* (functions you may no longer be allowed to call after some time – just redefine them to raise an exception).

The book distinguishes the following (irrelevant?) parameter-passing mechanisms:

- call by reference
- call by variable (a special case of call-by-reference, when the argument is a cell – in procedural languages, this is often called call-by-reference);
- call by value (the procedure cannot change the value of its argument);
- call by value-result (call-by-variable, when the argument is supposed to be modified to hold the result, e.g., a procedure that would increment its argument);
- call by name (the argument is a *function* that returns a reference; a procedure with such arguments is a *thunk*);
- call by need (call-by-name, but the argument is only evaluated once).

Explicit state allows the implementation of stateful (mutable, and even extensible) *collections* (arrays, dictionaries, etc.).

Contracts (or *invariants*: what should be true before and after each operation – you can use *assertions*) can be used to formally prove *partial correctness*; to show that loops are not infinite, find some integral positive quantity that decreases at each iteration.

The state chapter contains a few digressions on software design:

- do not dilute responsibilities;
- share knowledge;
- document the *interfaces*;
- start small;
- the components can communicate with procedures, coroutines, synchronously, asynchronously, via mailboxes (asynchronously with pattern matching) or a *tuple space* (a mailbox with several recipients);
- the *interfaces* should be independent of the computation model used for the implementation

and on the future of programming:

- “Components will make programming accessible to application users”; this is already the case for statistical or digital signal processing applications (R, matlab, puredata, etc.);
- Professional programmers will combine larger components – currently, they are still too complicated (Java Beans) and their interfaces are too vaguely

documented.

State does not blend well with concurrency: whenever possible, use message-passing concurrency.

Object-Oriented Programming

Inheritance allows ADTs to be built incrementally, avoiding code duplication, but spreading the implementation. (“Early on, it was believed that inheritance would solve the problem of software reuse. This has not worked out in practice.”)

In Oz, a class is a record containing a set of attribute names and a set of methods; methods have named and optional arguments; dynamic binding (virtual methods) and static binding (non-virtual method) are decided when the method is called, not when it is defined; it allows *encapsulation* and access control (private, public)

Reflection (e.g., examining, and perhaps even changing inheritance relations at runtime), through a *meta-object protocol*, can be used for debugging, customization, separation of concerns (AOP?): method wrapping (intercepting each method call, looking at and possibly modifying its arguments), serialization (creation of a *chunk* – a few chapters earlier, it was a *pickle*), cloning, etc.

You should **not** use inheritance to structure your program, but only to create types. (Will this be exemplified in the chapter on GUIs?) In particular, inheritance should not break invariants of the parent class; you should **not** violate the *substitution property*. Some people also subclass to fix (patch) parent classes, needlessly complicating the inheritance graph.

Avoid multiple inheritance when the classes inherited from have something in common.

A *mixin* is a class often used in multiple inheritance, that does not need to know anything about the classes it will be mixed with; for instance, a **Batcher** class, with a single **batch** method, that takes a list of messages (or 0-argument methods) and sends them to **self**.

Class diagrams (UML) are useful but not a panacea: they do specify the functionality (in particular, *invariants*) of the class; they do not reflect the dynamic behaviour of the application; they display the structure of the application at a rather low level.

The OOP chapter contains an introduction to Java, should you need one, and gives a design pattern example: the *composite* (just a *tree* type).

Object-based programming is object-oriented programming without inheritance: it provides encapsulation, state shared by several methods.

If you need to define several functions f_1, \dots, f_n that can operate on several types T_1, \dots, T_m , you can opt for a *type decomposition* (define a virtual class T , let T_1, \dots, T_m inherit from it, and implement all the methods; you can easily add a new type, but adding a new function requires modifying all the classes) or a *func-*

tional decomposition (within each function, check for the type of the argument and act accordingly; it is very easy to add a new function, but cumbersome to add a new type – you have to modify all the functions). S3 classes in R are a functional decomposition – I call this *method-oriented programming*.

An *active object* is a port object which is an instance of a class, *i.e.*, an instance of a class, listening for (concurrent) messages and launching a method for each received message. The *Flavius Josephus problem* illustrates active objects: $n = 20$ soldiers are standing in a circle are committing a sequential collective suicide, by killing every $k = 3$ rd (remaining) soldier – what should be your position if you want to remain alive?

Active objects can be used to implement a simple concurrent event manager.

Shared state concurrency

Coroutines can be seen as a manual scheduling of threads in a sequential environment.

Prefer the message-passing model for multi-agent programs, consider the shared-state approach for data-centric programs (programs that access and update a large, central database).

The *maximally concurrent model* uses one thread per instruction; only data dependencies affects their execution; you do not have to explicitly create threads – you might not want to use it, though.

The kernel language provides an atomic **Exchange** operation that can be used to implement concurrent ADTs (ADTs whose operations can be run simultaneously).

Shared-state concurrent programming uses various forms of locks to create atomic actions:

- *simple lock*;
- *reentrant lock* (when a thread is inside a lock, it can enter it again (e.g., by calling the same function recursively)). *monitor* (wait points, to wait before, not after, entering a lock; e.g., a thread filling a bounded buffer would wait for enough room to be available in the buffer before requesting a lock to add an element; monitors use **wait** and **notify** operations; often, methods are *guarded*, *i.e.*, they wait until some condition is satisfied before starting);
- light (ACI) transactions (abortable, atomic, not persistent) or full ACID transactions – but how to add them to a *programming* language is still an open question, you will implement them by hand or rely on some library (or database) – databases can use *optimistic concurrency control* with *two-phase locking* (first grant locks without releasing any lock; then release locks without granting any lock; in strict 2-phase locking, all the locks are released at the same time) and *deadlock avoidance* (using the *wait-for graph*).

A *Tuple space* (aka *Linda*) is a (concurrent) multiset with non-blocking pattern matching capabilities (you

can add objects to the tuple space; you can extract one object of a given “type” to the tuple space, in a blocking or non-blocking way).

Relational programming

A *procedure* is a map (in the mathematical sense: it takes inputs and returns outputs); it can be replaced by a *relation* (in mathematical terms, you are replacing the category of sets by that of correspondances): the “function” can be multi-valued (or even sometimes fail to return a value) and the input and output arguments need not be the same for each call. You can do that in the declarative model, but you would end up with a lot of unbound variables: the relational model adds a **search** operation, that tries to assign a value to all currently unbound variables, while respecting all the constraints. There is often also a **fail** statement, which indicates that the current choice is wrong (and that another one should be tried): this allows for constraints that cannot be expressed by bounding variables, such as inequalities.

The search space can be huge and *generate-and-test* programs exhaustively examine it: this kind of *non-algorithmic programming*, without fine-tuning, can be used in databases (the amount of data is huge, but the search space small) or for toy (but perhaps instructive) examples.

Encapsulated search runs the program in an environment that controls how the search tree is explored (depth first, breadth first, etc.) and how many solutions are returned (just one, all of them, on-demand generation of new solutions, etc.); it also hides multiple bindings to the rest of the application. It can be obtained by adding a **Solve** function to the model.

Propositional logic only uses \vee , \wedge , \neg (you can use those to define \Rightarrow , \Leftrightarrow) and can be used to express, prove or disprove *tautologies*. *First-order predicate logic* adds quantifiers (\forall , \exists) and allows atoms to have arguments; for instance, it can be used to express genealogical relations and questions. For performance reasons, languages based on first-order predicate logic (Prolog) restrict the form of the axioms, e.g., to *Horn clauses*

$$\forall x_1, \dots, x_k \quad a_1 \wedge \dots \wedge a_n \implies a$$

and allow the user to provide *operational knowledge* (e.g., instead of specifying what a sort algorithm should do, specify what an efficient sort algorithm should do).

Pure Prolog does not allow higher-order programming, full prolog (which adds useful constructs with no corresponding logical semantics) only partially supports it.

Logic programming can be seen as a new “control structure” that can be added to other models (but the more stateful your program, the trickier it becomes).

Relational programming was traditionally used for natural language processing (NLP) – or, more generally, to parse ambiguous languages.

Relational programming can also be used to store re-

lations in a database; a *deductive database* can deduce tuples not explicitly stored (e.g., paths in a graph).

This chapter also contains an introduction to Prolog; most Prolog applications actually solve algorithmic problems (expert systems, deductive databases, parsing – most of the program is declarative, but the programmer somehow gives algorithmic cues to the computer).

Prolog is limited to *backtracking*, i.e., depth-first search.

Relational programming still evolves:

- Pure declarative, higher-order languages (Mercury);
- Multi-paradigm languages that allow a clearer separation of the declarative and non-declarative parts of the program (Oz);
- Constraint programming, either as a language feature (Oz, SICStus Prolog) or as a separate library (GeCode, Ilog).

Graphical User Interface Programming

GUI design is usually restricted to a single computation model such as:

- imperative (Tcl/Tk);
- object-oriented (Java);
- functional (Haskell and its fudgets);
- declarative (HTML);
- graphical.

The book advocates a multi-paradigm approach, with a declarative base augmented by objects and threads (it does not look very different from what is traditionally done; except that the widget description really *is* a data structure and (can but) does not have to be built in a procedural way):

- The structure of the widgets, their types, their initial values, their behaviour after simple events (resize) are purely declarative;
- Actions (procedures run when external events occur) are procedural;
- Handlers (objects that change the interface) are also procedural.

This allows you, for instance, to completely change the GUI (say, from Gtk to QT) while it is being used.

Distributed programming

There are various types of *distributed* systems:

- Shared memory multiprocessor;
- Distributed memory multiprocessor;
- Distributed memory multiprocessor with partial failure (so far, these are HPC (high-performance computing) and/or HA (high availability) *clusters*);
- Open distributed system (with naming and security problems).

Distributed programming is more complicated than concurrent programming:

- the processes are completely separated (they cannot share state or dataflow variables; the data has to be

converted (*marshaled*/serialized/pickled and unmarshaled/unserialized/unpickled) and sent around);

- resources (disk, memory, licence of commercial software, etc.) are localized;
- networks are several orders of magnitude slower than memory;
- failures are more common;
- not all components of the network may be trustworthy;
- nodes may be added or removed at runtime.

In the *network-transparent approach* (which assumes that none of those problems occur), the objects are local to a given node or machine (that synchronizes their usage and ensures their consistency) and respond to messages, whatever their origin – this is equivalent to concurrent programming.

Streams and ports can be readily used (the two ends of a stream can be launched in different processes). Other locking mechanisms can be used (e.g., distributed mutual exclusion using token passing).

Objects can be *stationary* (they remain on the same node – this is desirable if they access some local resources, e.g., disk) or *mobile* (the data is copied around (this is a *cache*) and the right to update the state is also moved around – this can be complemented by an *invalidation* mechanism that allows several nodes to hold a copy of the object).

Dataflow objects can be shared in an asynchronous way.

Distributed binding and distributed garbage collection can be slightly trickier.

This approach can be augmented:

- Network awareness (explicit use of message-passing for performance)
- *Naming* (language entities can be referred to by an (unforgeable) reference, name or ticket – a ticket exists outside the system – in particular, you will not be able to reclaim the memory used by an object if a ticket has been issued for it – tickets therefore often have an expiry time);
- Partial failure tolerance: you can detect (permanent) process failure (*fail-silent*) and (temporary) network failure, either in a synchronous, lazy way (you only notice the component is unavailable when you try to access it) or in an asynchronous, eager way (with a heart-beat mechanism to check what is alive and what is not; you may want to either wait or raise an exception when trying to access a failed resource); your application design should allow faults to be *confined*; fault tolerance is extremely difficult with shared states: prefer message-passing concurrency;
- Active fault tolerance (through replication and failover)
- Security (resilience to malicious failures), at several levels: application, language (check the *E* programming language), language implementation (you should not be able to tamper with compiled binaries or the virtual machine (VM)), operating system, net-

work, hardware.

Constraint programming

Alternate the following two steps:

- Local deduction: combine the constraints to reduce the space of possible solutions (the *computation space*), while keeping it manageable (e.g., a box $\prod [a_i, b_i]$); to facilitate this, the constraints are completed by *propagators*, i.e., function that explain how the constraint can help reduce the computation space (Oz already provides some of them; they can be seen as a generalization of the use of Horn clauses in Prolog);
- Search: split the problem P into $P \wedge C$ and $P \wedge \neg C$, where C is a cleverly-chosen new constraint; this choice is called a *distribution strategy*; the *search strategy* is the way the resulting tree is explored (depth-first, breadth-first or some domain-specific heuristic).

ChucK: a concurrent, on-the-fly, audio programming language

G. Wang and P.R. Cook

International Computer Music Conference
(2003)

ChucK is a *strongly-timed* audio programming language, based on data flows: data and time are clearly separated. The real-time problems are the computer's job: you just code in frozen time and say "proceed to the next sample" – or beat, or user-generated event (Midi, network, etc.). It features lightweight threads ("shreds") and a massively overloaded operator \Rightarrow (assignment, dataflow, etc.). Contrary to its predecessors, it does not seem to have escaped from the 1950s (Csound, SuperCollider) and is a real programming language, not a graphical one (Pure Data).

Also check G. Coleman's tutorial.

Beware: ChucK is not portable, it only runs on 32-bit machines.

Combining analysis and synthesis in the ChucK programming language

G. Wang, R. Fiebrink, P.R. Cook (2007)

The ChucK language has been extended with analysis operations (FFT, etc.); contrary to synthesis operations, they are not automatically computed for each sample (but usually less often) and have to be called (slightly) more explicitly; consequently, a new operator $\hat{=}$ (upchuck) was introduced besides \Rightarrow (chuck).

The Audicle: A Context-Sensitive, On-the-fly Audio Programming Environment

G. Wang and P.R. Cook

International Computer Music Conference
2004

The *Audicube* is a 3-dimensional IDE for ChucK, exploiting the real-time and on-the-fly nature of the language – think Compiz/Fusion (the faces of the

cube) and VRML (inside each face), to visualize data-flow relations, time relations (and program execution), parent-child thread relations, thread or process information à la top.

Music, a mathematical offering

D. Benson (2006)

Elementary (in its prerequisites) but excellent book that dispells a lot of misconceptions about the links between music and mathematics (in spite of a couple of overly vague mathematical statements such as "if the function f is absolutely integrable, i.e., L^1 , then $f(t) \rightarrow 0$ as $|t| \rightarrow \infty$ except perhaps on a set of measure zero", the book is eminently readable).

Here are some of the topics covered.

Sine waves are considered "pure" not because of Fourier analysis (you could use other bases) but because they are solutions of differential equations of the form $y'' + ay' + by = 0$, which describe the vibration of our eardrums (hence, the sounds we hear) and most "simple" systems (string and wood instruments).

Bessel functions, i.e. the Fourier decomposition

$$\sin(\phi + z \sin \theta) = \sum_{n=-\infty}^{\infty} J_n(z) \sin(\phi + nz)$$

appear in the description of percussion and brass instruments, *FM synthesis* and planetary motion (this last point was unclear).

Whether two sounds are consonant or dissonant does not only depend on the ratio of their fundamental frequencies, but also on their *timbre* (i.e., spectrum): when the spectrum has peaks (*partials*) at integral multiples of the fundamental frequency (string and wood instruments – such partials are called *harmonics*), the common belief that simple ratios are consonant is correct; but when the partials are not integral multiples of the fundamental (percussions and brass instruments), this is no longer true – you can even tweak the spectrum so that any interval you choose be consonant or dissonant. Pure sine wave (no partials at all) are not dissonant if they are sufficiently far apart. The "consonance function" for a given spectrum can be obtained as a linear combination of that of pure sine waves (which are obtained experimentally).

You cannot define an "instantaneous spectrum" (you have to have a non-zero window size; the smaller the window the more smeared the spectrum – this is actually *Heisenberg's uncertainty principle*), but the *Hilbert transform* can give you an *instantaneous frequency*.

The harmonics of a sound can be seen as a form of periodicity in its spectrum, which could be studied by another Fourier transform: on a logarithmic scale, this is called the *cepstrum*, $\mathcal{F} \ln \mathcal{F} f$; it is used in voice recognition to separate the partials (which are then called *formants*).

The book also presents a few musical paradoxes: *Shepard scale* (a scale whose pitch seems to be always in-

creasing, ad infinitum); *virtual pitch* (the pitch we hear is that of the fundamental, even if it is not present and only some of its integral multiples are there); *combination tones*, i.e., hearing $f_1 + f_2$, $f_1 - f_2$, $2f_1 - f_2$, $f_1 - 2f_2$ when frequencies f_1 and f_2 are sounded – this is not the *beat* phenomenon (we would hear $\frac{1}{2}(f_1 + f_2)$ and $\frac{1}{2}(f_1 - f_2)$ but results from the non-linearities (quadratic and cubic terms) in our ear – probably in the neural feedback.

When you compose music, limiting yourself to a set of allowable pitches or *scale* simplifies your work. For instance, you can start with a note and add “pleasant” multiples of it, such as octaves ($2/1$) and fifths ($3/2$). The *pythagorean scale* does just this: start with a note, add a fifth, another, and so on, but each time you exceed one octave, remove one octave; stop when you get close enough from your starting point. You never reach exactly the starting frequency, because $\log 3 / \log 2$ is irrational – its increasingly accurate rational approximations (via *continued fractions*) give rise to increasingly large scales (5, 12, 41, 53, etc.).

This set of notes is already a compromise, but we often want more: we want other simple ratios to be there. We have the octave $2/1$, the fifth $3/2$, the fourth $4/3$ (this is an octave minus a fifth, so we already have it), the third $5/4$ – more generally, *harmonics* brought down to the same octave $a/2^b$. For instance, we could use the 3-note scale $1:5/4:3/2$ (often written $4:5:6$ to emphasize that we are using the 4th, 5th and 6th harmonics – this is called a *major third*). *Just intonation* is obtained by taking three major thirds (CEG (I), the previous one FAC (IV) and the next one GBD (V)), giving 7 notes – should you want 12, you can fill in the 5 remaining ones as you want.

Classical harmony tends to move from triad to triad: the *mean-tone scale* asks for exact major thirds $5:4$ and wants the note in the middle to be exactly in the middle: CDE, FGA and GAB are exactly $1 : \sqrt{5}/2 : 5/4$ (the two remaining semitones are made equal). The problem is that the farther you move on the circle of fifths, the worse the fifths become (*wolf fifth*)

The *well-tempered scale* (or irregular temperament, or circulating temperament) tries to correct this.

Equal temperament is the easiest scale: 12 equally-spaced notes. This is the most common nowadays. The number of notes comes from the continued fraction approximating $\log 3 / \log 2$. Regarding continued fractions, you might want to notice that the golden ratio $[1, 1, 1, 1, \dots]$ is as far away as possible from the rationals.

In all those scales, the octave was pivotal: but you can remove it (especially with instruments with only odd harmonics, such as open-ended wood instruments like the clarinet) and consider, for instance, 13 notes in one octave and a half (Bohlen and Pierce) or focus on the ratios $3/2$ and $4/3$ instead of $2/1$ and $3/2$ (W. Carlos).

Since the Fourier transform of a *digital* signal is periodic, it can be written as a function of $z = \exp 2\pi i \nu \Delta t$

instead of ν : this is the *z-transform*.

Sound synthesis is slightly touched upon:

- *additive synthesis*: this is how cathedral organs work;
- *AM synthesis* (amplitude modulation): the *ADSR envelope* (attack-decay-sustain-release) is actually an example of AM synthesis;
- FM synthesis (frequency modulation), whose Fourier coefficients are *Bessel functions*; the book contains a small introduction to Csound, qualified of “tedious” – I would have said “antiquated”;
- Granular synthesis (no details)
- Phase vocoder: transform the windowed discrete Fourier transform;
- Chebychev polynomials: applying the function $T_2 : x \mapsto x^2 - 1$ doubles the frequency, i.e., $T_2(\cos \nu t) = \cos 2\nu t$; the other Chebychev polynomials are defined similarly and you can combine them, e.g., to turn sine waves into square waves.

The book ends with a chapter on symmetry – or *group theory*. Musical pieces exhibit some form of symmetry, in the rhythm (temporal) or the time \times pitch space: you can recognize the seven *frieze types*. (To avoid boredom, this is often just an approximate symmetry: for instance, the same motive can be transposed a step higher, while being constrained to remain in the same scale – some intervals will subtly change.) *Change ringing* (or *campanology*) is an Oulipo-like constraint on Church (bell) music composition, involving constrained paths in the symmetric group \mathfrak{S}_n .

In spite of its qualities, the book almost looks unfinished: when you reach the end, you still want more, you have the impression that only the surface has been scratched, that only the starting points have been exposed – in particular, there is hardly anything about composition, harmony, counterpoint, sonification or stochastic processes.

Optimization methods in portfolio management and option hedging H. Pham (2007)

Very clear (and complete) introduction to *continuous-time portfolio management*. After recalling the von Neumann–Morgenstern utility theory, with a clear motivation for the absolute and relative risk aversions and details on the *Allais paradox* (expected utility cannot reflect human preferences)

$$P_{X_1} = 0.33\delta_{2500} + 0.66\delta_{2400} + 0.01\delta_0$$

$$P_{X_2} = \delta_{2400}$$

$$P_{Y_1} = 0.34\delta_{2500} + 0.66\delta_0$$

$$P_{Y_2} = 0.33\delta_{2500} + 0.67\delta_0$$

$$X_2 > X_1, \quad Y_2 > Y_1$$

the author presents, on a discrete example, the two approaches to final-utility-maximizing multi-period portfolio management:

- Dynamic programming;
- The martingale approach:
 - Find the *risk-neutral measure*, i.e., a measure \mathbf{Q} for which the stock prices are a martingale; the price of a claim H is then $x = E^{\mathbf{Q}}[H]$;
 - Find the claim H solving the optimization problem

$$\begin{aligned} &\text{Maximize } E[U(H)] \\ &\text{such that } E^{\mathbf{Q}}[H] = x \end{aligned}$$

- Find a portfolio strategy leading to this wealth H .

The continuous-time analogues are then detailed, together with a few examples:

- Optimal strategy in a 1-stock Black-Scholes world (actively-rebalanced with constant weights);
- *Superreplication cost*, i.e., minimum initial capital of a strategy whose payoff almost surely dominates a given payoff $g(X_T)$, in a Black-Scholes world with non-constant volatility (no assumption whatsoever on the volatility, beyond measurability)

$$\frac{dX_t}{X_t} = \alpha_t dW_t$$

- Optimal strategy for a diffusion model

$$\frac{dS_t}{S_t} = \mu_t dt + \sigma_t dW_t$$

- *Quantile hedging*: since superhedging

$$P[\text{Payoff} \geq \text{Desired payoff}] = 1$$

can be expensive, one might prefer *VaR (value at risk) hedging*

$$P[\text{Payoff} \geq \text{Desired payoff}] \geq 1 - \alpha;$$

conversely, one can choose the initial investment x and look for the strategy that maximizes

$$P[\text{Payoff} \geq \text{Desired payoff}].$$

Stochastic control theory for optimal investment **M.T. Castillo and G. Parrocha**

The *Cramer–Lundberg model*, in non-life insurance, is

$$\text{Surplus} = \text{Initial capital} + \text{Income} - \text{Outflows}$$

$$R(t) = r + ct - \sum_{k=1}^{N(t)} X_k$$

$$dR = cdt - dS$$

where the aggregate claim $S(t) = \sum_{k=1}^{N(t)} X_k$ is a *compounded Poisson process* (or a *Cox process* or a *general renewal process* – those notions are not defined).

In order to control (diversify) the risk, an insurance company can invest part of its assets: the articles considers that a constant amount a is invested, a proportion $b(t)$ in a risky asset, a proportion $1 - b(t)$ in a

riskless asset.

$$dR_{\text{Risk}} = cdt - dS$$

$$\frac{d\text{Price}_0}{\text{Price}_0} = \rho dt$$

$$\frac{d\text{Price}_1}{\text{Price}_1} = \mu dt + \sigma dW$$

$$dI = a(1 - b) \frac{d\text{Price}_0}{\text{Price}_0} + ab \frac{d\text{Price}_1}{\text{Price}_1}$$

$$dU = dR + dI$$

$$U(0) = u$$

$$\text{Maximize } P[\nexists t \ U(t) < 0]$$

Finding the investment process b is a stochastic control problem, which can be solved with the Hamilton–Jacobi–Bellman (HJB) equation.

(The mathematical details in the article look fishy: before knowing anything about the solution, not even its existence, they start to assume it is twice differentiable...)

Some applications and methods of large deviations in finance and insurance **H. Pham (2007)**

Clear but rather technical presentation of *large deviation theory* and its applications in finance.

Large deviation theory is concerned with the asymptotic expansion of the probability of large events: for instance, the central limit theorem states that

$$P\left[\left|\frac{1}{n} \sum X_i - \mu\right| \geq a\right] \rightarrow_{n \rightarrow \infty} 0$$

and *Cramer’s theorem* states that

$$P\left[\frac{1}{n} \sum X_i \geq a\right] \sim_{n \rightarrow \infty} e^{-n\Gamma^*(a)}$$

$$\Gamma(\theta) = \ln E[e^{\theta X}]$$

$$\Gamma^*(x) = \sup_{\theta \in \mathbf{R}} [\theta x - \Gamma(\theta)].$$

Γ is called the *cumulant generating function* (cgf); it is the logarithm of the Laplace transform; Γ^* is called the *Fenchel–Legendre transform* of Γ ; you also encounter it as the dual of a convex function in variational analysis.

The idea behind the proof is that of *importance sampling*: change the probability distribution (in a tractable way, using an *exponential family*) to make the rare events more probable,

$$\mu_{\theta}(dx) = \exp[\theta x - \Gamma(\theta)] \mu(dx).$$

Indeed, large deviation theory can be used to prove theoretical convergence results for importance sampling.

Cramer’s theorem can be generalized: the *Gärtner–Ellis theorem* relaxes the independence assumption; *Freidlin–Wentzell theory* estimates the probability that a diffusion (a solution of a stochastic differential equation) leaves some domain, when the noise is small,

given that it remains in it when there is no noise at all (so that the event is indeed rare).

More generally, *large deviation principles* (LPD) state (more formally) that

$$P[Z_\varepsilon \in dx] \sim_{\varepsilon \rightarrow 0} e^{-I(x)/\varepsilon} dx$$

for some *rate function* I . In this context, *Varadhan's theorem* generalizes the *Laplace method*

$$\lim_{n \rightarrow \infty} \frac{1}{n} \ln \int_0^1 e^{n\phi(x)} dx = \max_{x \in [0,1]} \phi(x)$$

to

$$E \left[e^{\phi(Z_\varepsilon/\varepsilon)} \right] \sim_{\varepsilon \rightarrow 0} C \exp \left[\frac{1}{\varepsilon} \sup_x [\phi(x) - I(x)] \right].$$

Applications include:

- The *Cramer–Lundberg approximation* of the ruin probability of an insurer (initial reserve, regular premiums, iid claims arriving at the jump times of a Poisson process) when the reserve is large and its importance sampling estimator;
- Generalization to insurance-finance: if there is a drift in the asset prices, the insurer should invest and follow a buy-and-hold strategy – replacing the minimum ruin probability criterion with a less conservative one would lead to more complex/dynamic optimal strategies.
- Importance sampling to price very out-of-the-money options (change the drift to make exercise more probable);
- value at risk (VaR) estimation of a credit risk portfolio, in a 1-factor gaussian copula model, when the portfolio is large or the probability of default small.
- VaR of a passive strategy in the long term, when it gets closer and closer to the index it is tracking.

Specialising simulator generators for high-performance Monte-Carlo methods
G. Keller et al.

A scientific application of the pragmatic programmer's tip number 29, "Write code that writes code" – this could also be applied to (MCMC simulations of) mixed models (WinBugs, Jags).

This approach shifts part of the compiler design problem towards the end programmer; it looks similar to lex/yacc (or flex/bison) and the use of *hardware description languages*.

The need for open source software in machine learning
S. Sonnenburg et al.
Journal of machine learning (2007)

Open source tools are mature and suitable for large-scale real-world problems; their wider use would result in greater reuseability and interoperability – this is already the case in bioinformatics.

The article contains summary tables (definition, advantages, licences) screaming to be reused in bullet-point/Powerpoint/executive summary presentations.

The authors trace free software back to Sir Isaac Newton: *If I have seen further, it is by standing on the shoulders of giants.*

Proceedings of the Linux Audio Conference 2007

A few articles about *ambisonic* recording and *wave field synthesis* (WFS), scripting languages (PySndObj) and the usual suspects (Pure Data, etc.).

High-dimensional modelling and simulation with asymmetric normal mixtures
A. Tsanakas and A. Smith (2007)

A *gaussian mixture* is a random variable of the form $X = \sqrt{H}Z$, where $Z \sim N(0,1)$ and $H > 0$ (for instance, H could follow a discrete distribution with two values σ_1^2 and σ_2^2).

In higher dimensions, this becomes $X = \sqrt{H}LX$, where $\Sigma = LL'$ is the desired dispersion matrix and $E[H] = 1$ (H is still 1-dimensional).

This can be generalized by also randomizing the mean, yielding *asymmetric gaussian mixtures*,

$$\begin{aligned} X &= \gamma^{-1}(H-1)u + \sqrt{H}LZ \\ Z &\sim N(0, \mathbf{1}) \\ H &> 0, \quad E[H] = 1, \quad \text{Var } H = \gamma^2 \\ u &\in \mathbf{R}^n, \quad u'\Sigma^{-1}u \leq 1 \\ \Sigma &\text{ positive definite.} \end{aligned}$$

In high dimension, the dispersion matrix Σ can be parametrized by a Kronecker product.

Markov chain Monte Carlo convergence diagnostics: a comparative review M.K. Cowles and B.P. Carlin
J. Amer. Statist. Assoc. 91 (1996)

Presentation and comparison of 13 convergence diagnostics – beware, all can fail.

Constructing free energy approximations and generalized belief propagation algorithms
J.S. Yedidia et al. (2004)

Surprisingly clear presentation of the belief propagation algorithm (BP) for factor graphs.

Instead of looking for the optimal probability distribution P_{opt} , the free energy approximation looks for a simpler distribution Q (say, one where all the variables are independent (this could be seen as an "average" of one-variable models), or more generally a simply connected graphical model) that minimizes the Kullback–Leibler distance $D(P_{\text{opt}}||Q)$ – the magic is that it can be computed without knowing P_{opt} .

Variational approximations between mean field theory and the junction tree algorithm
W. Wiegerinck (2000)

Another article on the same subject.

Understanding belief propagation and its generalizations
J.S. Yedidia et al. (2002)

Earlier article on generalized belief propagation.

A differential approach to inference in bayesian networks
A. Darwiche

The author associates a polynomial (in several variables) to a bayesian network so that operations in the network (parameter estimation, marginal probability computations, etc.) are evaluations of the polynomial or its derivatives. The size of the polynomial is exponential, but manipulations on the parsing tree of the polynomial (which the author calls an “arithmetic circuit”) can make those evaluations can be amenable.

A logical approach to factoring belief networks
A. Darwiche

A more formal article on the subject.

An introduction to variational methods for graphical models
M.I. Jordan et al.
Machine Learning 37 (1999)

Variational methods come from the following remark: a convex function f is characterized by the affine functions above it,

$$f(x) = \text{Max}\{ \phi : \phi'x \geq f^*(\phi) \}.$$

To prove an assertion about f , it might suffice to prove it for all or one of those affine functions – in particular, this can lead to upper bounds of quantities involving f .

This idea can be applied to the likelihood of a graphical model: under mild assumptions (e.g., all the probabilities are from the exponential family), a graphical model is characterized by the set of independent models (graphical models with a discrete, edge-less graph – these are called *mean-field* models) more (or less) likely than it.

In particular, a graphical model can be fit by finding an independent model close to the optimal model – this is different from finding the independent model best fitting the data.

The fit can be improved by allowing more structure on the approximate graphical models: for instance, you can progressively complexify it, towards the graphical model being studied, until it becomes untractable.

Model-independent mean field theory as a local method for approximate propagation of information
M. Haft et al. (1997)

Another presentation of *mean field theory* (MFT), that suggests to average several mean field solutions (this really sounds like bayesian model averaging (BMA): for instance, you could approximate a grid by horizontal chains and vertical chains and hope to get a reasonable result by averaging those two simply connected models).

The bayesian structural EM algorithm
N. Friedman

The structure and parameters of a bayesian network can be learned “la Gibbs”, with an EM (expectation-maximization) algorithm: find the best structure for the current parameters, find the best parameters for the current structure, iterate until convergence.

Learning bayesian network models from incomplete data using importance sampling
C. Riggelsen and A. Feelders

Data augmentation (DA) is a simulation-based EM (expectation minimization) algorithm.

Probabilistic Graphical Models
M. Hauskrecht (2005)

Lecture notes, with a very useful list of references.

Probabilistic reasoning over time in Artificial Intelligence: A Modern Approach
S. Russell and P. Norvig

A readable introduction to dynamic bayesian networks (DBN): backward-forward message passing (for hidden Markov models (HMM)), application to the Kalman filter and extended Kalman filter (EKF), transient failure model, persistent failure model, particle filter, with applications to speech recognition (it also mentions A^* -search, with no details) and exercises.

Graphical models and automatic speech recognition
J.A. Bilmes
in Mathematical foundations of speech and language processing (2003)

Yet another introduction to graphical models, this time targeting automatic speech recognition (ASR).

Among the examples:

- Chain graphs (partly directed, partly undirected);
- Decision trees (yes, this is how trees look like, when turned into a bayesian network)

- A multivariate gaussian distribution is an undirected graphical model: the (blocks of) zeroes in the inverse of the variance matrix correspond to edges removed from the clique formed on the variables

- A multivariate gaussian distribution is a directed graphical model, the Choleski matrix yielding a “tree”, its zero entries pruning it;
- Principal component analysis (PCA):

- Factor Analysis (FA):

This chapter also mentions GMTK (graphical model toolkit), “open source” but with no source code available (not under active development).

Introduction to Monte Carlo methods D.J.C. MacKay

A presentation of *importance sampling*, *rejection sampling*, *Gibbs sampling* and the *Metropolis algorithm*, with some of their improvements: *hybrid Monte Carlo* (augment the state space with momentum variables), *overrelaxation* (in Gibbs sampling, do not sample from the conditional distribution, but bias it away from the current value), *simulated annealing*.

An introduction to MCMC for machine learning C. Andrieu et al. Machine Learning (2003)

Concise presentation of MCMC (Markov Chain Monte Carlo), terser than Liu’s book, with insightful pictures to represent *rejection sampling*

and *particle filters*.

Graphical models and their role in databases A. Deshpande VLDB 2007 Tutorial

A *graphical model* is a decomposition of a joint distribution on many (typically millions) variables as a product of distributions on fewer (two or three) variables.

In a *directed graphical model* or *bayesian network*, the decomposition is described by a directed acyclic graph (DAG), and the factors, called *potentials*, are conditional probabilities:

$$p(x_1, \dots, x_n) = \prod_x p(x | \text{parents}(x)).$$

In an *undirected graphical model* or *Markov random field* (MRF), the decomposition is described by the *cliques* (complete subgraphs) of a graph, and the potentials need not be probabilities (hence the need for the normalization factor Z):

$$p(x_1, \dots, x_n) = \frac{1}{Z} \prod_{C \text{ Clique}} \psi_C(x_C).$$

Those directed or undirected graphs model *conditional independence* relations between sets of variables.

One can then compute marginal probabilities or the most likely labels of the remaining variables:

$$p(x_B) = \int p(x_A, x_B) dP_B$$

$$x_B | x_A = \underset{x_B}{\text{Argmax}} p(x_A, x_B).$$

Inference on a chain is easy:

$$\begin{aligned} p(x_5) &= \sum_{x_1, x_2, x_3, x_4} p(x_1, x_2, x_3, x_4) \\ &= \sum_{x_1, x_2, x_3, x_4} p(x_1) p(x_2 | x_1) p(x_3 | x_2) p(x_4 | x_3) p(x_5 | x_4) \\ &= \sum_{x_1} p(x_1) \sum_{x_2} p(x_2 | x_1) \sum_{x_3} p(x_3 | x_2) \sum_{x_4} p(x_4 | x_3) p(x_5 | x_4) \\ &= \sum_{x_1} p(x_1) \sum_{x_2} p(x_2 | x_1) \sum_{x_3} p(x_3 | x_2) \underbrace{\sum_{x_4} p(x_4 | x_3) p(x_5 | x_4)}_{B_3(x_3)} \\ &\quad \underbrace{\sum_{x_2} p(x_2 | x_1) \sum_{x_3} p(x_3 | x_2) B_3(x_3)}_{B_2(x_2)} \\ &\quad \underbrace{\sum_{x_1} p(x_1) B_2(x_2)}_{B_1(x_1)} \end{aligned}$$

This can be generalized to simply-connected graphs, under the name *variable elimination algorithm*: e.g., for a hidden markov model (HMM), this is the *Viterbi algorithm*.

For more a general directed acyclic graph, just consider its *junction tree* (some articles claim this is an approximate algorithm, others (this one) that it is exact but NP-hard):

- Form the *moral graph*: join the parents of each node and forget the orientation;
- Triangulate the graph;
- The junction tree has vertices the maximal cliques of the triangulated (or *chordal*) graph and edges their separators.

But this is NP-hard, because the cliques can be very large: you can try with approximate junction trees, whose nodes are arbitrary clusters in the triangulated graph and use *loopy belief propagation* (not detailed) if loops arise. When all else fails, MCMC (Gibbs) sampling still works.

Depending on the application, the structure of the graph can be imposed or learnt (this is NP-hard); similarly, the parameters can be imposed (from domain knowledge) or learnt.

A time dimension can be added: for instance, the hidden variable model

becomes a Kalman filter

or more general *dynamic bayesian networks* (DBN) – this example is only partially oriented (this is called a *chain graph*)

General applications include:

- Error correcting codes: *turbo codes*;
- Medical diagnostic: QMR (Quick medical reference);
- Vision (Potts model or, for binary variables, Ising

model).

Database-specific applications include:

- Approximate aggregate over some of the many columns of a table (*i.e.*, marginal of the joint distribution of the columns);
- Estimate intermediate result sizes (e.g., that of `income>90 000` and `homeowner=yes`) for query plan optimization;
- Join uniformity estimation (how likely is a tuple from one relation to join with tuples from another);
- *Probabilistic relational models* (PRM, sometimes called *statistical relational models*), to extend or replace the relational model to represent uncertainties in the data;
- Record matching;
- Deduplication (with a logistic regression or a support vector machine (SVM), this can end up as a simple linear combination of the differences of the features of the records): duplication can appear in several columns and duplicates found in one can help find more in another (joint deduplication); deduplication can look for similarities in attributes (cells in a table) or records (rows).

Information extraction (e.g., named entity recognition (NER)) applications include:

- Protein and gene names from publications;
- Room attributes from hotel websites;
- Addresses and qualifications from resumes for human resources databases;
- Job postings in newsgroups;
- Emails in help centers;
- News monitoring.

Sensor networks present more challenges: the data are not only large, incomplete and imprecise, they are streaming (calling for dynamic bayesian networks), spacial (calling for added space dimensions, as we added time) and distributed – the part of the network describing the spacial distribution of the sensors can also describe the location of the databases and help devise distributed, *in-network* algorithms.

Representing and querying correlated tuples in probabilistic databases

P. Sen and A. Deshpande

Graphical models can be used to estimate tuple dependencies in a database, for query plan optimization.

Bayesian networks without tears

E. Charniak

AI Magazine (1991)

An early introductory article on bayesian networks, that allow to model probability distributions on many discrete variables without requiring “absurdly many numbers”: construct a directed acyclic graph (DAG)

whose vertices are the variables and such that two variables x and y are conditionally independent given a set of variables Z if and only if x and y are d -separated given Z , *i.e.*, there is no d -connecting path between them – that is a path whose every interior node is either (i) linear $\bullet \rightarrow \bullet \rightarrow \bullet$ or diverging $\bullet \rightarrow \bullet \leftarrow \bullet$ and not in Z , or (ii) converging $\bullet \rightarrow \bullet \rightarrow \bullet$ and in Z or with a descendant in Z (this notion can also be explained with the *ten rules of Bayes ball*.)

The computation of every node's belief is NP-hard in general – but linear for *polytrees* (simply-connected graphs).

Applications include: medical diagnostic (often with some decision theory), map learning, story understanding.

An introduction to graphical models K.P. Murphy (2001)

After giving a few examples of graphical models, such as factor analysis,

mixture of gaussians:

linear dynamic models (Kalman filters)

or Pearl's classical artificial intelligence example (whether the sprinkler is switched on depends on whether it is cloudy; when I come back the grass is wet: does it mean it rained?)

the article mentions, without any detail, inference algorithms, exact (variable elimination, with memoization (dynamic programming) if you need several marginals) or approximate (sampling (Monte Carlo) methods, variational methods (mean field approximation), loopy belief propagation (Pearl's algorithm, *e.g.*, used to decode *turbo codes*)).

Learning a bayesian network can be more or less complicated, depending on whether you know the graph structure (if not, you can greedily add edges) and on the presence of hidden variables – adding a hidden variable can simplify a graph:

Graphical models M.I. Jordan

Hierarchical bayesian models (as in BUGS) are a special case of graphical models.

The decomposition of the joint probability distribution

$$p(x_1, \dots, x_n) = \frac{1}{Z} \prod_C f_C(x_C)$$

can also be represented with the associated *factor graph*: a bipartite graph, whose round edges are the variables and square edges the potentials f_C .

Marginal distributions can be computed (exactly) with the variable elimination algorithm: just write the humongous sum and shift the summation signs as far right as possible; this amounts to choosing an *elimination order* on the variables – choosing the best one, that will lead to the fewest operations, is NP-hard. If you need several marginals, just add memoization to the elimination algorithms – this is the *sum-product algorithm*.

One can replace sums by maximums (simply because maximum and product still form a commutative semiring) to get the most probable value of a set of variables.

Sampling algorithms can be used for approximate computations: for Gibbs sampling, you just have to condition on the *Markov blanket* of a node (its neighbours in the unoriented case; its parents, children and co-parents in the oriented case).

Variational inference proceeds as follows:

- Formulate the problem as an optimization problem;
- “Perturb” it, to make it simpler, typically by adding or removing constraints (inner or outer approximation)
- Solve the new problem.

Applications include:

- Phylogenetic trees: graphical models can account for dependence between sites and lateral gene transfer (the graph structure is unknown: we can relax the requirement that it be a tree);
- Multi-locus linkage analysis in pedigrees (large pedigrees often contain many loops);
- Error correcting codes, such as *low-density parity check* (LDPC) codes, whose factor graphs look like

(the codes actually used are selected at random)

- Computational linguistics, with a host of generalizations of hidden Markov models (HMM): higher order Markov chains,

coupled HMM,

factorial HMM,

Recursive conditioning **A. Darwiche**

Cutset conditioning is an inference algorithm for graphical models that replaces the problem by several simpler ones, obtained by conditioning on (fixing the values of) a set of nodes (a cutset): this can discard loops.

Recursive conditioning applies the same idea but really cuts the graph in two at each step (you still have to choose the elimination order on the nodes). You can tune the amount of memoization used by the algorithm to control the tradeoff between its space and time complexity – it is an *any-time*, *any-space* algorithm.

Bounded RD **S. Monti and G.F. Cooper**

Another algorithm derived from *recursive decomposition* (cutset conditioning) that progressively refines interval bounds on marginal probabilities.

Inducing features of random fields **S. Della Pietra et al. (1995)**

The authors build *stepwise maxent models* as follows. Start with a graph, whose vertices are the variables to be included and whose edges represent time of spacial relations – or just take a complete graph. First add atomic features and then features of the form

atomic feature \times active feature

where the support of the candidate feature is connected in the underlying graph. To estimate the gain of a candidate feature, you can freeze the weights of the active ones: this allows the quick evaluation of thousands of features.

The article also presents the *improved iterative scaling* (IIS) algorithm.

A comparison of algorithms for maximum entropy parameter estimation **R. Malouf**

Presentation of the *improved iterative scaling* (IIS) algorithm.

Adaptive smoothing of digital images: the R package adimpro **J. Polzehl and K. Tabelow** **Journal of statistical software (2007)**

Image smoothing can be adaptive and edge-preserving: the intensity of the smoothing varies locally, with more smoothing in “homogeneous” (for some model) regions.

Interactive multivariate data analysis in R with the ade4 and ade4TkGUI packages **J. Thioulouse and S. Dray** **Journal of statistical software (2007)**

Just a GUI for the *ade4* package, that also provides factor analysis of a mixture of quantitative and qualitative variables (*dudi.hillsmith* and *dudi.mix* functions).

Numerical computing and graphics for the power method transformation using Mathematica **T.C. Headrick et al.** **Journal of statistical software (2007)**

The *power method* constructs a non-gaussian random variable Y from a gaussian one Z ,

$$Y = \sum_{k=0}^n c_k Z^k.$$

It is actually used in the other direction, to transform non-gaussian data into gaussian-looking data; the coefficients are chosen so as to match the cumulants of the data – this is a method of moments estimator.

This can be generalized to multivariate data, often as follows:

- Each Y_i is a polynomial function of a single gaussian variable Z_i , chosen to have the right cumulants;
- The Z_i are jointly gaussian, with a correlation matrix chosen to produce the second cross-moments of Y .

Efficient training of conditional random fields H. Wallach (2002)

Graphical models are a way of describing a joint distribution as a product of functions of fewer variables. For instance, with independent variables

$$p(x_1, \dots, x_n) = \prod_i p(x_i);$$

or with a Markov chain

$$\begin{aligned} p(x_1, \dots, x_n) &= p(x_n | x_{n-1}, \dots, x_1) \times \\ &\quad p(x_{n-1} | x_{n-2}, \dots, x_1) \times \\ &\quad \dots \\ &\quad p(x_2 | x_1) p(x_1) \\ &= p(x_n | x_{n-1}) p(x_{n-1} | x_{n-2}) \dots \\ &\quad \dots p(x_2 | x_1) p(x_1) \\ &= p(x_1) \prod_{i>1} p(x_i | x_{i-1}). \end{aligned}$$

More generally, an oriented graph (with no cycles), defines an *oriented graphical model* (or *bayesian network*) with the decomposition

$$p(x_1, \dots, x_n) = \prod_i p(x_i | x_{\text{parents}(i)}).$$

Those models suffer from the *label bias* problem (never explained clearly).

Undirected graphical models (also called *Markov random fields*) model conditional independence relations: there is one node for each variable and, given sets of variables A , B and C , A is independent of C given B iff B separates A and C , *i.e.*, iff each path from a vertex in A to a vertex in C contains a vertex from B . The *Hammersley–Clifford theorem* then says that the joint distribution can be written as

$$p(x_1, \dots, x_n) \propto \prod_{c \text{ maximal clique}} \psi_c(x_c)$$

where the factors ψ_c , called *potential functions*, need no longer be probability distributions.

Conditional random fields (CRF) are undirected graphical models for $p(y|x)$ (instead of $p(y, x)$), often with exponential potential functions

$$\psi_c(y_c | x) = \exp \sum_k \lambda_k f_k(c, y_c, x).$$

They do not exhibit the label bias problem.

The often-touted algorithms to fit maximum entropy models, iterative scaling and their generalized and improved variants (IS, GIS, IIS), that do not require the gradient to be computed, are outperformed by general optimization algorithms such as *quasi-Newton* methods (here called “variable-metric”) such as (limited memory) BFGS: indeed, the gradient and the parameters are proportional.

An introduction to conditional random field for relational learning C. Sutton and A. McCallum

Another, more detailed, review article on conditional random fields (CRF), with applications mostly in HLT/NLP (human language technology, natural language processing) names entity recognition (NER, *i.e.*, recognition of person or place names in texts), information extraction (IE, *i.e.*, automatic building of relational databases), POS (part-of-speech) tagging, shallow parsing (recognising groups of words in sentences), word sense disambiguation (WSD), etc.

The authors also model long-distance dependencies with a *skip-chain CRF*.

Conditional random fields: probabilistic models for segmenting and labeling sequence data

J. Lafferty et al.
Proceedings of the international conference
on machine learning (2001)

The initial article about conditional random fields (CRF) and maximum entropy Markov models (MEMM): prefer that by C. Sutton and A. McCallum, above.

Unsupervised statistical models for general object recognition P. Carbonetto (2001)

Graphical models can also be used in image analysis, to align regions of an image (obtained by some segmentation algorithm) with human-provided annotations, and then predict those annotations.

One can neglect long-range dependencies by replacing likelihood

by pseudo-likelihood

Graphical models are usually estimated by *iterative scaling* (see somewhere below) or by heuristic algorithms such as *belief propagation*: form the *junction tree* of the graph, *i.e.*, the graph whose vertices are the maximum cliques and whose edges are their separators (it is a tree iff the graph is chordal: triangulate it first); and propagate beliefs as for a Markov chain.

The article also contains a clear (and correct – many people still think it is a data imputation algorithm) explanation of the *expectation-maximization* (EM) algorithm, to estimate a model with hidden or missing values:

- In the E-step, estimate the distribution of hidden|observed; if the hidden variables are discrete, you compute their frequency table; if the hidden variables are jointly gaussian, you compute their mean and variance; often, there is often no actual computation at this step, the distribution is just a formula that will be used in the next step;
- In the M-step, consider the joint distribution

observed, hidden|parameter,

integrate out the hidden variables using the distribution from the E-step, and maximize the corresponding expected log-likelihood; you may want to add a prior on the parameters to avoid overfitting;

- Repeat ad libidum.

A simple introduction to maximal entropy models for natural language processing **A. Ratnaparkhi (1997)**

Given a pair of discrete random variables $z = (x, y)$ and a data sample, we want to estimate the probability distribution $P(z)$ – but the random variables x and y have so many possible values (y can be the part-of-speech (pos) of a word and x the word and its context) that even with a large dataset, not all (x, y) combinations are observed.

The maximum entropy (maxent) estimator is the probability distribution with the largest entropy among those “compatible” with the data. One selects *features* $z \mapsto f_i(z)$ (for instance, boolean indicator that the word has a given prefix or is preceded by a given word) and ask that their expected value equal their observed mean. In other words, a maximum entropy estimator is an underdetermined generalized method of moments (GMM) estimator; it is the solution of a constrained optimization problem.

It can be shown that that estimator is

$$\left\{ \operatorname{Argmax}_{p \in P} H(p) \right\} = \left\{ \operatorname{Argmax}_{p \in Q} L(p) \right\} = P \cap Q$$

where

$$P = \{ p : \forall i \ E_p f_i = E_{\tilde{p}} f_i \}$$

p : model probabilities

\tilde{p} : observed probabilities

$$Q = \left\{ p : p(z) \propto \prod \alpha_i^{f_i(z)}, \alpha_i > 0 \right\}$$

$$H(p) = \sum p(z) \log p(z) \quad \text{entropy}$$

$$L(p) = \sum \tilde{p}(z) \log \tilde{p}(z) \quad \text{log-likelihood,}$$

i.e., the maximum entropy estimator is also the maximum likelihood estimator for probability distributions of the form $p(z) \propto \prod \alpha_i^{f_i(z)}$; these are sometimes called *log-linear models*, *Gibbs models*, *exponential models*, *multinomial logit models*.

This duality between maximum entropy and maximum likelihood leads to the *generalized iterative scaling* (GIS) algorithm to find the α_i . It assumes that

$$\forall z \quad \sum_i f_i(z) = C$$

$$\forall z \quad \exists i \quad f_i(z) = 1$$

$$\forall i \quad \forall z \quad f_i(z) \geq 0$$

and proceeds as follows

$$\alpha_i^{(0)} = 1$$

$$\alpha_i^{(n+1)} = \alpha_i^{(n)} \left(\frac{\tilde{E} f_i}{E^{(n)} f_i} \right)^{1/c}$$

$$E^{(n)} f_i = \sum_x p^{(n)}(z) f_i(x)$$

$$\tilde{E} f_i = \sum_x \tilde{p}(z) f_i(z) = \frac{1}{|\text{Sample}|} \sum_{x \in \text{Sample}} f_i(z).$$

While \tilde{E} is easy to compute (it is just a sum over the sample), $E^{(n)}$ usually involves an exponentially large number of terms; if $z = (x, y)$, it can be approximated as a sum over the sample $\{(x_1, y_1), \dots, (x_N, y_N)\}$:

$$E^{(n)} f_i \approx \sum_j \tilde{p}(x_j) \sum_y p^{(n)}(y|x_j) f_i(y, x_j).$$

Reduction of maximum entropy models to hidden Markov models **J. Goodman**

Maximum entropy models can be reformulated as hidden Markov models (HMM): just turn the formula in the GIS (generalized iterative scaling) algorithm into a graph (the HMM depends on the sample, though).

A gaussian prior for smoothing maximum entropy models **S.F. Chen and R. Rosenfeld (1999)**

To avoid overfitting a maximum entropy model, one can:

- Add more constraints (it is already a constrained optimization); but even reasonable constraints such as forbidding zero probabilities can make the problem unfeasible;
- Shrink the n -gram model towards the $(n - 1)$ -gram model, *i.e.*, avoid zero probabilities in $p(w_{n+1}|x_n \cdots w_1)$ by shrinking it towards $p(w_{n+1}|x_n \cdots w_2)$;
- Replace the constrained optimization

$$\text{Minimize } D(q||p_{\text{unif}}) \text{ such that } U(q) = 0$$

by a penalized entropy maximization

$$\text{Minimize } D(q||p_{\text{unif}}) + \tau U(q)$$

where $U(q)$ is often a weighted average of the squared constraint breaches

$$U(q) = \sum_i \frac{1}{\sigma_i^2} \left(\sum_x q(x) f_i(x) - \tilde{p}(x) f_i(x) \right)^2;$$

- Replace the constraints $E f_i = \tilde{E} f_i$ by fat constraints $|E f_i - \tilde{E} f_i| < \varepsilon$; this is equivalent to an entropy penalized by a step function;
- Apply the smoothing to the equivalent maximum likelihood problem: this can be interpreted as a gaussian prior.

Maximum entropy estimation in economic models with linear inequality restrictions

R.C. Campbell and R.C. Hill

You can define a maximum entropy estimator for linear regression, *i.e.*, the estimation of β in $y = x\beta + \varepsilon$, as follows: impose $\beta_i \in [\beta_i^{\min}, \beta_i^{\max}]$, and write it as $\beta_i = p_{1i}\beta_i^{\min} + p_{2i}\beta_i^{\max}$ where $p_{1i} + p_{2i} = 1$; p can be interpreted as a probability; proceed similarly for the error terms (some suggest $\varepsilon_j \in [-3\hat{\sigma}, 3\hat{\sigma}]$, where $\hat{\sigma}$ comes from some other estimator); solve the optimization problem

$$\begin{aligned} &\text{Maximize } \sum p \ln p \\ &\text{such that } y = x\beta + \varepsilon \\ &\quad p_1 + p_2 = 1. \end{aligned}$$

This can also be used for the general linear model (GLM).

Maxent models, conditional estimation and optimization

D. Klein and C. Manning
HLT-NAACL, ACL (2003)

Generative models (or joint models, such as naive Bayes classifiers, hidden Markov models (HMM), probabilistic context-free grammars, n -gram models) predict joint probabilities $p(y, x)$, while *discriminative models* (or conditional models, such as logistic regression or support vector machines (SVM) – logistic regression is actually the conditional analogue of the naive Bayes

classifier) only predict conditional probabilities $p(y|x)$. Since the latter do not have to predict the marginal distribution $p(x)$, they usually perform better.

An *exponential* (or log-linear, or maxent) model is a model of the form

$$p_\lambda(y|x) \propto \exp \sum_i \lambda_i f_i(x, y)$$

where the f_i are called *features* (often binary variables such as “the word is capitalized”, “the previous word is a verb”, “the word is ‘car’”, “the word ends in ‘-ic’”, “the word starts with ‘re-’”, “the word is in a dictionary of place names”, etc. – often, there are hundreds of thousands of them, but only a handful are non-zero).

Those models tend to overfit the data and need to be smoothed, e.g., with a prior (adding virtual data or dropping features with low counts are bad ideas – actually, including features that are always zero in the training set makes wrong answers less likely; along the same idea, redundant features, such as 2-grams and 1-grams, are an insurance against the lack of data).

This presentation also clearly presents general-purpose optimization algorithms: line search, gradient ascent (a line search in the direction of the gradient; the search path is then a succession of orthogonal segments), *conjugate gradient* (modify the gradient towards the previous search direction to avoid those right angles), Lagrange multipliers for constrained optimization.

Bivariate option pricing using dynamic copula models

R.W.J. van den Goorbergh et al.

Insurance mathematics and economics (2005)

Rainbow options, *i.e.*, options on several underlyings (call-on-max, put-on-min, call-on-min, put-on-max) can be priced by modelling the (two) underlyings as follows:

- Each underlying follows a GARCH process with gaussian innovations;
- The dependence between the innovations is described by a copula, from a family of copulas parametrized by Kendall’s τ , depending on time:

$$\tau_t = \gamma_0 + \gamma_1 \log \text{Max}(\sigma_{1,t}^2, \sigma_{2,t}^2).$$

Wouldn’t it be better to model dependence using *cointegration* instead of copulas?

One size fits all

Part 1: An idea whose time has come and gone

Part 2: Benchmarking results

M. Stonebraker et al. (2005, 2007)

Traditional database management systems (DBMS) try to provide a single solution to all your data problems; but now that some of those problems have received more attention, specialized systems outperform them by one or two orders of magnitude:

- Traditional DBMS cater to *datawarehousing* with bitmap indices (instead of B-trees), materialized views and optimizer tactic for star schema queries are outperformed by *column stores* (Vertical, MonetDB), that do not retrieve whole rows, allow for compression and better indexing or sorting; and remember that the TPC-H datawarehouse benchmark is biased to overlook problems of generalist DBMS...
- Traditional DBMS tackle *stream processing* (monitoring traffic congestion and suggesting alternative routes; tracking military vehicles and personnel; financial feeds) in a 2-stage process (update the database, then use the data); furthermore log-based recovery and synchronization needs do not fit well in a real-time setup; Stream engines (Streambase, Coral8, Apama) do not have that legacy;
- Text search (Google with GFS, BigTable and MapReduce);
- Scientific databases require specialized storage (dense or sparse matrices or higher dimensional arrays, compression (MPEG, etc.)) and optimized operations on them (matrix multiplication, pivot, interpolation, concatenation, approximate search for a small subarray); some of the authors are developing such a system, called ASAP.

***The end of an architectural era:
It's time for a complete rewrite***

**M. Stonebraker et al
VLDB 2007**

Traditional DBMS are also beaten in the OLTP arena (they authors' *H-store* prototype wins the TPC-C benchmark by almost two orders of magnitude):

- Log-based recovery goes against high availability (HA);
- Dynamic locking is outperformed by optimistic transactions (run the transaction as if there were no locking problems, unroll if and when a problem occurs – this is called transactional memory in multithreaded programming languages), especially with short-lived OLTP transactions;
- Traditional DBMS were designed at a time when data could not fit in memory: *main memory* databases can outperform them;
- The multithreading overhead is not needed, since OLTP transactions are extremely short (larger transactions should be sent to a different, OLAP system);
- Traditional DBMS are optimized for a shared memory or shared disk environment, not shared-nothing grids (with peer-to-peer communications), which provide higher reliability and hot upgrades;
- Traditional DBMS were designed in a time when hardware was expensive and people cheap and therefore require a lot of human fine-tuning: self-tuning, self-healing – self-everything – systems are eventually cheaper;
- JDBC increases the overhead and complicates or hides the program logic.

It's time to stop calling circuits "hardware"

F. Vahid (2007)

The software-hardware frontier is getting blurrier: sequential programming, event-based programming, data flow programming, *FPGA* (field programmable gate array, *i.e.*, "programmable chip") cover the whole spectrum from *temporal modelling* (formerly software) to *spacial modelling* (formerly hardware). FPGAs are still underused – some people talk of using them to speed up financial computations.

***ks: Kernel density estimation
and kernel discriminant analysis
for multivariate data in R***

**T. Duong
Journal of statistical software (2007)**

A *kernel density estimate* if

$$\hat{f}_H(x) = \frac{1}{n} \sum_i K_H(x - X_i)$$

where X_i are the observations,

$$K_H = |H|^{-1/2} K(H^{-1/2}x),$$

K is a kernel (such as $K(x) = (2\pi)^{-d/2} \exp(-\frac{1}{2}x'x)$, its choice is not crucial), and H is a positive definite matrix.

The article explains how to choose H , beyond the naive choice of "sphering the data" (replacing X by $(\text{Var } X)^{-1/2}X$ and choosing a diagonal H , check the **sm** and **KernSmooth** packages), based on the (*asymptotic*) *mean integrated square error*

$$\text{MISE}(H) = E \int_{\mathbf{R}^d} (\hat{f}_H(x) - f(x))^2 dx.$$

***Self- and super-organizing maps in R:
the kohonen package***

**R. Wehrens and L.M.C. Buydens
Journal of statistical software (2007)**

To map a high-dimensional data set to two dimensions, one can use:

- Principal component analysis (PCA);
- Multidimensional scaling (MDS): similar to PCA, but starts directly from the distance matrix, not the coordinates – there are also non-linear variants;
- self-organizing maps (SOM): a variant of the k -means algorithm that takes into account proximity between cluster centers.

SOM can also be used for supervised classification: learn two maps in parallel, one with the predictive variables, the other with the variable(s) to predict; often each will have its own distance and the algorithm will use a linear combination of these. *Super-organizing maps* generalize this to more than two layers.

Copulas: a personal view
P. Embrechts

A review article on current topics, uses, misuses, problems and workarounds in copula theory, with interesting references:

- Copulas were designed to study continuous variables (or rather: variables with continuous margins): with non-continuous variables, everything that could possibly go wrong will;
- Fitting a copula to your data is only half the story: do not forget goodness of fit tests!
- Correlation is not always a good measure: given two continuous marginal distributions F_1 and F_2 , the set of attainable correlations is a closed interval that can be much smaller than $[-1, 1]$ – e.g., with $\text{LN}(0, 1)$ and $\text{LN}(0, 4^2)$, it is $[-2.5 \cdot 10^{-4}, 1.4 \cdot 10^{-2}]$...
- There is no good answer to the question “which copula to use?”: at the very least, you should have a look at elliptic and extreme value copulas, but do not expect them to suffice – our copula catalogue is still mostly empty (some would even say useless);
- Even if you do not know which copula to choose, there is hope: given several sources of risk X_1, \dots, X_n (market risk, operational risk, etc.), the knowledge of their marginal distribution, and a risk aggregation function $\psi(X_1, \dots, X_n)$, we can find bounds of this aggregated risk

$$\psi_{\min} \leq \psi(X_1, \dots, X_n) \leq \psi_{\max}$$

For instance, $\inf\{\text{VaR}_\alpha(\sum X_i), X_i \sim F_i\}$; one sometimes also assumes properties for the copula, instead of optimizing on the set of all copulas.

A primer on copulas for count data
C. Genest and J. Nešlehová
Astin bulletin (2007)

The definition of a copula assumes that the margins are continuous: otherwise, the “copula function” $C(u, v)$ is no longer uniquely defined – and even worse, naive definitions are never a copula. Given two discrete random variables X and Y , one can consider the *set* of copulas C such that

$$\forall x, y \quad F_{X,Y}(x, y) = C(F_X(x), F_Y(y)).$$

(One of those copulas has good properties, though: the *bilinear extension*, i.e., the simplest piecewise affine, continuous copula.)

Even if the variables are independent of monotonic-dependent (this notion becomes trickier than functional monotonic dependence), this set is rather large: one can compute pointwise bounds of those copulas; these lead to bounds on Spearman’s correlation and Kendall’s τ (the difference between those bounds is at least one). The definitions of Kendall’s τ and Spearman’s ρ do not account for ties; in particular, depending on the marginal distribution, they may not span all of $[0, 1]$; they can be replaced by Kendall’s τ_b

$$\tau_b(X, Y) = \frac{\tau(X, Y)}{\sqrt{P(X_1 \neq X_2)P(Y_1 \neq Y_2)}}$$

and Spearman’s grade correlation coefficient (many other concordance measures have been suggested); dependence in the copula (positive quadrant dependence, left tail dependence, positive likelihood ratio dependence) leads to dependence in the initial variables (for the bilinear extension, this is even equivalent).

The joy of copulas:
bivariate distributions with uniform marginals
C. Genest and J. MacKay
American Statistician (1986)

Elementary (but interesting) exercises leading to the definition of archimedean copulas, an example of a singular distribution with smooth margins

$$\phi(t) = (1 - t)^\alpha, \quad \alpha \geq 1$$

$$C(x, y) = \phi^{-1}(\phi(x) + \phi(y)),$$

and a “geometric” interpretation of Kendall’s τ for archimedean copulas

$$\tau = 4 \int_0^1 \frac{\phi(t)}{\phi'(t)} dt + 1.$$

Copulas: tales and facts
T. Mikosch (2005)

Copulas do not really fit in the theory of stochastic processes and time series analysis – this is worrying, since the banking and finance industry, responsible for the *copula epidemic*, mainly use them in this context.

More work needs to be done on copula estimators and goodness of fit tests (Should we estimate margins and copula simultaneously? Should we use a parametric fit of the margins or their empirical distribution to fit the copula? Does a good fit for the margins and for the copula lead to a good fit for the multivariate distribution?).

The effects of increasing dimension (on, say, the quality of copula estimators) remains largely unstudied: most authors stick to the 2-dimensional case. For stochastic processes, you would even need infinite-dimensional copulas.

Our catalogue of copulas is still mostly empty: archimedean copulas are rarely meaningful in practical situations, elliptic copulas are bad at measuring “tail dependence” (I use quotes because the notion of upper and lower tail dependence is limited to the 2-dimensional case), there is no *canonical* multivariate distribution on which to build an extreme value copula (the Gumbel copula is popular, but is far from being the only choice).

The author also disagrees with the need to transform the margins, and with the choice of a uniform distribution.

**Discussion of
“copulas: tales and facts” by T. Mikosch
C. Genest and B. Rémillard
Extremes (2006)**

Harsh criticism of the previous article.

**Copulas: tales and facts – rejoinder
T. Mikosch**

After summarizing the responses to the article (e.g., someone mentioned that pseudo-likelihood copula estimators (use the empirical distribution of the marginals to fit a parametric copula) are inefficient), the author also clarifies what he means by “dependence structure” for stochastic processes: the whole distribution, which is determined by all the finite-dimensional marginals – this includes the 1-dimensional margins and therefore leads to large misunderstandings with copula specialists.

**Everything you always wanted to know about
copula modelling but were afraid to ask
C. Genest and A.-C. Favre
Journal of hydrologic engineering (2007)**

The following graphics can help modelling with copulas:

- Scatterplot of ranks, *i.e.*, plot of the sample copula;
- The Chi-plot plots the pairs (λ_a, χ_i) where

$$\begin{aligned} H_i &= \frac{\#\{j \neq i : X_j \leq X_i, Y_j \leq Y_i\}}{n-1} \\ F_i &= \frac{\#\{j \neq i : X_j \leq X_i\}}{n-1} \\ G_i &= \frac{\#\{j \neq i : Y_j \leq Y_i\}}{n-1} \\ \chi_i &= \frac{H_i - F_i G_i}{\sqrt{F_i(1-F_i)G_i(1-G_i)}} \\ \tilde{F}_i &= F_i - \frac{1}{2} \\ \tilde{G}_i &= G_i - \frac{1}{2} \\ \lambda_i &= 4 \operatorname{sign}(\tilde{F}_i \tilde{G}_i) \operatorname{Max}(\tilde{F}_i^2, \tilde{G}_i^2); \end{aligned}$$

large values of λ are outliers, large values of χ signal non-independence;

- The *K-plot* is the quantile-quantile plot of the H_i versus the distribution coming from independent variables (on this plot, you can also draw the curve obtained with perfect positive dependence).

The article also reviews a few copula estimators:

- If you are fitting a copula from a 1-parameter family, you can choose this parameter so as to produce the observed Kendall’s τ or Spearman’s ρ (this is a method of moments estimator); this can lead to actual tests;
- Maximum pseudo-likelihood estimators modify the log-likelihood

$$\sum_i \log c_\theta(FX_i, GX_i)$$

with the empirical marginal distributions

$$\sum_i \log c_\theta \left(\frac{R_i}{n+1}, \frac{S_i}{n+1} \right)$$

where R_i and S_i are the ranks of X_i and Y_i ;

- 2-step estimators: first estimating the marginal distributions, then the copula (this is another pseudo-likelihood);
- Kernel (non-parametric) estimators.

When modelling data with copulas, people often forget to check how good the fit is: the article presents an actual test; some graphics can also help:

- Compare the plot of the sample copula and that of simulated data from the fitted copula;
- The quantile-quantile plot of

$$\hat{C} \left(\frac{R_i}{n+1}, \frac{S_i}{n+1} \right)$$

against $C_{\hat{\theta}}(U, V)$ where $(U, V) \sim C_{\hat{\theta}}$.

The authors also remark that most measures of dependence are of the form

$$\iint J(u, v) dC(u, v)$$

where J can be chosen optimally if you know the family of copulas your data comes from; $J(u, v) = uv$ gives Spearman’s ρ , $J(u, v) = 4C(u, v) - 1$ gives Kendall’s τ , $J(u, v) = \Phi^{-1}(u)\Phi^{-1}(v)$ gives the van der Waerden statistic.

Also note that, for gaussian distributions, correlation, Spearman’s ρ and Kendall’s τ are very similar.

**Correlation and dependence in risk
management: properties and pitfalls
P. Embrechts et al. (1999)**

Correlation is a misleading measure of dependence for non-elliptic distributions, such as derivative returns in finance or loss in insurance; the article lists some of those fallacies:

- Marginal distributions and correlation need not determine the joint distribution, in particular, the value at risk (VaR) of linear portfolios is not determined by the marginal distributions and the correlation;
- Given the marginal distributions, not all correlations in $[-1, 1]$ are attainable;
- The worst-case VaR (quantile) of $X + Y$ need not occur when $\rho(X, Y)$ is maximal, *i.e.*, when X and Y are comonotonic (the variance will be maximal, but not the quantiles): the best you can say is

$$\operatorname{VaR}_\alpha(X + Y) \leq \inf_{C_\ell(u, v) = \alpha} F_1^{-1}(u) + F_2^{-1}(v);$$

this is not surprising since VaR is not a subadditive risk measure; consequently, low correlation need not mean high diversification.

The article also recalls:

- the link between correlation and regression

$$\rho(X, Y) = \frac{\text{Var } Y - \min_{a,b} E[(Y - (a + bX))^2]}{\text{Var } Y}$$

$$b = \frac{\text{Cov}(X, Y)}{\text{Var } X}$$

$$a = E[Y] - bE[X].$$

- other measures of dependence: rank correlation, Schweizer and Wolff

$$\rho_S(X, Y) = 12 \iint (C(u, v) - uv) du dv$$

$$\delta_1(X, Y) = 12 \iint |C(u, v) - uv| du dv$$

$$\delta_2(X, Y) = \left(90 \iint |C(u, v) - uv|^2 du dv \right)^{1/2}$$

$$\delta_3(X, Y) = 4 \sup_{u,v} |C(u, v) - uv|$$

comonotonicity, positive quadrant dependence

$$\forall x, y \quad P[X > x, Y > y] \geq P[X > x]P[Y > y],$$

positive association

$$\forall g_1, g_2 \text{ increasing}$$

$$E[g_1(X, Y)g_2(X, Y)] \geq E[g_1(X, Y)]E[g_2(X, Y)].$$

If all correlations are either $\rho_{\min}(F_i, F_j)$ or $\rho_{\max}(F_i, F_j)$ and satisfy some compatibility conditions, then the joint distribution is uniquely determined; it is called an *extremal distribution*.

It is not known if all linear correlation matrices are rank correlation matrices, but a sufficient condition is that the matrix of the $2\sin(\pi\rho_{ij}/6)$ be a linear correlation matrix (this is then the correlation matrix of the gaussian distribution with the prescribed rank correlation matrix, which you can use in simulations).

The article does not tackle serial and cross-correlation and estimators (of correlation, rank correlation and copulas).

On Blest's measure of rank correlation
C. Genest and J.F. Plante
Canadian journal of statistics (2003)

Many measures of concordance, for a copula C , are of the form

$$\int_{[0,1]^2} f(u, v) dC(u, v).$$

For instance:

$$\rho(X, Y) = 12 \int_{[0,1]^2} uv dC(u, v) - 3$$

$$\tau(X, Y) = 4 \int_{[0,1]^2} C(u, v) dC(u, v) - 1$$

This article examines the asymptotic distribution of Blest's measure of rank correlation, an estimator of

$$\nu(X, Y) = 2 - 12 \int_{[0,1]^2} (1 - u^2)v dC(u, v)$$

and suggest to symetrize it as

$$\xi(X, Y) = \frac{\nu(X, Y) + \nu(Y, X)}{2}$$

$$= -4 + 6 \int_{[0,1]^2} uv(4 - u - v) dC(u, v).$$

Correlation in a bayesian framework

A. DasGupta et al.

Journal of multivariate analysis (2000)

Asymptotic distribution of $\text{Cor}(\theta, \hat{\theta})$, where θ is a parameter in a model (seen as a random variable) and $\hat{\theta}$ an estimator of θ .

A characterization of quasi-copulas

C. Genest et al.

Journal of multivariate analysis (1999)

A *quasi-copula* is a function $Q : [0, 1]^2 \rightarrow [0, 1]$ so that for each track B (a path from $(0, 0)$ to $(1, 1)$, non-decreasing in both coordinates) there exist a copula C_B that coincides with Q on B .

Not all quasi-copulas are copulas.

Forecasting multifractal volatility

L. Calvet and A. Fisher (2001)

The *multifractal model of asset returns* (MMAR) is a brownian motion B compounded with a random trading time θ

$$\log P_t - \log P_0 = B[\theta(t)]$$

where the trading time θ is the cumulative distribution of a *multifractal measure*.

Given two sequences of positive real numbers m_0 and m_1 such that

$$\forall t \quad m_{0,t} + m_{1,t} = 1,$$

define a sequence of probability measures on $[0, 1]$ as follows: $\mu_0 = \lambda$ is the Lebesgue measure; μ_1 has weight $m_{0,1}$ on $[0, \frac{1}{2})$ and weight $m_{1,1}$ on $[\frac{1}{2}, 1]$; μ_2 splits each of the intervals $[0, \frac{1}{2})$ and $[\frac{1}{2}, 1]$ in two, and assigns a fraction $m_{0,2}$ (resp. $m_{1,2}$) to the left (resp. right) one; etc. In formulas,

$$\mu_n = \left(\sum_{i_1=0}^1 \cdots \sum_{i_n=0}^1 m_{i_1,1} \cdots m_{i_n,n} \mathbf{1}_{[x, x+2^{-n}]} \right) \lambda$$

where $x = \sum_{k=1}^n i_k 2^{-k}$. This is a *binomial measure* on $[0, 1]$. Instead of splitting each interval in two, one can uniformly split them into b subintervals. Instead of using deterministic sequences $m_{k,t}$, one can use a discrete random variable M taking values m_0, \dots, m_{b-1}

with probabilities p_0, \dots, p_{b-1} : this is a *random multifractal measure*. One can ask that the weight be exactly preserved at each step or only on average: $E[M] = 1/b$.

The *Poisson multifractal* also randomizes the splitting points (with a Poisson process). The authors have yet to study option pricing and stochastic portfolios in this context.

***Multifractality in asset returns:
theory and evidence***

L. Calvet and A. Fisher (1996, 2001)

Earlier article on the MMAR.

***Volatility comovement:
a multifrequency approach***

L.E. Calvet et al. (2004)

Multifractal volatility can be generalized to bivariate time series; the model can be estimated via maximum likelihood (in closed form) or a particle filter.

***Theoretical foundations of asset allocation and
pricing models with higher-order moments***

E. Jurczenko and B. Maillet (2006)

A random variable X D_4 -dominates Y if it is preferred over Y for each utility function in

$$D_4 = \{U : \mathbf{R} \rightarrow \mathbf{R} : U' > 0, U'' < 0, U''' > 0, U'''' < 0\}.$$

(This chapter was not interesting.)

***Community structure
in social and biological networks***

M. Girvan and E.J. Newman (2001)

To the usual stylized facts of social networks

- Small world: the average distance between two nodes is small, often logarithmic in the number of vertices;
- Power law degree distribution;
- Network transitivity (or clustering): the probability that two nodes are connected is higher if they are connected to a third, measured by the *clustering coefficient*

$$C = 3 \frac{\text{Number of triangles}}{\text{number of connected triples of vertices}}$$

the authors add one more: those graphs can be partitioned into communities. The following algorithm performs better than hierarchical clustering. The *betweenness* of an edge is the number of shortest paths that run through it; if there are several shortest paths between two nodes, they are given the same weight so that those weights sum up to one. Communities appear when you remove edges with the highest betweenness.

***A general approach to integrated risk
management with skewed, fat-tailed risks***

J.V. Rosenberg and Tl. Schuermann (2005)

Recipes to aggregate different sources of risk (market, credit, operational), measured by the value-at-risk (VaR), without really falling in the gaussian trap.

***Bayesian analysis for penalized spline
regression using WinBUGS***

C.M. Crainiceanu et al.

Journal of statistical software (2005)

Penalized models can be seen as bayesian models (indeed, the penalty can be turned into a prior distribution). As a result, one can tweak bayesian inference software (e.g., Bugs, Jags) into fitting penalized models.

***A software tool for the exponential power
distribution: the normalp package***

A.M. Mineo and M. Ruggieri

Journal of statistical software (2005)

General error distributions (GED), aka *exponential power distributions* (EPD), aka normal distributions of order p , are a family of distributions generalizing the gaussian distribution and designed to be used as error distributions. They have three parameters: mean, shape ($p = 2$ for the gaussian, $p = 1$ for the Laplace and $p = \infty$ for the uniform distribution) and dispersion ($\sigma_p = (E|X - \mu|^p)^{1/2}$).

Along with the usual `d`, `p`, `q`, `r` functions, the package also provides an `lmp` function for regression with EPD errors.

EbayesThresh:

R programs for empirical Bayes thresholding

I.M. Johnstone and B.W. Silverman

Journal of statistical software (2005)

When fitting data with wavelets, we want most of the coefficients to be zero – to this end, we have to threshold them. This article suggests to model the coefficients as a mixture of a Dirac density in zero (coefficients to be thresholded) and a Laplace distribution (aka *double exponential*), to which noise has been added. They use bayesian methods to perform the thresholding.

This can be applied to other situations where you have a series of random variables, measured with noise, most of which are zero.

The same idea is also used for discrete distributions, e.g., with the *zero-inflated Poisson distribution* (ZIP) – check the `zicounts` package in R.

A boosting approach for automated trading

G. Creamer and Y. Freund

Workshop on data mining for business applications, KDD 2006

Monkeying with the goodness-of-fit test

G. Marsaglia

Journal of statistical software (2005)

To test if qualitative variables x_1, \dots, x_n are iid and follow a given distribution, one can:

- Look at $Q_1 = \sum \frac{(\text{observed} - \text{expected})^2}{\text{expected}}$;
- Look at the same thing, Q_2 , for pairs $(x_1, x_2), (x_2, x_3), \dots$;
- Look at $Q_2 - Q_1$.

A clue for cluster ensembles

K. Hornik

Journal of statistical software (2005)

What to do when a clustering algorithm is not stable.

A comparison of immune and genetic algorithms for two real-life tasks of pattern recognition

A.O. Tarakanov and Y.A. Tarakanov

Journal of unconventional computing (2005)

Immunocomputing (IC), *i.e.*, k -nearest neighbours after dimension reduction via singular value decomposition (SVD), perform better than neural nets, which perform better than genetic algorithms (GA) – on those datasets, chosen because IC was working on them.

Negative selection algorithm for aircraft fault detection

A. Dasgupta et al.

Negative selection algorithms (NSA) are just a k -nearest neighbours algorithm after a principal component analysis (PCA) and/or k -means dimension reduction step.

On-line negative databases

F. Esponda et al.

Negative selection (the immune system recognizes the self by storing information about the non-self) can obscure information and help design privacy-enhancing negative databases.

Squashing flat files flatter

W. DuMouchel et al.

Instead of adapting statistical methods to large datasets, you can make large datasets smaller: random sampling is an option, but *surrogate data* can perform better: cluster the data in a large number of clusters (k -means or simply bins, with a weight on each bin), examine the statistical properties of the cluster centers, *e.g.*, moments, and generate random (or non random) data with similar properties.

The caveat is that the “statistical properties” you replicate must capture the information you want.

Downside consumption risk and expected returns

V. Polkovnichenko (2006)

Yet another article showing that investors are averse to downside risk: with *rank-dependent expected utility* (RDEU), utility is weighted by *decision weights* which are transformations of the cumulative objective probabilities of ranked events – *cumulative prospect theory* is a special case of RDEU.

Equilibrium underdiversification and the preference for skewness

T. Mitton and K. Vorkink

Review of financial studies (2007)

Preference for skewness, *i.e.*, maximization of

$$E[X] - \frac{1}{2\tau} \text{Var } X + \frac{1}{3\phi} \text{Skew } X,$$

as with “Lotto investors”, explains underdiversified portfolios.

Opinion divergence and post-earnings announcement drift

K.L. Anderson et al. (2007)

Opinion divergence can be measured as

- The *Herfindhal* measure of divergence,

$$\text{HI} = \sum_{i=1}^N \left(\frac{V_i}{V_{\text{total}}} \right)^2$$

where V_i is the volume traded by market maker i on that day;

- The standardized unexplained volume (SUV), *i.e.*, standardized residual (on the day of interest) of the regression (over the past two months)

$$\text{volume} \sim \text{returns}_+ + \text{returns}_-$$

- The standardized price volatility (SPV), *i.e.*, the standardized residuals of the regression of the daily volatility against volume and returns.

On the interaction between ultra-high frequency measures of volatility

G.M. Gallo and M. Velucchi (2007)

Comparison of realized variance $\sum x_t^2$ and *bipower variance*

$$\sum |x_t x_{t-1}|$$

(the latter is supposed to be robust to jumps) in the context of *multiplicative error models* (MEM), *i.e.*, GARCH-like models used to model positive quantities (volume, duration, range, etc.): they are almost undistinguishable.

Neoclassical factors

L. Zhang and L. Chen (2007)

The Fama–French model can be replaced by a 3-factor model: market, investment/assets, earnings/assets; this also captures *momentum* effects.

***Asset based style analysis for equity strategies:
the role of the volatility factor***

D.E. Kuenzi and X. Shi

Journal of alternative investments (2007)

When trying to explain or replicate hedge fund returns, do not forget to include a volatility factor (calls and puts (the authors' advice), change in VIX, straddle, convertible bonds), lest you remain blind to all non-linear effects, such as Lo's "capital decimation" strategy.

Who moves stock prices? Monthly evidence

B. A. Ødegaard (2007)

Change in institutional ownership might help predict monthly returns.

***A better tool than Allen's relations for
expressing temporal knowledge in interval data***

F. Morchen

**Theory and practice of temporal data mining
(2006)**

Allen's relations between intervals, used in temporal reasoning (before, meets, overlaps, starts, finished, equals), are not *robust* enough for data mining. The *time series knowledge representation* (TSKR) uses a musical analogy (tones, chords, phrases) and only considers the interaction of participating intervals and accounts for noise.

Quantile trees for marketing

C. Perlich and S. Rosset

DMBA 2006

Quantile regression can be used to focus on customers with high growth potential.

***Adaptive event detection
with time-varying Poisson processes***

A. Ihler et al.

KDD 2006

(Bugs-like) graphical model example.

Data mining in the real world

F. Fogelman Soulié

Data mining is widely used for customer relation management (CRM), fraud detection, credit scoring, etc. and *extreme data mining*, *i.e.*, data mining in databases beyond 10TB, is starting to emerge. It is characterized by:

- Heterogeneous data;
- Poor data quality (missing values, outliers – or even "unlabeled data", *i.e.*, "massively missing values");
- Large volume (billions of rows, thousands of columns), that prevents the user from hand-choosing the variables and calls for *data duplication avoidance*;
- Fast model calibration (ideally hours, should be linear in the number of rows or columns);

- Automated model quality assessment (they use a robustness indicator, KR, from Vapnik's structural risk minimization theory);
- Real-time model application;
- Industrialization (we would say "productionalization") within the same project, not as a separate, long-term project;
- Model control (check deviations on the data distribution);
- Data mining standards (JDM, PMML) to export the results;
- Process control and workflow;
- Exploratory modeling (the end-user will want to *understand* the model);
- Predictive modeling;
- Unskilled users.

***A review of some semiparametric regression
models with application to scoring***

J.L. Berthet and V. Patilea

"Scoring" means predicting a binary variable, whose values are interpreted as "bad" ("default") or "good" ("non-default"); the problem is usually asymmetric: while the "good" observations are homogeneous, there are many ways of being "bad". Between parametric methods (logistic regression, linear discriminant analysis (LDA)) and non-parametric methods (*k*-nearest neighbours (kNN), classification trees, neural networks, support vector machines), one can also consider semiparametric methods, such as logistic generalized additive model (GAM):

$$P[\text{non-default}] = m_1(X_1) + \dots + m_n(X_n)$$

$$P[\text{non-default}] = m(\lambda_1 X_1 + \dots + \lambda_n X_n)$$

This is very similar to a dimension reduction before the logistic or GAM reduction, but the dimension reduction step takes the variable to predict into account (this sounds like the difference between principal component regression (PCR) and partial least squares (PLS)).

Stochastic skew in currency options

P. Carr and L. Wu

Journal of financial economics (2007)

Traditional jump-diffusion stochastic volatility models fail to account for the time-varying skew of the risk-neutral distribution.

Time reversal invariance in finance

G. Zumbach (2007)

Most time-series models are time-reversal invariant – price time series are not...

Group dynamics of the Japanese market

W.S. Jung et al. (2007)

When building a minimum spanning tree (MST) on the correlation matrix of stock returns to find sectors, you might want to remove the influence of the global market (here, S&P 500) first.

Information flow between composite stock index and individual stocks
O. Kwon and J.-S. Yang (2007)

Individual stocks are influenced by the market.

Multiagent cooperative search for portfolio selection
D.C. Parkes and B.A. Huberman

Investment strategies can be averaged (as in bayesian model averaging (BMA) or “multi-alpha”).

Information diffusion based explanations of asset pricing anomalies
A. Bolmatis and E.G. Sekeris (2007)

For not-so-liquid stocks, you might want to replace the Fama-French factors by

- Age (number of days since the IPO);
- proportion of non-trading days in the past year.

The supervisor’s portfolio: the market price risk of German banks from 2001 to 2003 – analysis and models for risk aggregation
C. Memmel and C. Wehn
Bundesbank (2005)

The value-at-risk (VaR) of a portfolio can be estimated from the *time series* of the VaR of its constituents.

Non-linearities in exchange rate dynamics: chaos?
V. Vandrovysh (2006)

The hypothesis that exchange rates are chaotic is rejected by the *correlation dimension* and the *Lyapunov exponent*.

Shortfall: a tail of two parts
R. Martin and D. Tasche
Risk (2007)

Expected shortfall can be decomposed into a systematic and a specific part:

$$Y = X\beta + \varepsilon$$

$$E[Y|Y > y] = E[X|Y > y]\beta + E[\varepsilon|Y > y].$$

Under gaussian (or some other distributional) assumptions, this can be explicitly computed.

Cointegration and exchange market efficiency: an analysis of high frequency data
A. Trapletti et al. (1999)

Were markets efficient, a triangle of high frequency exchange rates would be cointegrated and the cointegration term would be a *martingale difference* (testing properties of the cointegration term instead of the cointegration itself is easier: it does not require a long period – just a lot of data, but with tick data, there is enough).

Markets are not efficient; arbitrage opportunities, profitable trading strategies do exist.

Predicting tick-by-tick price fluctuations by evolutionary computations
M. Tanaka-Yamawaki

Genetic algorithms (GA) can predict the direction of the next tick given previous tick directions.

The volatility effect: lower risk without lower return
D.C. Blitz and P. van Vliet (2007)

Stocks with low volatility earn higher risk-adjusted returns: equity investors overpay for risk.

Optimal hedge ratio estimation and effectiveness using ARCD
E. Kostika and R.N. Markellos

A GARCH-like model (auto-regressive conditional density) for generalized Student distributions, allowing time-varying variance, skewness and kurtosis.

Efficient time series matching by wavelets
K.P. Chan and A.W.C. Fu

The Haar wavelet transform can be used to reduce the dimension of time series, before indexing with an R-tree.

Similarity search over time series data using wavelets
I. Popivanov and R.J. Miller
ICDE (2002)

Wavelet transforms can be used as a data reduction technique for time series data – contrary to popular belief, the Haar wavelet is not always the best choice.

Time series feature extraction for data mining using DWT and DFT
F. Mörchen (2003)

When using the discrete Fourier transform (DFT, as in JPEG) or the discrete wavelet transform (DWT, as in JPEG2000) for time series dimension reduction, you can select the largest coefficients instead of the first ones.

An econometric model of serial correlation and illiquidity in hedge fund returns
M. Getmansky et al.
Journal of financial economics (2004)

Time-varying leverage and high water mark incentive fees cannot account for all the autocorrelation in hedge fund returns: illiquidity (e.g., non-synchronous trading) and/or return smoothing play a larger role.

This calls for an econometric model of smoothed returns: observed returns are a moving average of true economic (unobserved) returns. a hidden Markov chain

Mimicking portfolios with conditioning information

W. Ferson et al.

Journal of financial and quantitative analysis (2006)

To replicate a non-investible asset, you can look for the linear combination of assets in your universe whose returns have the largest correlation – this is an example of *partial least squares* (PLS).

Option pricing with aggregation of physical models and nonparametric statistical learning
J. Fan and L. Mancini (2007)

Traditional option pricing models can be combined with nonparametric (machine learning) approaches to correct their errors.

Asian options versus vanilla options
G. Ye

Asian options need not be cheaper than vanilla options.

Market timing with candlestick technical analysis
B.R. Marshall et al. (2007)

Technical analysis (TA) is not profitable....

The impact of option strategies in financial portfolios performance: mean-variance and stochastic dominance approaches
F. Abid et al. (2007)

Stochastic dominance is very rare: given to investment strategies, you should not expect one to dominate the other. However, if the strategies are related (say, a 1-parameter family of strategies, or a strategy with or without an overlay), all hope is not lost.

Individual vs aggregate preferences: the case of a small fish in a big pond
D.W. Blackburn and A.D. Ukhov (2006)

The risk preferences (utilities) of individual investors sometimes aggregate in a counterintuitive way: an economy of risk-seeking agents can be risk-averse as a whole. The notion of a “representative agent” is therefore not well defined...

Long memory modeling of realized covariance matrices
R. Chiriac and V. Voev (2007)

A time-dependent variance matrix can be modeled with an ARMA (here, a fractionally integrated ARMA) model on its Cholesky matrix.

Estimating high-frequency based (co-)variances: a unified approach
I. Nolte and V. Voev (2007)

Microstructure noise and non-synchronous observation complicates the estimation of the covariance of diffusion processes. Those effects can be studied and remedied by examining the effects of changes in the sampling frequency.

Quantile estimation with adaptive importance sampling
D. Egloff and M. Leippold (2007)

Importance sampling can also be used to estimate quantiles, not just expectations.

How well do financial and macroeconomic variables predict stock returns: time series and cross-sectional evidence
A.S. Reng Rasmussen (2006)

Yet another list of variables to predict future returns.

What happened to the quants in August 2007?
A.E. Khandani and A.W. Lo (2007)

This may have been caused by the unwind of a large portfolio.

The paradox of quantitative investing and ways to deal with it
T. Suwabe et al.
Goldman Sachs (2007)

The authors build a BMA-CAPM (*bayesian model averaging* capital asset pricing model) on a hundred variables, to decompose the momentum (in excess of the industry average) into common and specific components: the latter can be used as a reversal (it used to work), the former as a momentum (noisier, only works in the past three years).

One could also try:

- a time-series (Northfield-like) risk model (this means one regression per date and per stock);
- support vector machines (SVM) or regularization path regression (least angle regression (LAR), lasso, etc.) instead of BMA.

Costly short-selling and stock price adjustment to earnings announcements
A.V. Reed (2007)

Costly short-selling, or short-selling constraints, reduces the speed at which the price adjusts to private information, increases volatility (around earnings announcements), reduces the information content of price and volume. (This looks like a textbook example of the omitted variable syndrome...)

A stochastic volatility model with fat tails, skewness and leverage effects
D.R. Smith (2007)

One can try to reproduce the **leverage effect**, $\text{Cor}(r_t, v_{t+1}) < 0$, *i.e.*, shocks are correlated with future volatility, as follows.

- This first attempt exhibits leverage, but not negative skewness;

$$\begin{aligned} y_t &= \mu + e^{x_t/2} + \varepsilon_t \\ x_{t+1} &= \omega + \phi_t x_t + \eta_t \\ \begin{pmatrix} \varepsilon_t \\ \eta_t \end{pmatrix} &\sim N \left(\begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} 1 & \rho\sigma \\ \rho\sigma & \sigma^2 \end{pmatrix} \right) \end{aligned}$$

- If you ask that shocks be correlated with contemporaneous volatility, this is no longer a martingale;
- Use the first model with a copula instead of a gaussian distribution.

Who needs hedge funds?
A copula-based approach to hedge fund return replication
H.M. Kat and H.P. Palaro (2005)

Hedge fund replication usually tries to mimic the distribution of the returns of a hedge fund, but hedge funds are often used as an overlay to an already existing portfolio: the authors suggest to also replicate the dependency between the hedge fund and the existing portfolio, as follows.

- Infer the joint distribution of the hedge fund and the existing portfolio using copulas (gaussian, Student, Gumbel, Cook-Johnson (aka Clayton), Frank, symmetrised Joe-Clayton (SJC)) and marginal distributions (gaussian, Student, Johnson S_U);
- Among all the payoff functions, find the cheapest that produces this distribution (this is Dybvig's *payoff distribution pricing model* (PDPM) generalized to a 2-dimensional payoff distribution); it suffices to consider path-independent payoff function (any payoff distribution generated by a path-dependent payoff function can also be generated by a path-independent payoff function); if the Sharpe ratio of the underlying asset is high enough and the correlation with the investor's portfolio low enough, the payoff function will be non-decreasing;
- Price and find a replicating strategy for this payoff function.

Estimation of value at risk using Johnson's S_U -normal distribution
P. Choi (2001)

Value at risk (VaR) estimation can be univariate (you only have the returns of a portfolio) or multivariate (you know the returns of the constituents of your portfolio, *i.e.*, you want to estimate a quantile of $\sum_i w_{it} r_{it}$, where r and perhaps also w is a random variable); it can be conditional (e.g., conditional heteroskedasticity, but you could also have models with conditional third or fourth moments; the article also mentions exponential smoothing (RiskMetrics), which is a special case of IGARCH) or unconditional (extreme value theory (EVT)).

The article studies VaR estimation in a GARCH model with S_U -normal innovations.

A random variable Y is S_U -normal if it is of the form

$$Y = \sinh(\lambda + \theta X)$$

where $\theta > 0$ and X is standard gaussian. Those distributions can be skewed and have fat tails.

Reinforcement learning: a survey
L.P. Kaelbling et al.
Journal of artificial intelligence research (1996)

In *reinforcement learning*, the agent has to make choices and receives some feedback on those choices. Contrary to supervised learning, he is not told which action would have been the best; furthermore, the consequences of an action need not be immediate.

The agent typically tries to maximize one of the following quantities (they do not lead to the same optimal policies):

- N -step optimal control

$$E \left[\sum_{t=n+1}^N r_t \right], \quad n \in \llbracket 0, N \rrbracket$$

- N -step receding horizon control

$$E \left[\sum_{t=n+1}^{n+N} r_t \right]$$

- Infinite-horizon discounted model

$$E \left[\sum_{t=1}^{\infty} \gamma^t r_t \right]$$

- average reward model (this one does not penalize for long learning times)

$$\lim_{N \rightarrow \infty} E \left[\frac{1}{N} \sum_{t=1}^N r_t \right]$$

Asymptotic convergence results are useless: a fast convergence to a near-optimal solution is better than a sluggish convergence to the optimal.

Algorithms have to make a trade-off between exploration (of the possible choices and their consequences) and exploitation.

Dynamic programming can be used to maximize those performance measures.

With a 1-step, immediate-reward model, one can use greedy strategies, *Boltzman exploration* or *interval-based techniques* (for each action, store the number of trials and the number of successes and compute a confidence interval on the probability of success). These algorithms can be adapted to multi-step, immediate-reward problems.

Markov decision processes (MDP) can be used to model delayed reward. If the decision process were known (we do assume that the states and transition probabilities are known, though), we could compute the value of each state for the discounted model and, from there, the optimal policy.

Value iteration estimates the value of each node and derives a strategy (since a strategy is a finite object, it converges in a finite number of steps); *policy iteration* directly estimates the policy.

But we do not know the model.

The *adaptive heuristic critic* algorithm is similar to policy iteration, but the value function is computed iteratively, from the $TD(0)$ algorithm:

$$V(s) \leftarrow V(s) + \alpha(r + \gamma V(s') - V(s))$$

where r is the reward, s the current state, s' the next state. The $TD(\lambda)$ algorithm also updates states that were recently visited.

The *Q-learning* algorithm (if you do not know which algorithm to implement, use this one) estimates $Q(s, a)$,

the expected discounted reinforcement of taking action a while in state s , with the $TD(0)$ or $TD(\lambda)$ algorithm, with a decreasing α . You must first explore the states (but the algorithm is robust) and, after convergence, you can act greedily.

Other algorithms (*certainty equivalence*, *Dyna*, *prioritized sweeping*) learn the model at the same time as the optimal policy: they make a better use of the data and converge faster.

In case of very large state spaces, you can aggregate some states and solve a coarser problem (*multi-grid methods*, *state aggregation*); you can also replace the mappings (transition probabilities, value functions, policies, etc.) by a simpler representation obtained by *supervised learning*. There are other *generalization* algorithms.

Computer science and game theory

J.Y. Halpern

arXiv:cs/0703148

Complexity plays a role in game theory:

- Agents can have *bounded rationality*, i.e., have limited computational power (e.g., they can be finite automata); this can lead to cooperation in the prisoner's dilemma;
- Many problems about *Nash equilibrium* are NP-hard;
- One cannot design a non-dictatorial voting scheme immune to manipulation by voters, but this manipulation can be made computationally unreasonable; there are similar problems in *combinatorial auctions* (auctions where you can bet on bundles of objects; but pricing 2^N objects is too long);
- Agent-based games (e.g., *Byzantine agreement*) are very similar to distributed computing, networking protocols, fault-tolerance, mediator-less cryptography.

This (concise) article also mentions random graphs, bayesian and Markov networks, reinforcement learning.

What every investor should know about commodities

part 1: univariate return analysis

H.M. Kat and R.C.A. Oomen (2006)

Commodities do not offer a risk premium: the average return is not significantly different from zero; the returns depend (slightly) on the business cycle, on monetary conditions, on the futures curve (upward sloping (contango) or downward sloping (backwardation)).

Commodities are not more volatile than stock, as measured by the 2.5%–97.5% range, the standard deviation, the GARCH(1,1) $\gamma = \alpha + \beta$ parameter (it measures the persistence of volatility); they are more volatile in backwardation; energy is more volatile in recessions and less in expansion phases; volatility shocks tend to persist ($\gamma > 0.9$).

Commodity returns are not skewed, when skewness is measured as normalized third moment, as L -moment

$$\frac{X_{.75} - 2X_{.50} + X_{.25}}{X_{.75} - X_{.25}},$$

as the normalized difference between mean and median

$$\frac{\bar{X} - X_{.50}}{\frac{1}{T} \sum_{i=1}^T |x_i - X_{.50}|}$$

or as the GARCH skew parameter.

All commodity returns have fat tails, as measured by the fourth moment, the L -moment

$$\frac{X_{.875} - X_{.625} + X_{.375} - X_{.125}}{X_{.75} - X_{.25}},$$

a ratio of fractile ranges

$$\frac{X_{.975} - X_{.025}}{X_{.75} - X_{.25}}$$

or the number of degrees of freedom of a GARCH(1,1) model with Student innovations.

Commodity returns are autocorrelated.

***What every investor should know
about commodities
part 2: multivariate return analysis
H.M. Kat and R.C.A. Oomen (2006)***

Commodity returns are correlated within groups but not between groups, except “softs”.

Commodity returns are weakly correlated with stock or bond returns, as measured by correlation or Kendall’s tau, but this depends on the business cycle; there is little persistence in correlation dynamics, as measured by a GARCH(1,1)-DCC model, except metals.

There is tail dependence, as measured by the symmetrized Joe Clayton copula (SJC), which has two parameters for tails and head dependence, within groups but not between groups; there is no difference between head and tail dependence: correlation is sufficient.

There is no tail dependence between commodities and stocks or bonds.

Commodity futures are correlated with unexpected inflation, as measured by inflation minus interest rate or change in inflation.

***On more robust estimation of skewness
and kurtosis: simulation and application to
the S&P500 index
T.H. Kim and H. White (2003)***

One can define quantile-based measures of skewness:

$$\begin{aligned} SK_1(\alpha) &= \frac{X_{1-\alpha} - 2X_{.5} + X_{\alpha}}{X_{1-\alpha} - X_{\alpha}} \\ SK_2 &= \frac{\int_0^{1/2} (X_{1-\alpha} - 2X_{.5} + X_{\alpha}) d\alpha}{\int_0^{1/2} (X_{1-\alpha} - X_{\alpha}) d\alpha} \\ &= \frac{E[X] - X_{.5}}{E[|X - X_{.5}|]} \\ SK_3 &= \frac{E[X] - X_{.5}}{\sigma(X)} \end{aligned}$$

(SK_3 is not compatible with “skewness ordering” – but this notion is not defined) and kurtosis (those measures are usually corrected by subtracting the value for a gaussian distribution):

$$\begin{aligned} KR_1 &= \frac{(X_{7/8} - X_{5/8}) + (X_{3/8} - X_{1/8})}{X_{3/4} - X_{1/4}} \\ KR_2(\alpha, \beta) &= \frac{E[X|X > X_{1-\alpha}] - E[X|X < X_{\alpha}]}{E[X|X > X_{1-\beta}] - E[X|X < X_{\beta}]} \\ KR_2(\alpha, \beta) &= \frac{X_{1-\alpha} - X_{\alpha}}{X_{1-\beta} - X_{\beta}} \end{aligned}$$

(with $\alpha = 0.05$, $\beta = .5$ in KR_2 and $\alpha = 0.025$, $\beta = .25$ in KR_3).

***Significance tests harm progress in forecasting
J.S. Armstrong (2005)***

Significance tests should be avoided:

- readers and authors misinterpret them;
- the choice of the null hypothesis is problematic;
- there is a publication bias against non-rejection of the null;
- it distracts the authors from other issues: they often fail to assess importance (with *effect sizes* or confidence (with *confidence intervals*)).

Furthermore, if you have enough data, everything is statistically significant.

***Forecasting with many predictors
J.H. Stock and M.W. Watson (2005)
Handbook of economic forecasting***

The authors review several classes of forecasting algorithms: forecast combination (without any discussion of bagging or boosting), bayesian model averaging (BMA, rarely used, but better than an equal-weighted combination of predictors), *empirical Bayes methods* (the prior is not a prior, it comes from the data) and dynamic factor models (no mention of biased estimators or regularization paths).

In a *dynamic factor model* (DFM), unobserved AR factors \mathbf{f} and their lags explain the observed variables X_{it} :

$$\begin{aligned} \mathbf{f}_t + \Gamma_1 \mathbf{f}_{t-1} + \dots + \Gamma_k \mathbf{f}_{t-k} &= \boldsymbol{\eta}_t \\ X_{it} &= \lambda_{i0} \mathbf{f}_t + \dots + \lambda_{i\ell} \mathbf{f}_{t-\ell} + u_t \end{aligned}$$

while a (static) factor model would be

$$X_{it} = \lambda_i f_t + u_{it}.$$

Dynamic factor models can be reformulated as static factor models and estimated by maximum likelihood; there are also principal-component-analysis-based approximations.

The article interprets this model in terms of the *spectral density matrix* without bothering to define it.

Dynamic principal component analysis (PCA) is similar; the corresponding latent variables can be obtained by performing a PCA dimension reduction on the spectral density.

Principal components at work: the empirical analysis of monetary policy with large datasets
C.A. Favero et al. (2002)

Comparison of two estimators of *dynamic factor models*, based on static (time-domain) and dynamic (frequency-domain) PCA (principal component analysis): the performance is similar, but dynamic PCA is more parsimonious.

Moment problems via semi-definite programming: applications in probability and finance
P. Popescu and D. Bertsimas (2000)

The Markov, Chebychev, Chernoff inequalities provide bounds on some probabilities $P[X \in \Omega]$ given some moments or joint moments of arbitrary random variables. More generally, one can try to solve the following optimization problem:

$$\begin{aligned} &\text{Maximize } E[\phi(X)] \\ &\text{such that } \forall i \quad E[f_i(X)] = q_i \end{aligned}$$

for all random variable $X : \Omega \rightarrow \mathbf{R}^m$.

For instance, in finance, one can look for bounds on the price of an option given the moments of the underlying and/or other option prices (we only have to assume that the option price is the expected discounted payoff under the risk-neutral measure; we do not know anything about that measure except that it is a probability measure).

The *feasibility* of that optimization problem can be expressed in terms of positive semi-definiteness – e.g., in a multi-dimensional context, the second centered moment (the variance matrix) should be positive semi-definite.

In the *dual* problem (under reasonable conditions, there is a strong duality theorem), the expectation disappears but we have an infinite number of constraints:

$$\begin{aligned} &\text{Minimize } y'q \\ &\text{such that } \forall x \in \Omega \quad y'f(X) \geq \phi(x). \end{aligned}$$

Fortunately, those constraints can often be expressed as semi-definite constraints and the problem can be solved.

In higher dimensions, beyond the second moment, the problem of finding optimal bounds is NP-hard.

This is a review article: there are more detailed publications by the same authors.

Second order cone programming approaches for handling missing and uncertain data
P.K. Shivaswamy et al.
Journal of machine learning research (2006)

In the support vector machine (SVM) binary classification optimization problem

$$\begin{aligned} &\text{Minimize } \frac{1}{2} \|z\|^2 + C \sum_i \xi_i \\ &\text{such that } \forall i \quad y_i(\langle w, x_i \rangle + b) \geq 1 - \xi_i \\ &\quad \forall i \quad \xi_i \geq 0 \end{aligned}$$

uncertainty can be introduced by transforming the constraints into

$$P[y_i(\langle w, x_i \rangle + b) \geq 1 - \xi_i] \geq 1 - \kappa_i.$$

The *Chebychev inequality* gives a worst-case bound on this probability, provided you know the first two moments of x .

This can be generalized to classification into more than two groups and to regression.

Applications of second order cone programming
M.S. Lobo et al. (1998)

Many optimization problems can be recast as second order cone programs (SOCP): quadratically-constrained quadratic programs (QCQP), optimization problems in which the objective is a sum or max of norms; FIR (finite impulse response) filter design, robust linear programming, robust least squares, robust portfolio optimization.

Interior-point methods adapted to SOCP are faster than those adapted to the more general semidefinite programs (SDP).

Second-order cone programming
F. Alizadeh and D. Goldfarb (2002)

More detailed article on the same subject.

Introducing Mr. Risk
A. Meucci

Very simple (but readable and rigorous) article about portfolio construction: variance matrix (*i.e.*, risk model) construction, optimization, warning on the confusion between linear and log-returns, myopic allocation (multi-period asset allocation in the special case where the weights are constant), portfolio insurance via delta hedging, decomposition of homogeneous risk measures (e.g., the value at risk) using *Euler's formula*.

The last chapter presents *sensitivity analysis*: after choosing a few risk factors, you can express the future price of an asset as a function of those risk factors; this can be approximated by a Taylor expansion,

$$\Delta \text{price} = \frac{\partial \text{price}}{\partial \text{risk}} \Delta \text{risk} + \frac{1}{2} \Delta \text{risk}' \frac{\partial^2 \text{price}}{\partial \text{risk}^2} \Delta \text{risk}.$$

For instance, in fixed income, you can use time and yield as risk factors; the corresponding derivatives are called *carry* and *duration*

$$C = \frac{\partial \pi}{\partial t} \quad D = -\frac{1}{\pi} \frac{\partial \pi}{\partial y};$$

this leads to the *duration approximation*

$$\Delta \pi \approx C \Delta t - \pi D \Delta y.$$

Similarly, the *delta approximation* is a first-order approximation of the price change of a (vanilla) option using stock indices.

Second-order approximations can be used to compute the value at risk (VaR) of a portfolio.

The article ends with a detailed example: the risk of a portfolio of mortgages.

Caml trading: experiences in functional programming on Wall Street
T. Minsky
The monad reader (2007)

Benefits of functional languages in finance.

Financial econometrics
A.W. Lo (2007)

This soon-to-be-published book (this was only the preface) is a collection of old articles. The table of contents is interesting, though:

- Models of asset returns: time-varying moments, fat tails, long memory, regime shifts, cointegration;
- Asset pricing models: CAPM and its tests, multifactor models (APT), performance measurement, tests of market timing or security selection ability;
- Dynamic asset pricing models: variance bounds controversy (?), equity premium puzzle, consumption-based CAPM, stochastic discounted factor model, incomplete markets, term structure;
- Market microstructure: price discovery (Walrasian tatonnement, etc.), price discreteness, irregular trading intervals, bid-ask spread, binomial “trees”, state-space density estimation, price jumps, serial correlation, functional central limit theory (?)’
- Non-standard finance: survivorship bias, data snooping, Bayesian methods, event study, generalized method of moments, robust statistics, nonlinear dynamical systems, neural networks, technical analysis, random matrix theory.

A jigsaw puzzle of basic risk-adjusted performance measures
H. Scholz and M. Wilkens
Journal of performance measurement (2005)

Performance measures based on total risk

- Sharpe ratio;
- RAP (risk-adjusted performance or *Modigliani’s* M^2): expected returns of the portfolio, leveraged so that its volatility equals that of the market portfolio;
- DR^{RAP} (differential returns based on RAP): difference in expected returns between the market portfolio and the portfolio, leveraged to have the same volatility as the market portfolio;
- TRA (total risk alpha): difference in expected returns between the portfolio and the market portfolio, leveraged to have the same volatility as the portfolio studied;

can be modified by replacing the total risk σ by the market risk β :

- Treynor ratio;
- MRAP (market-risk-adjusted performance);
- DR^{MRAP} (differential returns based on MRAP);
- Jensen’s alpha.

The authors explain those definitions with pictures.

Symmetric versus asymmetric conditional covariance forecasts: does it pay to switch?
S. Thorp and G. Milunovich
Journal of financial research (2007)

Multidimensional, asymmetric GARCH models in portfolio optimization can lower realized portfolio risk.

Model comparison of coordinate-free multivariate skewed distributions with an application to stochastic frontiers
J.T.A.S. Ferreira and M.F.J. Steel
Journal of econometrics (2007)

Most multivariate families of distributions used to model skewness are not coordinate-free: the coordinate axes play a special role, skewness is only allowed in some (coordinate-dependent) directions – those families are not closed under orthogonal transformations.

Coordinate-free multivariate skew distributions can be obtained as follows: choose n univariate skewed distributions, apply an invertible n -dimensional affine transformation.

Univariate skewed distributions can be obtained as follows, from a symmetric distribution with pdf (probability distribution function) f and cdf (cumulative distribution function) F :

- Hidden truncation: $s(x) \propto f(x)F(\alpha x)$;
- Inverse scale factor (scale the distribution by a different factor depending on the sign): $s(x) \propto f(\gamma^{-\text{sign } x} x)$;
- More generally, one can consider $s(x) = f(x)p(F(x))$

for various choices for p , e.g.,

$$p(u) = \frac{u^{\tau-1}(1-u)^{1/\tau-1}}{B(\tau, 1/\tau)}.$$

***Enjoy the joy of copulas*
J. Yan (2006)**

Presentation of the `copula` R package to sample from, plot or fit gaussian, Student, Clayton, Frank or Gumbel copulas in any dimension.

***Analyst recommendations, mutual fund herding and overreaction in stock prices*
N.C. Brown et al. (2007)**

Mutual funds herd after consensus analyst changes – exploiting their overreaction can earn you 6% per year.

***A robust version of the KPSS test based on indicators*
R.M. de Jong
Journal of econometrics (2006)**

In the KPSS test, instead of demeaning the data $x_i \leftarrow x_i - \bar{x}$, just use $x_i \leftarrow \text{sign}(x_i - \text{median } x)$: this does not change the asymptotic distribution, relaxes assumptions about the moments and increases the power of the test in presence of fat tails (but reduces it otherwise).

***Multivariate archimedian copulas, d -monotone functions and ℓ_1 -norm symmetric distributions*
A.J. McNeil and J. Nešlehová**

Archimedian copulas are exactly the ℓ_1 -symmetric copulas that avoid the origin.

The article also characterizes functions that generate d -dimensional archimedian copulas.

***On the interaction between ultra-high frequency measures of volatility*
G.M. Gallo and M. Velucchi (2007)**

The realized variance (*i.e.*, variance estimated from tick data) $\sum x_t^2$ and the *bipower variance* $\sum |x_t x_{t-1}|$, robust to jumps, are almost undistinguishable in the context of *multiplicative error models* (MEM), *i.e.*, GARCH-like models used to model positive quantities (volume, duration, range, etc.).

***Estimating copula functions from limited data*
D. Allwright et al. (2006)**

The problem of estimating the value at risk (VaR) of a random variable without any distributional assumption (or when the distribution has too many parameters, say, a 2-parameter Pareto distribution or a mixture of gaussians or exponentials) remains the same in higher dimension: it is impossible when $p^n > \alpha$, where p is the quantile to estimate, $1 - \alpha$ is the confidence level and n the number of observations (say, $p = 0.99$, $\alpha = 0.05$).

***Zero-intelligence realized variance estimation*
J. Gatheral and R.C.A. Oomen (2007)**

Realized variance estimators (*i.e.*, variance estimators using high frequency data) should avoid market microstructure artefacts such as the *bid-ask bounce* – one can do better than aggregate the data, *i.e.*, throw away 99% of it. The article compares twenty such estimators on simulated data (using the *zero-intelligence limit order book model*: orders arrive at random, following a Poisson distribution, and are randomly cancelled). Their conclusions are:

- Do not forget to correct for any bias in your estimator;
- Prefer mid-quotes to trade prices, they are much less noisy;
- Use subsampling or kernel estimators (a *kernel variance estimator* is a linear combination of $\text{Cov}(x_t, x_t)$, $\text{Cov}(x_t, x_{t-1})$, $\text{Cov}(x_t, x_{t-2})$, etc., with well-chosen decreasing coefficients).

***Issues in creating a sentiment measurement based on internet stock message boards*
Y.C. Zhang and P.E. Swanson**

Internet message boards (thelion.com, Yahoo finance, the motley fool, raging bull, etc.) can be used to build a sentiment index; reply messages should be given a lower weight (0.125); the *maximum entropy text classifier* (not clearly presented) performs better than the naive Bayes one.

***Some methods for training mixtures of experts*
P. Moerland (1997)**

Ensemble learning algorithms typically combine several learning algorithms (or *experts*) using fixed weights (the weights were determined from the training sample but they do not change and depend on each new observation).

On the contrary, you could have several experts controlled by a *gating expert* assigning weights to each of them, depending on the observation to classify.

***Voting with a parametrized veto strategy: solving the KDD cup 2006 problem by means of a classifier committee*
D. Tikk et al.
SIGKDD Explorations (2006)**

Combine several (neural-network-based) supervised learning techniques with a committee vote, using weights from the average performance of a 10-fold cross-validation test and the confidence value of each algorithm, with a veto to control the maximum allowed error rate.

***Maximizing classifier utility when training data is costly*
G.M. Weiss and Y. Tian
SIGKDD Explorations (2006)**

Formalization of what emergency medicine already does – for instance, this is one of the motivations of *decision trees*, which use *few* variables.

***Portfolio management using value at risk
A comparison between genetic algorithms
and particle swarm optimization*
V.A.D. Filho (2006)**

Non-linear, multi-modal optimization problems, such as value-at-risk (VaR) portfolio optimization (the article is limited to 50 assets) can be solved by *particle swarm optimization* (PSO) or *genetic algorithms* (GA).

In PSO, particles (portfolio weights vectors) fly around and their velocity is updated from their previous velocity (with a linearly decreasing inertia), the best position encountered so far by the particle and the whole swarm:

$$v_{i,t+1} = wv_{i,t} + c_1r_1(\text{best}_i - x_i) + c_2r_2(\text{best}_{\text{swarm}} - x_i) \\ r_1, r_2 \sim U(0, 1).$$

Constraints can be taken care of in different ways:

- *bumping*: when a particle hits a boundary, its velocity is set to zero (but the particles may become trapped near local extrema near the boundary);
- *random positioning*: when a particle hits a boundary, it is put somewhere else, randomly;
- *amnesia*: when a particle hits a boundary, it continues as if there were no boundary but stops recording the best position so far;
- *penalty* function.

In the GA, individuals are selected for reproduction by a *roulette wheel* (with a probability proportional to their fitness) or by a *tournament* (pairs of individuals are selected at random and the best one is chosen); the crossover can be *basic*

$$(x, y) \mapsto (x_{1..k} \sqcup y_{k+1..n}, y_{1..k} \sqcup x_{k+1..n})$$

or *arithmetic*

$$(x, y) \mapsto (px + (1 - p)y, (1 - p)x + py);$$

the mutation operator is

$$(x_k, x_\ell) \leftarrow (x_k + r, x_\ell - r) \\ k, \ell \sim U(\llbracket 1, n \rrbracket) \\ r \sim U(0, 1).$$

PSO is faster but GA are more robust.

***Stochastic analysis of an agent-based model*
A. Veglio and M. Marsili
arXiv:0705.4025**

An agent-based herding model.

***Extending Black–Litterman analysis beyond
the mean-variance framework*
L. Martellini and V. Ziemann
Journal of portfolio management (2007)**

The authors extend the Black–Litterman framework to take into account skewness and kurtosis: the simply replace the benchmark portfolio (used to compute the implied alpha) by the minimum VaR (value at risk) portfolio, where the VaR is computed from a Cornish–Fisher expansion and the CAPM (capital asset pricing model) is replaced by a 4th moment CAPM. The classical Black–Litterman formula is then applied.

This is an approximation of Meucci’s generalization: he considered the whole returns distribution, not just its first moments.

***On dynamic measures of risk*
J. Vcitanic and I. Karatzas (1998)**

An agent has some initial capital x , some liability C to be met at time T and tries to find a strategy π so that his wealth at time T exceeds the liability:

$$X^{x,\pi}(T) \geq C.$$

He can do so provided the initial capital x is large enough,

$$x \geq E_{\text{risk-neutral}} \left[\frac{C}{S_0(T)} \right]$$

(where S_0 is the price of the risk-free asset). If not, its risk can be measured as

$$\inf_{\pi} E_{\text{real-world}} \left[\frac{C - X^{x,\pi}(T)}{S_0(T)} \right]^+$$

or even, to account for model uncertainty,

$$\sup_{P \in \mathcal{P}} \inf_{\pi} E_P \left[\frac{C - X^{x,\pi}(T)}{S_0(T)} \right]^+.$$

***The Epps effect revisited*
B. Tóth and J. Kertész
arXiv:0704.1099**

Stock correlations decrease as the sampling frequency increases: this is the *Epps effect*. The classical explanations:

- the maximum cross-correlation is the same but is not attained at a zero time lag;
- asynchronicity of ticks

are not sufficient. The article provides a physicist’s explanation for the remaining effect.

Also check arXiv:0704.3798, by the same authors.

***Price discovery in the US stock and stock
options markets: a portfolio approach*
R. Holowczak et al. (2006)**

Many articles try to guess the direction of the information flow between the stock and option markets, *i.e.*, in

which market price discovery occurs (with inconclusive results).

To remove the non-linear effects of options, the authors consider synthetic forwards, *i.e.*, portfolios made of a put-call pair, with a linear payoff.

Price discovery seems to occur in stock markets, except in case of unusual option trading activity.

Structural breaks in financial time series **E. Andreou and E. Ghysels (2006)**

Not accounting for structural changes can lead to over-complicated models.

Here are some partial-sum-based (CUSUM) statistics to test for a structural break:

- Fluctuation = $\frac{\bar{X}_{[m+1,n]} - \bar{X}_{[1,m]}}{\sigma/(n-m)}$;
- PS = $\sum_{i=m+1}^{m+k} (X_i - \bar{X}_{[1,m]})$;
- PG = $\sum_{i=1}^n X_i - \text{Min}_{1 \leq i \leq n} \sum_{i=1}^n X_i$.

The asymptotic framework developped by Kuan, Hornik and Leisch to detect structural changes in linear regressions can be adapted to non-linear processes (GARCH, etc.) and can help determine various thresholds beyond which those partial sum statistics should be considered suspicious.

To spot multiple breaks, one can use *penalized likelihood* methods or, for stochastic volatility (GARCH, etc.) models, *minimum description length* (MDL)-based tests (no details given).

The bulk of the article is devoted to checking the conditions under which those tests are valid.

Notes sur les mesures de performance **D. Herlemont** **YATS (2004)**

The *Sharpe ratio* is not compatible with *strong dominance* and can be manipulated (just write out-of-the-money puts); non-gaussian arbitrage oportunities can have an arbitrarily small Sharpe ratio.

A *Bonnet–Nagot risk measure* π satisfies:

- $X \perp\!\!\!\perp Y \implies \text{Max}_{\alpha, \beta} \pi(\alpha X + \beta Y) = \pi(X) + \pi(Y)$
- The maximum is reached for $\alpha = \lambda(X)$ and $\beta = \lambda(Y)$ where $\lambda(Z)$ only depends on Z .

Up to an affine transformation, a Bonnet–Nagot measure of risk coincides with the Sharpe ratio for gaussian distributions.

They can be characterized in terms of the log-Laplace transform $H_X(\lambda) = -\ln Ee^{-\lambda X}$ as

$$\pi(X) = \sup_{\lambda} \mathcal{J}(H_{\lambda X})$$

where $\mathcal{J} : \mathcal{C}^\infty(\mathbf{R}, \mathbf{R}) \longrightarrow \mathbf{R}$ is linear and continuous.

Examples include:

- The Sharpe ratio:

$$\mathcal{J}_{\text{SR}}(H) = H'(0) + \frac{1}{2}H''(0)$$

- The *Hodges* (or *Stutzer*) measure:

$$\mathcal{J}_{\text{Hodges}}(H) = H(1)$$

- The Bonnet–Nagot measure:

$$\mathcal{J}_{\text{BN}}(H) = H(1) + aH(\alpha).$$

(The link with Acerbi's *coherent* measures of risk is mentionned but not explained.)

The Stutzer measure is actually the rate of convergence to zero of the ruin probability (studied in *large deviation theory*); the Stutzer criterion is a (riskier) alternative to the Kelly criterion, which maximizes the rate of growth instead.

Information uncertainty and stock returns **X.F. Zhang (2004)**

Greater information uncertainty produces higher returns following good news and lower returns following bad news; “news” are measured by forecast revisions or short-term momentum; uncertainty is measures by firm size, fir age, analyst coverage, analyst forecast dispersion, returns volatility, cash flow volatility. In other words: the more volatile or uncertain the stock, the better momentum works.

The underlying dynamics of credit correlations **A. Berd et al.** **Journal of credit risk (2007)**

The default of a basket of companies is usually modelled as follows:

- Consider boolean, time-dependent *loss variables* $Y_{it} = 1_{R_{it} \geq d_{it}}$, where R_{it} are *latent* variables and d_{it} thresholds (e.g., $R_{it} = R_t$ is the time of default of company i and $d_{it} = t$);
- For fixed t , study the *copula* of the latent variables (use a 1-factor gaussian copula);
- Consider the *loss distribution*, *i.e.*, the distribution of $\sum_i \ell_i Y_i$.

The *correlation surface* $\rho(K, p)$ is the correlation parameter of the gaussian copula that produces the same expected loss for the tranche $[0, K]$ and default probability p .

Pricing forward contracts in power markets by the certainty equivamence principle: explaining the sign of the market risk premium **F.E. Benth et al. (2006)**

Explanation of the risk premium for commodities, from a 2-agent model (consumer and producer), each with a different utility, and an underlying with a stochastic price.

Asset price dynamics with heterogeneous groups

G. Caginalp and H. Merdan
Physica D (2007)

Asset price dynamics can be modeled by a system of differential equations, similar to the predator-prey systems in biology.

Generalized canonical regression
A. Estrella (2007)

Linear regression assumes that there is a single dependent variable

$$y = \sum_i \beta_i x_i + \varepsilon;$$

with several dependent variables, one can use *multiple regression*

$$\forall j \quad y_j = \sum_i \beta_{ij} x_i + \varepsilon_j$$

(often with some added structure to account for dependencies between the y_j) or *canonical regression*:

$$\sum_j \alpha_j y_j = \sum_i \beta_i x_i + \varepsilon$$

(the left-hand side is “the most predictable linear combination”).

The traditional assumptions of canonical regression are too restrictive: this article relaxes them and derives the asymptotic distribution of the coefficients, in order to design statistical tests.

Forwards and European options on CDO tranches

J. Hull and Al. White
Journal of credit risk (2007)

Options on CDOs, once the parameters (default probability, expected recovery rate) have been estimated, are not that different from vanilla European options.

The article also clearly recalls what CDS and CDO are:

- In a *credit default swap* (CDS), the buyer makes periodic payments (quarterly in arrears) until default or maturity; in case of default (credit rating change, delayed payment, bankruptcy, etc.), the sellers pays the notional value times one minus the recovery rate (and the buyer makes a final accrual payment);
- A *collateralized debt obligation* (CDO) is a claim on a portfolio of CDS; the portfolio is cut into *tranches* (the order statistics of the CDS);
- iTraxx are CDO tranches on 125 European firms;
- CDX are CDO tranches on 125 US firms.

Modelling asymmetric exchange rate dependence
A.J. Patten (2005)

Conditional copulas, i.e., the colula of $XY|Z$, can be used to assess how the relation between two variables depends on a third.

(Instead of considering a copula depending on a an exogenous variable, one could consider a higher-dimensional copula – but the exogenous variable likely plays a very different role.)

The performance of model-based option trading strategies
B. Eraker

Option pricing models should not be assessed by comparing predicted and actual prices but by looking at the profitability of the corresponding strategy (in efficient markets, these would be equivalent).

The weights in the resulting strategy depend on the price difference and its sensitivity to estimation errors – this is an optimization problem.

Improved option pricing using artificial neural networks and bootstrap methods
P.R. Lajbcygier anf J.T. Connor
International journal of neural systems (1997)

If you are unsatisfied with your option pricing model, just try to predict its residuals with a neural network, a bootstrap or a bagging algorithm.

Non-parametric determination of real-time lag structure between two time series: the “optimal thermal causal path” method

D. Sornette and A.-X. Zhou
arXiv:cond-mat/0408166

The time-warping algorithm can be generalized in a fuzzy (Boltzmann) way to make it robust to noise.

The authors apply these results to the study of causal relations between macroeconomic time series.

On developing a financial prediction system: pitfalls and possibilities
S. Zemke (2002)

A bullet-point list of *machine learning* ideas to be applied to finance.

Model uncertainty and forecasting, a practitioner point of view
B. Bellone and E. Michaux (2006)

The article examined several ways of tackling model uncertainty:

- Linear regression bayesian model averaging (BMA), good in the short term;
- Dynamic factor models (DFA, i.e., regression on the factors of a factor analysis and their lags), good in the long term;
- Median BMA (model obtained from the variables with an inclusion probability beyond 1/2);
- General-to-specific (GETS) algorithm (a stepwise variable selection, with multiple steps and tests).

The authors use a Scilab econometric toolbox, “Grocer”, developed at the ENSAE.

***Momentum, reversal
and the trading behaviors of institutions***
R.C. Gutierrez and C.A. Prinsky
Journal of financial markets (2007)

Cumulated residual returns (from a 5-year CAPM model) can help devise a long-term profitable strategy, while the other component of the momentum (“relative momentum”) reverts after one year.

The article builds a long-short portfolio on the signal

$$\alpha = \frac{\text{cumulated residual returns}}{\sqrt{\text{cumulated variance of the residual returns}}}.$$

This effect is linked to institutional ownership.

***Macroeconomic factors
and Japan’s industry risk***
P. Nguyen
**Journal of multinational financial management
(2007)**

The *risk* of an industry can be defined as the average cash flow, weighted by firm size, divided by the (equal-weighted) volatility of those cash flows.

***Analyzing digits for portfolio formation
and index tracking***
P.N. Posch and W.A. Kreiner

The Newcomb–Benford law (or *first-digit law*),

$$P[X_1 = d] = \log_{10} \left(1 + \frac{1}{d} \right), \quad d \in \llbracket 1, 9 \rrbracket$$

is already used to detect fraud in tax sheets and company reports.

The authors put this distribution in a 1-parameter family

$$P_d(\lambda) \propto (d+1)^{1-\lambda} - d^{1-\lambda}$$

and compute this parameter, the *digital-fit factor* (DFF) for the price of the members of an index: it moves in the opposite direction as the index (the incorrectly use correlation to assess this – the time series are integrated).

They then try to use it to design an investment strategy, but their strategy is merely a leverage-increasing strategy, and they even forget to use their DFF...

***A statistical derivation
of the significant-digit law***
T.P. Hill
Statistical science (1996)

(Theoretical article on Benford’s Law.)

***Synchronizing multivariate
financial time series***
F. Audrino and P. Bühlmann (2001)

When combining data from markets in different time zones, care should be taken: two time series X , Y from

(say) New York and London can be seen as sampled at two different times, London close and New York close, with every other value missing. This is a missing value problem: models can be fitted using the EM algorithm.

The article applies this idea to the CCC-GARCH(1,1) model.

Alternatively, one can use one data point per day at a time when both markets are opened.

With weekly data, the problem disappears.

***Correlations and volatilities
of asynchronous data***
P. Burns et al. (1998)

Earlier article on the same subject.

***Why risk and return are uncorrelated:
a relative status approach***
E. Falkenstein (2006)

Expected utility models where utility is a function of the wealth relative to other market participants predict there is no risk premium.

Long-term dependence in stock returns
J.T. Barkoulas and C.F. Baum

Long memory (or “fractal dynamics”) can be tested using:

- Hurst’s rescaled-range (R/S) analysis;
- Lo’s modified R/S analysis;
- Geweke’s spectral regression: in an ARFIMA model,

$$\Phi(L)(1-L)^d(Y_t - \delta) = \Theta(L)\varepsilon_t$$

$$(1-L)^d = \sum_{k \geq 0} \frac{\Gamma(k-d)}{\Gamma(-d)\Gamma(k+1)} L^k$$

the fractional integration parameter d can be estimated as the opposite of the slope in the regression

$$\ln I(\xi) \sim \ln \sin^2 \frac{\xi}{2}$$

where $I(\xi)$ is the periodogram of y at frequency ξ .

Some stocks exhibit long memory, but the effects disappear when they are aggregated into stock indices.

***Residual-based tests for fractional
cointegration: a Monte Carlo study***
I. Dittmann (1998)

Comparison of many *fractional* cointegration tests (Geweke, modified rescaled range, ADF, etc.): prefer the Phillips–Perron T -test, it is usually more powerful.

Symbolic representation of long time-series
G. Hébrail and B. Huhueney

To plot a very large and somewhat periodic time series, perform a fast Fourier transform (FFT) to find the

largest period, cut the time series accordingly, cluster the chunks with a self-organizing map (SOM) and use a different icon for each cell.

***Dynamic portfolio selection
by augmenting the asset space***
M.W. Brandt and P. Santa-Clara
Journal of finance (2006)

You can replace the (difficult) choice of a dynamic strategy by a static choice of managed portfolios; the authors use a constant linear combination of “state variables” and maximize

$$E \left[(\theta z)' r - \frac{\gamma}{2} (\theta z)' r r' (\theta z) \right]$$

where z are the state variables, θ their weights, θz the weight of the stocks, r the forward returns, γ the risk aversion.

***On default correlation:
a copula function approach***
D.X. Li
RiskMetrics (2000)

(Non-gaussian) copulas should be used to model the joint distribution of time-until-default (some people use a binary variable indicating a default in the next year, which is very imprecise) instead of the correlation (as CreditMetrics does).

This can be used to price credit default swaps or first-to-default swaps.

Analyzing active investment strategies
M. Ammann et al.
Journal of portfolio management (2006)

Analysis of variance (anova) can help find out which strategy (“style”) an asset manager is following.

Managing guarantees
M.A.H. Dempster
Journal of portfolio management (2006)

The methods of asset-liability management (ALM), *i.e.*, dynamic stochastic programming, can be used to implement guaranteed strategies, thereby competing with portfolio insurance.

The technical details might be “a challenge even for sophisticated users”.

Pairs trading: the new generation
S. Hartman et al.
ABN Amro (2006)

A pairs trading strategy can be improved by selecting pairs with attractive fundamentals (or even playing them against pairs with poor fundamentals).

***A liquidity-augmented
capital asset pricing model***
W. Liu

Journal of financial economics (2006)

The CAPM (capital asset pricing model) overlooked the *liquidity premium*.

To account for all the dimensions of liquidity (quantity, speed, cost, price impact – speed is often forgotten), the author develops yet another measure:

$$LM_x = \left(n_x + \frac{\lambda_x}{\text{turnover}_x} \right) \frac{21x}{N_x}$$

where $x = 1, 2, 12$ months, n_x is the number of zero daily trading volume in the past x months, N_x is the number of trading days in the past x months, turnover_x is the sum of the daily turnover (number of shares exchanged divided by the number of outstanding shares) over the past x months, λ_x is chosen so that

$$0 < \frac{\lambda_x}{\text{turnover}_x} < 1$$

for all stocks.

***Equity portfolios generated by functions
of ranked market weights***
R. Fernholz (Intech, 2000)

Functionally-generated portfolios have weights of the form

$$w_i = f(\text{MCap}_i).$$

They can be generalized to

$$w_i = f(\text{rank}(\text{MCap})_i).$$

***Parameters for estimation of entropy to study
price manipulation in stock market***
Y.V. Reddy and A. Sebastin

Confusing article presenting various entropy estimators (approximate entropy, sample entropy) and applying them to price, time, quantity data.

***Portfolio choice with jumps:
a closed form solution***
Y. Aït-Sahalia et al. (2006)

By imposing a factor structure on the asset returns, one can derive a closed form solution to the portfolio choice problem for Levy returns.

(The article is technical, I have not read the details.)

***Forecasting exchange rates:
a robust regression approach***
A. Preminger and R. Franck (2005)

Robust regression can also be used to fit autoregressive models.

***The PIN anomaly
around M&A announcements***
N. Aktas et al.
Journal of financial markets (2006)

The *probability of informed trading* (PIN) can be estimated from the following model (add a few independence assumptions), via maximum likelihood:

- α : probability of information availability on a given day;
- δ : probability of a positive price change after an event;
- μ : rate of arrival of uninformed buyers and sellers;
- ε : rate of arrival of informed traders;
- $$\text{PIN} = \frac{\alpha\mu}{\alpha\mu + 2\varepsilon}$$

***Fund manager use of public information:
new evidence on managerial skills***
M. Lacperczyk and A. Seru
Journal of finance (2007)

The *reliance on public information* (RPI), defined as the R^2 of the regression of holdings changes against analyst recommendation changes, is a measure of a portfolio manager's lack of skill.

***On the use of data envelopment analysis in
assessing local and global performances of
hedge funds***
H. Nguyen-Thi-Thanh (2006)

Yet another article on the applications of data envelopment analysis (DEA) to hedge fund comparison – previous ones forgot the fees.

***On the relationship between changes in stock
prices and bond yield in the G7 countries:
wavelet analysis***
S. Kim and F. In
**Journal of international financial markets,
institutions and money (2007)**

Wavelet correction analysis (a time series of length N yields wavelet coefficients that can be arranged in a pyramid, $N/2$ coefficient on the first row, $N/4$ on the second, etc.; one can then compute the variance (and covariance, if you have several time series) of each of these rows) allows the authors to examine short- and long-term relations between stock and bond returns: except in Japan, they are negatively related.

***Mean-semivariance behavior: downside risk
and capital asset pricing***
J. Estrada
**International review of economics and finance
(2007)**

The CAPM (capital asset pricing model) can be augmented by a downside risk:

$$\text{return} = \alpha + \beta \cdot (\text{market returns}) + \beta_- \cdot (\text{market returns})_-$$

The authors prefer to *replace* the beta β by the downside beta β_-

***The fundamentals
of commodity futures returns***
G.B. Gorton et al (2007)

Inventories have a non-linear effect on the risk premium.

***Beyond the gaussian copula:
stochastic and local correlation***
X. Burtschell et al.
Journal of credit risk (2007)

People still use the *1-factor gaussian copula*

$$\begin{aligned} \text{Cor}(X_i, X) &= \rho \\ i \neq j &\implies X_i|X \perp\!\!\!\perp X_j|X \end{aligned}$$

to price CDO tranches. The authors suggest a *stochastic correlation model* with a gaussian copula of the form

$$\begin{aligned} \text{Cor}(X_i, X) &= \rho_i \\ i \neq j &\implies X_i|X \perp\!\!\!\perp X_j|X \\ \rho_i &\in \{0, \rho, 1\} \end{aligned}$$

where the ρ_i are discrete random variables.

***Extreme returns from extreme value stocks:
enhancing the value premium***
K. Anderson and C. Brooks
Journal of investing (2007)

The relation between the P/E and future returns is not linear: considering quintiles is not sufficient. The authors use the *idiosyncratic P/E*, defined as the current price divided by the earnings over the past 8 years, corrected for the influence of market, size and sector.

***Residual income approach
to equity country selection***
S. Desrosiers et al.
Financial analysts journal (2007)

Valuation methods usually applied to companies (P/E, ERP, etc.) can also be applied to countries.

Dynamic nonmyopic portfolio behavior
T.S. Kim and E. Omberg
Review of financial studies (1996)

In the *Kelly principle* (see below, Herlemont (2004)), one can replace growth rate maximization by expected utility maximization.

Portfolio selection with transaction costs
M.H.A. Davis and A.R. Norman
Mathematics of operations research (1990)

The Kelly strategy, in continuous time, with transaction costs.

Investment performance measurement, risk tolerance and optimal portfolio choice
M. Musiela and T. Zariphopoulou (2007)

In this and related articles, the second author advocates that utility or other satisfaction measures should be time-dependent – *forward utility, dynamic performance*, etc.

Revisiting calendar anomalies in Asian stock markets using a stochastic dominance approach
H.H. Lean et al.
Journal of multinational financial management (2006)

First order *stochastic dominance* for the *January effect* has disappeared; weekly and monthly seasonality is still present (there are statistical tests for stochastic dominance, such as the Davidson and Duclos test).

Stochastic dominance is a very strong result, but it captures effects not visible if you only look at the first two moments.

Mean reversion versus random walk in G7 stock prices: evidence from multiple trend break unit root tests
P.K. Narayan and R. Smyth
Journal of international financial markets, institutions and money (2007)

Even after accounting for multiple breaks in the trend, index prices are not stationary.

Inference in inequality from household survey data
D. Bhattacharya (2006)
Journal of econometrics (2007)

Using the survey design can improve the estimator of the *Gini coefficient*.

On the importance of measuring payout yield: implications for empirical asset pricing
J. Boudoukh et al.
Journal of finance (2007)

Try replacing dividend yield by *payout* (dividends plus repurchases) or net payout (dividends plus repurchases minus issuances) yields.

The impact of constraints on value-added A non-cynical approach
B. Scherer and X. Xu
Journal of portfolio management (2007)

Confusing article trying to explain how to use Lagrange multipliers to measure the impact of constraints on the information ratio (the authors have apparently never heard about “matrices”, they forget to define the quantities in their formulas, they do not understand the

difference between “term” (an element of a sum) and “factor” (an element of a product), etc.).

Alternative metrics
S. Zaker

Journal of alternative investments (2007)

Empty article reminding us to provide *confidence intervals* whenever we compute information ratios (IR).

Building a hedge fund portfolio with kurtosis and skewness
M. Anson et al.

Journal of alternative investments (2007)

Polynomial goal programming (PGP) solves multi-objective optimization problems as follows:

- Solve the problem for each objective separately; let f_i^{Max} be the optimum of the i th objective f_i ;
- Minimize $\prod (1 + (f_i^{\text{Max}} - f_i))^{\alpha_i}$ under the same constraints; the α_i are user-chosen parameters.

The authors prefer PGP to a linear combination of the objectives – the methods are actually equivalent, under a monotonic transformation of the objective functions.

An analysis of trade-size clustering and its relation to stealth trading
G.J. Alexander and M.A. Peterson
Journal of financial econometrics (2007)

Stealth traders tend to use medium-sized *rounded* (500, 1000, 5000) transaction in an attempt to disguise their trades.

Optimizing benchmark-based portfolios with hedge funds
I. Popova et al.

Journal of alternative investments (2007)

To maximize the expected utility, the probability of outperforming a benchmark, possibly corrected with the expected shortfall, in a non-gaussian set-up:

- generate N scenarios; the authors model hedge fund returns as a mixture of two gaussians, designed to fit the first four moments, corrected for various biases (survivorship, autocorrelation, etc.);
- optimize; this gives an upper bound on the true optimal value;
- estimate the expected utility of the resulting weights on a new random sample of N scenarios; you get a lower bound;
- if the confidence interval given by those bounds is too small, increase N .

Shrinking the covariance matrix
D.J. Disatnik and S. Benninga
Journal of portfolio management (2007)

Comparison of several covariance matrix estimators (sample variance, shrinkage with an optimized shrinkage coefficient, equal-weighted portfolio of variance estimators, diagonal matrix): the shrinkage estimators

give better risk forecasts for the unconstrained minimum variance portfolio but no estimator leads to a good forecast of the standard deviation of the constrained (long-only) minimum variance portfolio.

***How do performance measures perform?
Examining precision and stability***

G. Hübner

Journal of portfolio management (2007)

Performance or risk measures such as *beta*, *Jensen's alpha* (the intercept of the regression of the returns against the market returns), *Treynor ratio*

$$GTR_i = \alpha_i B_{\text{market}} R / B_i R$$

where $r_i = \alpha_i + B_i R + \varepsilon_i$, *information ratio* (IR), *Sortino ratio*, Modigliani's M^2 (not defined), Ω can be compared with:

- the rank correlation;
- the *concordance correlation coefficient*

$$\rho = \frac{2\sigma_{XY}}{\sigma_X^2 + \sigma_Y^2 + (\mu_X - \mu_Y)^2};$$

- Cohen's Kappa, after binning the stocks into winner and losers for each measure (it estimates the number of matching pairs not due to chance),

$$\kappa = 2 \frac{WW + LL}{N} - 1.$$

The author prefers the Treynor ratio.

***Where do alphas come from?
A new measure of the value of active
investment management***

A.W. Lo (2007)

Performance is traditionnally measured by ratios,

$$\text{Sharpe ratio} = \frac{E[\text{excess returns}]}{\sigma(\text{excess returns})}$$

$$\text{Treynor ratio} = \frac{E[\text{excess returns}]}{\beta}$$

$$\text{Information ratio} = \frac{\alpha}{\sigma(\text{noise})}$$

where

$$\text{excess returns} = \alpha + \beta \cdot (\text{market excess returns}) + \text{noise}$$

(for our market-neutral strategies, $\beta = 0$, so the Sharpe ratio and the information coefficient coincide).

The author suggests a decomposition of the expected portfolio returns into a passive and a non-passive com-

ponents:

$$\begin{aligned} E[\text{excess returns}] &= E \left[\sum_i w_i r_i \right] \\ &= \sum_i E[w_i r_i] \\ &= \sum_i (\text{Cov}(w_i, r_i) + E[w_i]E[r_i]) \\ &= \sum_i \text{Cov}(w_i, r_i) + \sum_i E[w_i]E[r_i] \\ \text{Active component} &= \sum_i \text{Cov}(w_i, r_i) \\ \text{Passive component} &= \sum_i E[w_i]E[r_i] \end{aligned}$$

$$\text{Active ratio} = \frac{\text{active component}}{\text{active component} + \text{passive component}}$$

***Exchange rates and the conversion of
currency-specific risk premia***
A. Eisenberg and M. Rudolf
European financial management (2007)

In an economy without arbitrage oportunities, there is a positive *stochastic discount factor* (SDF) that prices all assets

$$P_{i,t} = E_t \left[\frac{M_T}{M_t} X_{i,T} \right]$$

where $X_{i,T}$ is the payoff of asset i and M_T/M_t is the SDF.

In an international setup, there is one SDF for each currency. In a complete market, the exchange rate can conveert stochastic discount factors accross currencies (in incomplete markets, the SDF is not unique).

Hedging by sequential regressions revisited
A. Černý and J. Kallsen (2007)

One can compute a hedging strategy in an incomplete market in a sequence of 1-period least squares regressions backward in time.

The promise and peril of real options
A. Damodaran

Standard discounted cash flow models assume that the cash flows are deterministic; they are actually probabilistic and even contain *embedded options*, which have to be taken into account to properly value a cash flow or any corporate decision.

Examples include: the option to delay, expand, abandon a project, patents, natural ressources, etc.

The article recalls what an option is.

***Investment under uncertainty
and volatility estimation risk***
G. Dotsis et al.

Real option pricing requires an estimate of the volatility from very few data points, but practitioners often neglect to compute the resulting confidence interval: it can be large, and asymmetric.

***Evolution analysis of large-scale software
systems using design structure matrix
and design rule theory***
M.J. LaMantia et al.

Modular software is good: the option (as in “option pricing” – these are *real options*) to replace a component makes it more valuable – a counter-example being the “complexity disaster” Windows Vista.

The *design structure matrix* (DSM) represents dependencies between the modules; once spotted, circular dependencies can be removed by adding one more module.

***The effect of shortfall as a risk measure for
portfolios with hedge funds***
A. Lucas and a. Siegmann

The choice of the downside risk measure used to optimize a portfolio of hedge funds is important: the expected shortfall can lower small losses while increasing the risk of large crashes; quadratic shortfall and semi-variance do not have this problem.

***Variance, volatility swaps
and hedging your equity portfolio***
S.E. Satchell
Journal of asset management (2007)
(editorial)

Volatility and variance swaps (whose valuation and hedging are model-independent in a jump-free world) seem to provide a hedge against market collapse – as did *portfolio insurance* until October 1987.

***Volatility filter for index tracking and
long-short market-neutral strategies***
J. Miao
Journal of asset management (2007)

Only rebalance your portfolio when the volatility regime changes.

Portfolio size and diversification
L.R. Irala and P. Patil (2007)

Portfolio diversification benefits become negligible beyond 15 stocks – other authors claim it never becomes negligible.

***Nonparametric estimation of state-price
densities implicit in financial asset prices***
Y. Ait-Sahalia and A.W. Lo
Journal of finance (1998)

The *state price density* (SPD, *i.e.*, the density of the prices of Arrow–Debreu securities, often called *risk-neutral density*) can be computed:

- parametrically, using a model of the underlying asset price dynamics (e.g., a geometric brownian motion for the Black–Scholes model);
- parametrically, by imposing the family of the distribution and using actual option prices;
- in a bayesian way (as above, but with a prior).

The authors present a non-parametric estimator of the risk-neutral density using a *kernel regression* (sometimes called *local regression*).

***Effects of stochastic interest rates and
volatility on contingent claims***
N. Kunitomo and Y.-J. Kim (2005)

Black-Scholes option pricing makes three assumptions: the log-returns of the underlying are gaussian, the volatility is constant, the interest rate is constant. Generalizations often only relax one of those assumptions: the authors relax two of them.

***Option valuation with conditional
heteroskedasticity and non-normality***
P. Christoffersen et al. (2006)

Discrete risk-neutral valuation.

***The shape and term structure of the index
option smirk: why multifactor stochastic
volatility models work so well***
P. Christoffersen et al. (2007)

Prefer 2-factor stochastic volatility models:

$$dS = rSdt + \sqrt{V_1}Sdz_1 + \sqrt{V_2}Sdz_2$$

$$dV_1 = (a_1 - b_1V_1)dt + \sigma_1\sqrt{V_1}dz_3$$

$$dV_2 = (a_2 - b_2V_2)dt + \sigma_2\sqrt{V_2}dz_4$$

***Options prices under arithmetic brownian
motion and their implication for
modern derivatives pricing***
Q. Liu (2007)

Risk-neutral option pricing under *arithmetic* brownian motion (unrealistic, but a good interview question) violates the no-arbitrage principle.

***The risk and return characteristics of the
buy-write strategy on the Russel 2000 index***
N. Kapadia and E. Szado
Journal of alternative investments (2007)

The *buy-write strategy* (write a call and buy the underlying) on the S&P 500 beats the S&P 500 on a risk-adjusted basis (lower returns but much lower volatility); for the Russel 2000, it still works with 1-month at-the-money options.

Commonality in the time-variation of stock-stock and stock-bond return comovements

R.A. Connolly et al.

Journal of financial markets (2007)

Implied volatility (of equity index options) can help predict the link between stock and bond returns.

A reduced rank regression approach to coincident and leading indexes building

G. Cubadda (2005)

To monitor the business cycle, one can build a *coincident index* (that changes when a recession occurs) and a *leading index* (that changes before a recession starts).

The article uses *reduced rank regression* (a vector autoregressive (VAR) model with a reduced rank restriction) to build those indices from a set of cointegrated macroeconomic variables.

Do losses linger?

R. Garvey et al.

Journal of portfolio management (2007)

Traders who experienced a loss in the morning are more risk-seeking in the afternoon: this *disposition effect* is in agreement with *prospect theory*, defined here as the maximization of an *s-shaped* “utility”, function of gains and losses instead of total wealth.

Expected returns and Markov-switching illiquidity

T.R. Henry and J.T. Scruggs (2007)

When the markets are liquid, the prices are driven by fundamentals; when the markets become illiquid, trading volume has a greater impact on prices. The authors use a 2-state Markov switching model for illiquidity, returns and volatility to quantify this *illiquidity premium*.

The market P/E ratio, earnings trends and stock return forecasts

R.A. Weigand and R. Irons

Journal of portfolio management (2007)

The relation between P/E and future returns is linear when $P/E \geq 20$, but not beyond (in the US).

Coming to portfolios near you: investment ideas you should be paying more attention to

S. Welch

Journal of wealth management (2007)

“Postmodern portfolio theory” uses:

- a downside risk measure;
- minimum acceptable returns (MAR);
- non-gaussian returns.

The article also suggests to separate the strategy into *core* (passive) and *satellite* (absolute returns).

Tilted nonparametric estimation of volatility functions

P.C.B. Phillips and K.-L. Xu (2007)

In a heteroskedastic regression

$$Y = m(X) + \sigma(X)\varepsilon$$

or in a non-linear time-series model

$$Y_i = m(Y_{i-1}) + \sigma(Y_{i-1})\varepsilon_i$$

one can fit the variance σ^2 by local polynomials, à la Nadaraya–Watson.

Global and regional sources of risk in equity markets: evidence from factor models with time-varying conditional skewness

A.R. Hashmi and A.S. Tay (2004)

The GARCH model can be generalized with modified Student innovations (to account for skewness) and auto-regressive skewness.

Market timing with aggregate and idiosyncratic stock volatilities

H. Guo and J. Higbee

Journal of portfolio management (2007)

The model

$$\text{market returns} \sim \text{market variance}$$

is not significant, but if you add idiosyncratic volatility, it is. This can be used to time the market.

Optimal gearing: not all long-short portfolios are efficient

S. Johnson et al.

Journal of portfolio management (2007)

Confusing article: the authors, who worship Grinold and Kahn (for the latter, this is even self-worshipping) and do not understand the difference between = and \implies , try to prevent the reader from making even worse confusions.

We don't quite know what we are talking about when we are talking about volatility

D. Goldstein and N.N. Taleb

Journal of portfolio management (2007)

Warning about the confusion between mean absolute deviation (MAD) and standard deviation.

***Implied volatility from Asian options
via Monte Carlo methods***
C.-O. Ewald et al.

Many people calibrate the volatility surface using European options and then use it with Asian ones (e.g., to compute their vega), oblivious to the dependence of the volatility surface on the type of option.

The article uses the “logarithm trick”

$$\frac{\partial E[h(X_\sigma)]}{\partial \sigma} = E \left[h(X_\sigma) \frac{\log f(X_\sigma, \sigma)}{d\sigma} \right]$$

(where $f(\cdot, \sigma)$ is the density of the law of X_σ)

to express the vega of an Asian option as a weighted expectation of $h(X_\sigma)$, which can then be computed via Monte Carlo methods.

***Optimizing the retirement portfolio: asset
allocation, annuitization and risk aversion***
W.J. Horneff (2006)

Investment advice for retirement is either *life annuity* (i.e., the payment of the same sum every year until death) or *phased withdrawal plan* (a normal portfolio, say 60% stock, 40% bond, from which we take a fixed proportion for consumption every year – the proportion can also be chosen as $1/T$, where T is the maximum or expected number of remaining years of life).

The article suggests a blend of the two. They do not seem to mention *portfolio insurance*.

***A multivariate commodity analysis and
applications to risk management***
R.H. Börger et al.

Asset (here, commodity futures) returns are not gaussian and can be modeled by a *generalized hyperbolic distribution*, the mixture of a gaussian and a *generalized inverse gaussian*:

$$X = \mu + W\gamma + \sqrt{W}AZ$$

where $Z \sim N(0_k, I_k)$, $W \sim GIG(\lambda, \chi, \psi)$, $\mu, \lambda \in \mathbf{R}^d$, $Z, A \in \mathbf{R}^{d \times k}$.

This gives better value-at-risk and expected shortfall estimations.

***The m out of n provisional call: an auxiliary
reversed binomial tree approximation***
Q. Liu (2006)

A *convertible bond* (CB) is a bond, with an option to transform it into a stock.

A *hard call* is a CB which may be exercised anytime after (say) the first two years.

A *soft-call* is a CB which may only be exercised if the underlying stock closes above a prespecified trigger m out of n consecutive days.

Even though this is a path-dependent option, it can be priced with a binomial “tree” (a lattice, really) without keeping all the path histories in memory.

Composing contracts:

an adventure in financial engineering
S. Peyton Jones et al.
Functional Pearl, ICFP (2000)

Haskell (or any other functional language) can be used to *describe* complicated financial contracts (options on options on...on options, with complicated cash flows) – the industry lack such a precise notation – and then to price them (but there are still optimizations to be made; and one might prefer to use C for the final computations).

***Constructive homological algebra
and applications***
J. Rubio and F. Sergeraert (2006)

Another unlikely application of functional programming.

Random walks and electric networks
P.G. Doyle and J.L. Snell (1984)
arXiv:math/0001057

Around Polya’s theorem, claiming that random walks return to the origin in dimension 2 but not beyond – in other words, wind instruments are possible in our 3-dimensional world but not in Flatland.

***The electrical resistance of a graph captures its
commute and cover time*** A.K. Chandra et al.
(Article on the same subject.)

***Random matrix theory and robust covariance
matrix estimation for financial data***
G. Frahm and U. Jaekel
arXiv:physics/0503007

The authors “develop” (physicists tend to forget to define the quantities the use) a robust M -estimator of the variance matrix, the *spectral estimator* for which the largest eigenvalue follows the Marčenko–Pastur distribution, even for a heavy-tailed elliptic random vector.

***Stochastic programming models for asset
liability management***
R. Kouwenberg and S.A. Zenios (2001)
in *Handbook of asset and liability management*

Scenario trees for a stochastic program, in an asset liability management (ALM) context, can be generated with one of the following methods:

- random sampling from the model (you might want to trim down the resulting tree, as in *importance sampling*);
- adjusted random sampling (use *antithetic sampling to fit every odd moment of the underlying distribution*);
- produce returns that match the first few moments of the distribution (this optimization problem can be longer to solve than the final ALM problem).

You should make sure not to introduce arbitrage opportunities because of discretization or approximation

errors: the no-arbitrage condition can be added as a linear constraint.

Stochastic programming needs model generation tools – in particular, there is still no stochastic optimization language.

ALM can also be tackled with mean-variance optimization: just add a “liability” asset with a prescribed weight.

This chapter also defines a *myopic* investor: a multi-period investor who behaves as a 1-period investor, for instance because of his constant relative risk aversion (CRRA), if he has a power utility.

***Extending algebraic modelling languages
for stochastic programming***
P. Valente et al.

It is easier to formulate optimization problems using a declarative language (AMPL, GAMS, AIMMS, MPL, to name a few) than with a list of huge matrices.

This article advocates the use of a similar language, SAMPL, for *stochastic programs*. It also reviews the various types of stochastic programs and gives a few examples (in particular, how to turn a multistage stochastic program into a deterministic one: expand all the scenarios and add non-anticipatory constraints).

SAMPL is implemented in SPInE (commercial).

Also check SMPS (not an algebraic language).

Efficient tests of stock return predictability
J.Y. Campbell et al.
Journal of financial economics (2006)

When performing statistical tests, do not overlook the effects of *autocorrelation*.

***Optimal continuous-time hedging
with leptokurtic returns***
A. Černý (2005)

When the market is incomplete, perfect hedging is impossible and one can resort to utility-based (dynamic) mean-variance hedging.

***Portfolio optimization with stochastic
dominance constraints***
D. Dentcheva and A. Ruszczyński (2003)

In a scenario-based optimization, stochastic dominance constraints are straightforward to express.

(*missing title*)

The ARMA model can be generalized into a non-linear ARMA (NARMA)

$$y_{n+1} = F(y_n, \dots, y_{n-k}, \varepsilon_n, \dots, \varepsilon_{n-\ell}) + \varepsilon_{n+1}$$

or even a non-linear ARMA with exogenous variables (NARMAX) model

$$y_{n+1} = F(y_n, \dots, y_{n-k}, \varepsilon_n, \dots, \varepsilon_{n-\ell}, x_n, \dots, x_{n-k}) + \varepsilon_{n+1}$$

Universal portfolios
T.M. Cover
Mathematical finance (1991)

Given the history of total returns of a set of stocks x_{tj} , one can compute, a posteriori, the best constant-weight (rebalanced) strategy and try to beat it or at least to attain the same asymptotic rate of growth, without peering into the future but by allowing for changing weights.

The author suggests, at each time k , to average all the possible constant-weight strategies \mathbf{b} , weighing them by their past performance $S_k(\mathbf{b})$:

$$b(1) = \left(\frac{1}{m}, \dots, \frac{1}{m} \right)$$

$$b(k+1) = \frac{\int_B \mathbf{b} S_k(\mathbf{b}) d\mathbf{b}}{\int_B S_k(\mathbf{b}) d\mathbf{b}}$$

$$S_k(\mathbf{b}) = \prod_{t=1}^k \mathbf{b}' \mathbf{x}_t$$

where $B = \{ \mathbf{b} \in \mathbf{R}^m : \mathbf{b} \geq 0, \mathbf{b}' \mathbf{1} = 1 \}$ is the set of long-only fully-invested strategies.

This works, simply because the wealth of the strategy is the average wealth of the experts, all of which have an exponential growth rate, and an average of exponentials has (under suitable assumptions) the same asymptotic growth rate as the maximum. Buy-and-hold strategies are beaten because they are not diversified enough.

For $m = 2$ stocks, the computations are easy. Using

$$\int_{\substack{b_1, b_2 \geq 0 \\ b_1 + b_2 = 1}} f(b_1, b_2) db = \int_0^1 f(u, 1-u) du$$

$$B(1+x, 1+y) = \int_0^1 u^x (1-u)^y du$$

one gets

$$b_1(n) = \frac{\sum_{P_1 \sqcup P_2 = \llbracket 1, n \rrbracket} \prod_{t \in P_1} x_{t1} \prod_{t \in P_2} x_{t2} B(2 + |P_1|, 1 + |P_2|)}{\sum_{P_1 \sqcup P_2 = \llbracket 1, n \rrbracket} \prod_{t \in P_1} x_{t1} \prod_{t \in P_2} x_{t2} B(1 + |P_1|, 1 + |P_2|)}$$

where $P_1 \sqcup P_2 = \llbracket 1, n \rrbracket$ are the partitions of $\llbracket 1, n \rrbracket$ in two parts. The beta function is related to the binomial coefficients and can be computed in the same way.

In dimension m , the computations are similar, with a “multivariate beta function” whose computations require an m -dimensional array. Since the sums have m^n terms, the complexity is $O(m^n + n^m)$. Last, but not least, the important terms in those huge sums are very close to one: numerical instability prevents us from doing the computations in this way. (Since these are high-dimensional integrals, monte Carlo methods (importance sampling) might be useful.)

There are no assumptions for this strategy (this is a worst-case scenario), but the constant-weight benchmark is only optimal if there is no time-dependence in the data, *i.e.*, if the data are iid.

This is an expanding window strategy: with enough data, the weights will hardly move – this is not a dynamic strategy.

Efficient algorithms for universal portfolios
A. Kalai and S. Vempala
Journal of machine learning research (2002)

The definition of Cover's universal portfolio is exactly the Monte Carlo Markov Chain (MCMC) setup:

$$w_{\text{universal}} = \frac{\int w \text{Performance}(w) dw}{\int \text{Performance}(w) dw}.$$

To prove the convergence of the chain, the authors do not integrate over the simplex of all portfolios but limit themselves to those all of whose weights are at least δ_0 and they slightly modify the performance function.

Nonparametric kernel-based sequential investment strategies
L. Györfi et al. (2005)

In contrast with Cover's approach, the authors consider a stationary and ergodic market: there can be time-dependency; their benchmark is the *log-optimal portfolio*

$$b_n = \text{Argmax} E[\log(b'_n x_n) | x_{-\infty \rightarrow n-1}].$$

A *universal strategy* is a strategy that attains the same (asymptotic) rate of return without knowing the distribution.

The *histogram-based strategy* is a performance-weighted average of elementary strategies or *experts*; an expert is the best strategy, over windows of size k , according to the past history, corresponding to a discretization ℓ of the past returns. They consider all possible window sizes and the discretizations are defined from nested partitions of the space of returns, so that the size of the cells uniformly converge to zero.

(This is not implementable: most of the cells would be empty, unless you have a humongous amount of data; it will converge very slowly.)

The *kernel-based strategy* replaces the rigid partitions by a moving window:

$$b^{(k,\ell)}(x_{1 \rightarrow n-1}, s) = \text{Argmax}_{\substack{b \geq 0 \\ b'1=1}} \prod_{\substack{k < i < n \\ \|x_{i-k \rightarrow i-1} - s\| \leq c/\ell}} b' x_i$$

where $x_{1 \rightarrow n-1}$ is the whole history and $s = x_{n-k \rightarrow n-1}$ is the recent history.

The *general kernel-based strategy* is

$$b^{(k,\ell)}(x_{1 \rightarrow n-1}, s) = \text{Argmax}_{\substack{b \geq 0 \\ b'1=1}} \frac{\sum_i w_i^{(k,\ell)} \log b' x_i}{\sum_i w_i^{(k,\ell)}} \\ w_i^{(k,\ell)} = K_k(\ell \cdot (x_{i-k \rightarrow i-1} - s))$$

where K_k is a kernel (on \mathbf{R}^{kd} , where d is the number of assets), such as $K_k = \mathbf{1}_{\|x\| \leq c}$.

This is an expanding window strategy; the stationarity assumption makes it non-robust to structural changes.

Universal portfolios with side information
T.M. Cover
IEEE transactions on information theory (1996)

In the definition of Cover's universal portfolio,

$$w_{\text{universal}} = \frac{\int w \text{Performance}(w) dw}{\int \text{Performance}(w) dw}$$

one can replace the uniform distribution dw by a Dirichlet($\frac{1}{2}, \dots, \frac{1}{2}$) prior – the worst-case performance is slightly better and, this being (bayesian) *conjugate* distribution, the computations are marginally faster.

Uniform or Dirichlet universal portfolios attain their worst-case performance for *Kelly market sequences*, *i.e.*, when, in each period, all stocks but one go bankrupt (similar to horse races, where a single horse wins).

This article also explains how to use side information: the benchmark no longer has constant weights but the weights are the function

$$\text{side information} \mapsto \text{weights}$$

that maximizes the total returns on the period. The corresponding universal weights are

$$w_{\text{universal}}(y) = \frac{\int w \text{Performance}(w|y) dw}{\int \text{Performance}(w|y) dw}$$

where y is the side information.

Universal portfolios can also be used to combine experts: if the experts have constant weights, just use them instead of all the constant reweighted strategies (the integrals become sums); even better, consider them as new assets, add them to the universe and compute the universal portfolio of this enlarged universe.

The article ends with some details about the exact computation of those portfolios, in the Dirichlet case – this is still exponential.

Gestion de portefeuille et croissance optimale
D. Herlemont (2004)
<http://yats.com/>

The *Kelly criterion* invests the same fraction of your wealth in a game (e.g., a coin-tossing game where you receive twice the value of your bet when you win); the fraction is chosen so as

- to maximize the long-term growth rate $\frac{1}{t} \log \frac{W_t}{W_0}$;
- to maximize the expectation of the logarithmic utility $u(W) = \log W$ (log-optimal portfolios are sometimes called *Kelly portfolios*);
- to maximize the median wealth;
- to minimize the expected time to reach a given wealth;
- to minimize the entropy (?).

The Kelly criterion can be generalized to any binomial setting (you earn α on tails and β on heads, as in *bracket tracking*, *i.e.*, profit taking and stop-loss rules) or for any distribution of returns.

Here are some more generalizations of the Kelly strategy:

- use power utility: this is the *fractional Kelly criterion*;
- impose a constraint on the maximum acceptable drawdown and only reinvest a constant fraction of the wealth in excess of the drawdown;
- maximize the growth rate of the utility:

$$\liminf \frac{1}{t} E[\text{utility } W(t)];$$

- add transaction costs – but the non-trading intervals can be very large and the rebalancing frequency very low (several years);

The Kelly criterion might still work if the asset has a negative trend: it only requires that $E[\text{returns}] > 0$, while a positive trend is the more restrictive condition $E[\log \text{returns}] > 0$; the Kelly criterion is a constantly-rebalanced strategy while the asset alone is a buy-and-hold strategy.

The drawdown of a Kelly strategy follows a power law with exponent 2 (under a gaussian assumption); even worse, assuming gaussian returns when they are skewed or have fat tails leads to an excessive leverage and larger losses.

The Kelly strategy is sometimes referred to as a *volatility pump*: for a log-normal process without drift, the optimal growth is proportional to the variance. D. Farmer likens this phenomena to tapping energy from waves or tides.

Cover's *universal portfolios* are a non-parametric analogue of the Kelly criterion:

- Cover averages the constant reweighted strategies, weighing them with their performance;
- Györfi et al. average experts, *i.e.*, non-parametric functions that use the returns in the past k periods to produce suggested weights;
- One could also average statistical experts, *i.e.*, parametric statistical models (regression, GARCH, etc.) that map previous returns to weights.

This article (mentions but does not) present a generalization of Györfi et al.'s non-parametric experts without a long-only constraint.

Optimal gambling systems for favorable games **L. Breiman (1961)**

In a favorable game, the *Kelly principle* bets each time the same fraction of the current wealth, chose so as to maximize the rate of growth or, equivalently, the expected logarithmic utility.

A new interpretation of information rate **J.L. Kelly (1956)**

Kelly's original, information-theoretic article.

Can we learn to predict the best stock?

A. Borodin et al.
Journal of artificial intelligence research (2004)

The authors add a new strategy to the list of portfolio selection algorithms:

- *exponentiated gradient*: greedily choose the best portfolio for yesterday's market with a penalty for moving far from yesterday's portfolio;
- Cover's universal portfolio:

$$b(k+1) = \frac{\int_B \mathbf{b} \text{Performance}_k(\mathbf{b}) d\mathbf{b}}{\int_B \text{Performance}_k(\mathbf{b}) d\mathbf{b}}$$

- where $d\mathbf{b}$ is the prior distribution on the weights, for instance a uniform or Dirichlet distribution;
- algorithms that predict the best stock, such as the prediction component of the Lempel-Ziv compression algorithm.

Choose a window size w , consider the stock log-returns in the previous two non-overlapping windows x_{-1} and x_{-2} and compute the cross-correlation matrix $\text{Cor}(x_{-2}, x_{-1})$. If stock i outperformed stock j in the most recent period and if the log-returns of i in period -2 are correlated with those of j in period -1 , shift your investment from stock i to stock j by a proportion

$$\begin{aligned} \text{claim}_{i \rightarrow j} &= 0 \quad \text{unless } \mu_{-1}(i) > \mu_{-1}(j) \\ &\quad \text{and } \text{Cor}(x_{-2}, x_{-1})(i, j) \\ \text{claim}_{i \rightarrow j} &= \text{Cor}(x_{-2}, x_{-1})(i, j) > 0 \\ &\quad + |\text{Cor}(x_{-2}, x_{-1})(i, i) -| \\ &\quad + |\text{Cor}(x_{-2}, x_{-1})(j, j) -| \end{aligned}$$

The strategy is too sensitive to the choice of the window size w , This can be improved on:

- Consider an equal-weighted average of all those strategies for $w \in \llbracket 2, 50 \rrbracket$;
- Instead of applying the strategy on stocks $\text{ANTICOR}_w(x_1, \dots, x_n)$, apply it on strategies: $\text{ANTICOR}_w(\text{ANTICOR}_2, \dots, \text{ANTICOR}_{50})$.

I would also try to change “correlation” into “cointegration”.

On the competitive theory and practice of portfolio selection **A. Borodin et al.**

Proceedings of the 4th Latin American Symposium on Theoretical Informatics (2000)

After an information-theoretic review of the portfolio selection problem, the authors present several prediction-based algorithms:

- the *add-beta prediction rule*, used to predict the next element of a binary sequence

$$\hat{P}[X_{T+1}] = \frac{\beta + \#\{X_i = 0, 1 \leq i \leq T\}}{2\beta + T}$$

can be used to predict the best performing stock - it is competitive with Cover's universal portfolio, but not universal (bad worst-case performance) and the convergence is likely to be even slower, especially for large markets (for which a lot of information is discarded);

- Lempel-Ziv trading.

Transaction costs do not affect the theoretical, asymptotic results, but on real data, they are a real problem; you can sometimes have decent results by rebalancing every month instead of every day, though.

On-line portfolio selection using multiplicative updates

D.P. Helmbold et al.

Mathematical finance (1998)

One can greedily choose the best portfolio for yesterday's market with a penalty for moving far from yesterday's portfolio, according to the *entropy distance*. The exact optimization problem

$$\begin{aligned} & \text{Maximize}_{\mathbf{w}_{t+1}} \eta \log(\mathbf{w}'_{t+1} \mathbf{x}_t) - d(\mathbf{w}_{t+1}, \mathbf{w}_t) \\ d(\mathbf{u}, \mathbf{v}) &= \sum_i u_i \log \frac{u_i}{v_i} \end{aligned}$$

would be too long to solve at each step; instead, it is approximated as

$$w_{i,t+1} = \frac{w_{i,t} \exp \frac{\eta x_{i,t}}{\mathbf{w}'_t \mathbf{x}_t}}{\sum_j w_{j,t} \exp \frac{\eta x_{j,t}}{\mathbf{w}'_t \mathbf{x}_t}}$$

(start with an equal-weighted portfolio). This *exponentiated gradient* portfolio selection strategy is linear in time and space and seems to have better small-sample properties than Cover's.

Efficient universal portfolios for past-dependent target classes

J.E. Cross and A.R. Barron

Mathematical finance (2003)

Very technical article explaining how universal portfolios in continuous time, without any stochastic model (just a couple of regularity assumptions about the paths), has a formulaic expression computable in $O(m^2)$ where m is the number of stocks.

Multivariate realized stock market volatility

G.H. Bauer and K. Vorkink (2006)

High frequency data allows us to compute the *realized volatility matrix* without using a moving, overlapping window or a statistical model.

Many variance matrix estimators are plagued by the positive-definiteness condition, which is non-trivial to impose: the article suggests to estimate the matrix logarithm of the variance matrix instead – the *matrix exponential* of a real symmetric matrix is positive definite and every positive definite matrix can be uniquely obtained in this way.

Construction of multivariate copulas and the compatibility problem

C. Laforge

Examples of bivariate copulas abound but examples of multivariate copulas are rare, besides the *archimedian copulas*

$$C(x_1, \dots, x_n) = \phi^{-1}(\phi(x_1), \dots, \phi(x_n)).$$

The *copula product*

$$C_1 * C_2(x, y) = \int_0^1 \frac{\partial C_1(x, t)}{\partial t} \frac{\partial C_2(y, t)}{\partial t} dt$$

can be generalized to produce a multivariate copula from n bivariate copulas

$$C(x_1, \dots, x_n) = \int_0^1 \prod_{i=1}^n \frac{\partial C_i(x_i, t)}{\partial t} dt$$

or, in terms of copula densities,

$$c(x_1, \dots, x_n) = \frac{\partial^n C(x_1, \dots, x_n)}{\partial x_1 \cdots \partial x_n} = \int_0^1 \prod_{i=1}^n c_i(x_i, t) dt.$$

For instance, the Gumbel copulas

$$C_i(x, y) = xy e^{\theta_i \ln x \ln y}$$

give rise to an n -parameter copula

$$C(x_1, \dots, x_n) = \frac{\prod_{i=1}^n x_i (1 - \theta_i \ln x_i)}{1 - \sum_{i=1}^n \theta_i \ln x_i}.$$

Selecting copulas for risk management

E. Kole et al. (2006)

To choose a copula among gaussian, Student (another elliptic copula, with more tail dependence and the strange property that the zero-correlation Student copula is not independent) and Gumbel (an archimedian copula (in particular, it is \mathfrak{S}_n -invariant) with even more tail dependence), one can use the traditional

goodness-of-fit tests for distributions, Kolmogorov–Smirnov and Anderson–Darling (a copula is a distribution on the cube $[0, 1]^N$):

$$D_{KS}^{\max} = \max_t |F(\mathbf{x}_t) - F_0(\mathbf{x}_t)|$$

$$D_{KS}^{\text{avg}} = \int_{\mathbf{x}} |F(\mathbf{x}) - F_0(\mathbf{x})| dF_0(\mathbf{x})$$

$$D_{AD}^{\max} = \max_t \frac{|F(\mathbf{x}_t) - F_0(\mathbf{x}_t)|}{\sqrt{F_0(\mathbf{x}_t)(1 - F_0(\mathbf{x}_t))}}$$

$$D_{AD}^{\text{avg}} = \int_{\mathbf{x}} \frac{|F(\mathbf{x}) - F_0(\mathbf{x})|}{\sqrt{F_0(\mathbf{x})(1 - F_0(\mathbf{x}))}} dF_0(\mathbf{x})$$

(The *tail dependence* can be defined as an asymptotic expansion of the copula in $(0, 0)$ and $(1, 1)$.)

***Why use QuantLib?*
N.P. Firth (2004)**

After recalling what free or open source software is, the author reviews a few “open source” financial libraries: Premia (X, Inria, non-free, closed to external contributions), Financial numerical recipes (C++, GPL, weak project management), Martingale (C++ and Java, GPL, weak project management) and Quantlib (C++, BSD licence, more active mailing list but dominated by a single company).

***Hedging contingent claims with constrained portfolios and nonlinear wealth dynamics*
D. Ebmeier (2007)**

A *super-replication strategy* for a contingent claim is a strategy whose payoff dominates (*i.e.*, is almost surely greater than) the contingent claim. The initial wealth of this strategy is an upper bound on the price of the contingent claim (one can similarly get lower bounds) and can be used to *hedge* the contingent claim.

This article examines what happens when the super-replicating strategy has to satisfy some constraints (*e.g.*, short-selling constraints).

***Optimal replication of contingent claims under portfolio constraints*
M. Broadie et al.**

Article on the same subject.

***Extreme observations and non-normality in ARCH and GARCH*
R. Bali and H. Guirguis
International review of economics and finance (2007)**

Traditional GARCH estimators are extremely sensitive to outliers, which produce biased coefficients and fat-tailed residuals; this article explains how to correct for outliers.

***Predictive systems: living with imperfect predictors*
L. Pástor and R.F. Stambaugh (2006)**

When trying to predict future returns, do not forget the time dimension: also use the lagged returns and predictors.

See also: mixed data sampling (MIDAS).

***The information content in implied idiosyncratic volatility and the cross-section of stock returns: evidence from the option markets*
D. Diavatopoulos et al. (2007)**

Realized idiosyncratic risk (after removing market, size and book-to-market) is a bad predictor of future returns; option-implied idiosyncratic risk is better.

***A note on the mean-variance analysis of self-financing portfolios*
Z. Bai et al. (2006)**

Beware of optimization as a drop-in replacement for a statistical procedure: even with large samples, it tends to create biased *estimators*.

***You don't have to bother Newton for implied volatility*
M. Li (2006)**

Implied volatility can be seen as a *special function* (like sine, exponential, Bessel functions, etc.) and computed in the same way, *e.g.*, with rational approximation.

***Stock market return, order flow and financial market linkages*
J.M. Moberg and G. Sucarrat (2007)**

Order flow imbalance (OFI) still works in small markets.

***The similarity between mean-variance and mean-Gini: testing for equality of Gini correlations*
E. Schechtman et al.**

Here is one more risk measure one can use instead of the standard deviation in a portfolio optimization: the *Gini mean difference* (GMD) of a random variable X is

$$\text{GMD } X = E |X_1 - X_2|$$

where X_1 and X_2 are iid with the law of X .

The article uses

$$\text{Cov}(X, F_X(X))$$

instead; considers the (non-symmetric) Gini matrix $\text{Cov}(X_i, F_X(X_j))$ where X_i and X_j are the returns of assets i and j and F_X is the cumulative distribution of the pooled returns of all the assets; and derives conditions under which “mean Gini optimization” reduces to a quadratic program.

Random intersection graphs with tunable degree distribution and clustering
M. Deijfen and W. Kets (2007)

An *intersection graph* is a graph whose vertices are subsets of a set X , with an edge between two subsets whenever they intersect.

A *random intersection graph* can be generated as follows: start with the set of vertices, assign a random weight (following a law you can choose/tune) to each vertex, assign a subset to each vertex, whose size is proportional to the weight, consider the corresponding intersection graph.

This produces a wide range of random graphs.

Primer on using neural networks for forecasting market variables
S.A. Hamid (2004)

Neural networks, trained on futures and spot prices, are better predictors of realized volatility (standard deviation of the daily log-returns over the next two months) than implied volatility is.

The article also contains a literature review and a list of financial applications of neural networks.

The value of transaction cost forecasts: another source of alpha
A. Coppejans and A. Madhavan
Journal of investment management (2007)

Predicting transaction costs can increase your capacity.

Predicting hedge fund failure: a comparison of risk measures
H. Park (2005, 2007)

Downside risk is a better predictor of failure than standard deviation.

Hedge fund investment through piecewise linear regression and optimization
F. Pan and B. Zeng (2007)

The size of a hedge fund has a non-linear impact on its return; it can be investigated by a piecewise linear regression.

Timing ability in the focus market of hedge funds
Y. Chen
Journal of investment management (2007)

Hedge funds do time the market.

How hedge fund beat the market
C. French and D. Ko
Journal of investment management (2007)

Hedge funds do not time the market.

Hedge fund risk dynamics: implications for performance appraisal
N.P.B. Bollen and R.E. Whaley

Computing the “alpha” of a strategy (say, a hedge fund) by removing the linear effect of a set of standard risk factors (market, book-to-market, size, etc.) cannot account for non-linearities or structural breaks: this article uses *optimal change point regression* to account for the latter (for the former, just use non-linear risk factors, as below).

Detecting structural breaks and identifying risk factors in hedge fund returns: a bayesian approach
L. Meligkotsidou and I.D. Vrontos

Another article on the same subject.

Can hedge fund returns be replicated? the linear case
J. Hasanhodzic and A.W. Lo
Journal of investment management (2007)

Linear clones of hedge funds often have inferior performance, but they are transparent, scalable and cheaper.

Hedge fund replication strategies: implications for investors and regulators
W. Fung and D.A. Hsieh (2007)

Hedge fund performance can be replicated, in a linear way, from a small set of *primitive trading strategies* (PTS) such as (since these are tradable, they are sometimes called *asset-based style* (ABS) factors):

- Call option on the market (to replicate a market timer);
- Lookback straddles (to replicate trend followers, who buy at the low and sell at the high: a *lookback call option* allows the owner to buy at the lowest price over the life of the option);
- BAA corporate bonds minus 10-year treasuries (to replicate fixed income hedge funds);
- “The merger fund” (to replicate a merger arbitrage strategy – no details given);
- Swap spread (?), yield curve spread (?), mortgage spread (?);
- US stock market;
- Small minus large stocks (to replicate long-short equity strategies);
- IFC emerging market index;
- CSFB high yield bond index (to replicate distressed securities hedge funds).

Will hedge funds regress towards index-like products
W. Fung and D.A. Hsieh (2007)

Detailed and badly typeset version of the above.

Statistical properties of short term price trends in high frequency stock market data
P. Sieczka and J.A. Hołyst
arXiv:physics/0703208

High frequency data fails the *runs test* (unsurprising, given their long memory): with the amount of data, one can even study the *distribution* of the run lengths.

Return predictability, economic profits and model mis-specification: how important are the better-specified models?
Y. Han (2007)

Simulations show that having the “right” return prediction model does not allow you to beat a good old VAR (vector auto-regressive model) – the choice of variables is important, though.

Furthermore, return *sign* forecasts, (rather than return prediction) are more profitable.

This article is a pledge for simple models.

Implied correlation from VaR
J. Cotter and F. Longin (2007)

In a gaussian setup, one can compute the correlation of two variables X and Y from the value-at-risk (VaR) at level α of X , Y and $xX + yY$ (*i.e.*, a portfolio of X and Y with weights x and y): this is the *implied correlation* – it depends on the level α , the weights x and y (and also the frequency of the data).

The article examines the distribution of the implied correlation (this is just a family of estimators of the correlation) – beware of the bias.

An empirical study of multi-objective algorithms for stock ranking
Y.L. Becker et al.

Genetic algorithms can be used to simultaneously optimize several goals: put the solutions on separate “islands”, one for each goal, and have some migrate from time to time.

This is very similar to *data envelopment analysis* (DEA) but I do not expect the algorithm to converge towards a uniquely defined (or meaningful) solution; if the migration rate is well chosen, it should converge to a (set of) point(s) on the efficient frontier, not far away from the optimal solutions of the one-goal problems.

The algorithm is applied to a stock selection problem with the following goals: information ratio (IR), information coefficient (IC) and intra-fractile hit rate (IFHR), *i.e.*, proportion of stocks in the top (resp. bottom) decile that outperform (resp. underperform) the average.

Portfolio selection using evolutionary computational techniques

This (author-less) article suggests to replace each return estimate by three values (say, the median and

the quantiles) and optimizes three goals: maximize the middle value of the portfolio, minimize the distance between middle and low, maximize the distance between middle and high, subject to VaR-like constraints. The author is oblivious of the dependency between the stocks; his use of *fuzzy logic* looks bogus, his use of *genetic algorithms* is irrelevant (he combines the three goals into one).

Stable models for the distribution of equity capital
R. Fernholz
Intech (2004)

Stochastic portfolio theory can be used to model the evolution of the distribution of market capitalization over time.

Diversity and relative arbitrage in equity markets
R. Fernholz et al.
Intech (2004)

A market is *diverse* if the weight of its largest stock satisfies

$$\exists \delta > 0 \quad \forall t \in [0, T] \quad \mu_{(1)}(t) < 1 - \delta;$$

it is *weakly diverse* if

$$\exists \delta > 0 \quad \frac{1}{T} \int_0^T \mu_1(t) dt < 1 - \delta;$$

it is *asymptotically weakly diverse* if

$$\exists \delta > 0 \quad \lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T \mu_1(t) dt < 1 - \delta.$$

In a weakly diverse market, there are arbitrage opportunities, e.g., invest

$$\frac{p}{w_1(0)^p} + (p - 1)$$

in the market and $-p$ in stock 1, where $p \gg 1$. The weights are so large that the strategy is not implementable; furthermore, there are market models, such as the *Atlas model* (defined in a later article by the same authors) that are almost diverse but with no arbitrage opportunity.

The article also investigates the consequences on long-term option pricing.

Relative arbitrage in volatility-stabilized markets
R. Fernholz and I. Karatzas
Intech (2004)

A more general condition than diversity for the existence of a relative arbitrage.

Stochastic portfolio theory: an overview
R. Fernolz and I. Karatzas
Intech (2006)

Clear and exhaustive review of stochastic portfolio theory.

Stocks as lotteries: the implications of probability weighting for security prices
N. Barberis and M. Huang (2007)

Prospect theory differs from expected (concave) utility theory:

- The utility function is concave over gains and convex over losses; it has a kink (*i.e.*, left and right derivatives are different) at the origin;
- The investor does not maximize the expected utility but a weighted utility: the probabilities are transformed (but these are not subjective probabilities, just decision weights: the investor is perfectly aware of the objective probabilities); as a result, low probabilities are overweight: the investor wants both lottery and insurance.

Prospect theory is incompatible with first-order dominance, but can be modified into *cumulative prospect theory*, which applies the weights to the cumulative distribution function. Often, one chooses

$$v(x) = \begin{cases} x^\alpha & \text{if } x \geq 0 \\ -\lambda(-x)^\alpha & \text{if } x < 0 \end{cases}$$

for the value function and

$$w(p) = \frac{p^\delta}{(p^\delta + (1-p)^\delta)^{1/\delta}}$$

for the weighting function. Psychological studies suggest $\alpha = 0.88$, $\lambda = 2.25$, $\delta = 0.65$.

Under gaussian assumptions (more generally, in the absence of skewness), cumulative prospect theory is consistent with the CAPM (capital asset pricing model); however, the weighting function creates mispricing for assets with skewed returns – but the authors are not convinced that it can be arbitrated away.

Cumulative prospect theory can explain that assets with a high idiosyncratic skewness, such as IPOs, private equity, distressed stocks, deep out-of-the-money options, are overpriced and earn a low average return – this leads to the *volatility smile*. It also explains why household portfolios lack diversification.

To test (and use) that positively skewed stocks earn lower average returns, one would need to forecast future skewness: past skewness does not work, but cross-sectional industry skewness does.

Probability elicitation, scoring rules and competition among forecasters
K.C. Lichtendahl and R.L. Winkler (2007)

Competitive forecasters tend to report more extreme probabilities.

A forecasting model for stock market diversity
F. Audrino et al.
Intech (2006)

To predict changes in market diversity and switch between a capitalization-weighted and a diversity- (or, better, equal-) weighted portfolio, one can use:

- an AR(1)-GARCH(1,1) model;
- a *generalized regime-switching* (GRS) model, *i.e.*, a mixture of AR(1)-GARCH(1,1)'s;
- a *generalized tree-structured* (GTS) model, *i.e.*, the analogue of a decision or regression tree whose leaves contain AR(1)-GARCH(1,1) models.

The predictive variables are:

- 1-month US treasury bill rate;
- 60-month zero-coupon bond rate;
- CPI;
- PPI of finished goods;
- Index of "help wanted" advertising in newspapers;
- Unemployment;
- Growth rate of industrial production;
- S&P 500 monthly log-returns;
- Large/small \times low-/mid-/high-value portfolio returns;
- Market returns minus 1-month treasury bill;
- SMB (large minus small) and HML (high minus low value) returns;
- Industry portfolios.

They find three regimes, that can be interpreted with the Fama–French factors.

The *diversity timing* strategy provides a "significant" 17bp increase in annual returns (after transaction costs) when compared with a monthly-rebalanced equal-weighted strategy.

Tree-structured GARCH models
F. Audrino and P. Bühlmann (2000)

The regression-tree idea can be applied to times series modeling: put GARCH(1,1) or AR(1)-GARCH(1,1) models in the leaves.

The authors use S-Plus but do not provide any code.

Estimating and predicting multivariate volatility thresholds in global stock markets
F. Audrino and F. Trojani (2003)

The tree-structured AR-GARCH model can be applied to national stock indices, the conditional variables being local and US market returns. There are usually three regimes: two driven by local information, one by US information.

Growth optimal investment strategy efficacy: an application on long run Australian equity data
B.F. Hunt
Investment management and financial innovations (2005)

The *growth optimal portfolio* is not diversified: it only contains 2 or 3 stocks. To increase diversity, one can regularize the sample variance matrix as in a ridge regression:

$$V = V_{\text{sample}} + \lambda I.$$

Incorporating estimation errors into portfolio selection: robust portfolio construction

S. Ceria and R.A. Stubbs
Journal of asset management (2006)

Robust optimization usually considers the worst-case scenario in ellipsoidal or box-shaped uncertainty regions, meaning that all the errors have a negative effect. This article suggests to consider the subset of those uncertainty sets where the errors cancel out.

Experiments in robust portfolio optimization
D. Bienstock (2007)

The *uncertainty sets* used in robust portfolio optimization are often boxes or ellipses (some add the further constraint that the deviations sum up to zero); this article presents two new shapes for the uncertainty shares: one using fractiles (just specify how bad the situation can be in each decile) and another using the *adversarial value-at-risk* (AVaR), that uses mixtures to model the higher correlation during crashes (I am not sure it is different from the VaR of a mixture).

The article also details how to efficiently implement those optimizations.

Equity-style timing: a multi-style rotation model for the Russel large-cap and small-cap growth and value style indexes

B.G. Arshanapalli
Journal of asset management (2007)

Market timing often uses logistic regression to switch between two market segments – beyond two, use *multinomial regression*.

Portfolio choice beyond the traditional approach
F. Peñaranda (2007)

Not very readable (if you do not already know what he talks about, you will not understand it) but correct and fairly complete survey of asset allocation, with all the formulas you may need. The topics include:

- the portfolio weights as a statistic, whose distribution can be studied (surprisingly, this was missing from Meucci's book);
- the difference between *posterior distribution* and *predictive distribution* (the posterior distribution is for the present, the predictive distribution is its projection to the investment horizon)
- *lower partial moments* (LPM) are linked to stochastic dominance (no details given) but are more computable and yield a complete order; mean-semi-variance optimization is a convex problem;

- generalizations of the Sharpe ratio: *Sortino ratio* (with the semi-variance), *Omega*, *rate of decay I* (this comes from *large deviation theory*)

$$P[\text{returns}_{0 \rightarrow T} \leq 0] \sim e^{-I \cdot T}$$

- (but the Sharpe ratio gives a ranking similar to most alternatives);
- log-utility is indifferent to the investment horizon;
- the *Black-Litterman* approach can be used to tilt a long-term strategy (strategic asset allocation or SAA) towards a short-term view (tactical asset allocation or TAA);
- dynamic asset allocation (with insufficient details) and the *intertemporal CAPM* (ICAPM).

The impact of EMU on the equity cost of capital
G.A. Hardouvelis et al.

Journal of international money and finance

European monetary integration can be modeled as a *time-weighted CAPM*

$$r_{it} = \lambda_{i,t-1} \beta_i^{\text{market}} r_t^{\text{market}} + (1 - \lambda_{i,t-1}) \beta_i^{\text{local}} r_t^{\text{local}}$$

$$\lambda_{i,t-1} = \exp - |\gamma'_i X_{i,t-1}|$$

where X is a set of predictive variables: country effects are becoming less important.

Performance and distress indicators of new public companies
N. Beneda

Journal of asset management (2007)

To choose among IPOs (initial public offerings), use Ohlson's *O ratio* (a measure of bankruptcy risk, apparently the result of a logistic regression, whose coefficients were set in stone 30 years ago), the market-to-book ratio and the market share of the underwriter.

Long-term economic relationships from cointegration maps
R. Vicente et al. arXiv:physics/0701062

Correlation is a cross-sectional distance, blind to dynamic phenomena: it can be replaced by a measure of cointegration.

The author suggests to estimate the cointegration from the model

$$a_1 x_{1,t} + a_2 x_{2,t} + b = \varepsilon_t$$

$$\varepsilon_{t+1} = \gamma \varepsilon_t + \eta_t$$

$$\langle \varepsilon_t \rangle = 0$$

$$\langle \varepsilon_t^2 \rangle = \sigma$$

$$0 \leq \gamma < 1$$

using bayesian computations and physicist's approximations:

$$\begin{aligned}\hat{\gamma} &= \text{Argmax} \log \int p(\gamma|\varepsilon)p(\varepsilon|x_1, x_2) d\varepsilon \\ p(\gamma|\varepsilon) &\propto 1_{[0,1]}(\gamma) \left[\sum_{t=1}^{T-1} (\varepsilon_{t+1} - \gamma\varepsilon_t)^2 \right]^{-\frac{T-2}{2}} \\ p(\varepsilon|x_1, x_2) &\propto \varepsilon_t - x_{1,t} \sin \hat{\theta} + x_{2,t} \cos \hat{\theta} \\ \hat{\theta} &= \frac{1}{2} \arctan \left(2 \frac{\langle x_1 x_2 \rangle}{\langle x_1^2 \rangle - \langle x_2^2 \rangle} \right)\end{aligned}$$

The estimator $\hat{\gamma}$ can be seen as a measure of dissimilarity and can be transformed (this can make the plots more or less readable):

$$d_\alpha(x_1, x_2) = \hat{\gamma}^\alpha.$$

The dissimilarity matrix is sometimes modified further (two times series are similar if they interact with the other time series in the same way – this idea is also used in *spectral clustering*):

$$D_{i,j} = \sqrt{\sum_{k=1}^N (d_\alpha(x_i, x_k) - d_\alpha(x_j, x_k))^2}.$$

Before plotting (this is the *heatmap*, common with bioarrays), the rows and columns of the dissimilarity matrix D can be reordered: a greedy algorithm looks for a permutation matrix P that minimizes

$$\mathcal{F}(P) = \text{tr}(PDP'W)$$

where the weight matrix W can be chosen as $W_{ij} = \exp(|i - j| \sigma)$ (neighbourhood weights) or $W = XX'$ for some vector X such that $X_i > X_j$ if $i > j$ (side-by-side weights): this is the SPIN algorithm.

Finally, one can apply a clustering algorithm such as SPC (*superparamagnetic clustering* – I have no idea what it means).

**Information dynamics
and origins of uncertainty**
P. Garbaczewski
arXiv:cond-mat/0703147

An uncertainty principle can be expressed in information-theoretic terms, between $S(\rho)$ and $S(\tilde{\rho})$ where ρ is a probability density, $-\ln \rho(x)$ the *surprise level*, $S(\rho) = \langle -\ln \rho \rangle$ the *Shanon entropy* and $\tilde{\rho} = \mathcal{F}\rho$ is the Fourier transform of ρ .

**Optimal execution of portfolio transactions:
a review**
E. Kochieva
Carisma (2007)

The market impact has a long-term component (information leakage) and a short-term one (liquidity-demand-related price jumps), which add to the background price dynamics.

Trade execution is a trade-off between *market impact* (which decreases with time) and *timing risk* (which increases with time); it can be evaluated with respect to a benchmark such as *pre-trade* price (the most often used), VWAP or post-trade price.

The *VWAP strategy* trades a fixed percentage of the market value in each period; the optimal trading rate can be estimated by a quadratic optimization (*efficient trading frontier*).

This static strategy can be replaced by a dynamic one, where the trading rate is a function of the price, or by a full-fledged *stochastic programming* approach.

Continuing work on optimal trade execution
D. Bienstock
Carisma (2007)

One can consider a market impact model of the form

$$p_{t+1}/p_t - 1 = \alpha * \text{size}^\pi$$

with a fixed (very small) α and π varying in $(0, 1)$ according to a Markov chain. The optimal trade execution strategy can be obtained by dynamic programming (or *approximate dynamic programming*). This strategy is not robust to a misspecification of the Markov transition probabilities – assuming that π is constant is preferable.

One can also assume that π is not chosen at random but by an adversary (under some constraints to keep it around a certain value $\bar{\pi}$; the corresponding optimal strategy is more robust.

One can also consider what happens when two traders compete.

Someone also suggested to try with a hidden Markov model (HMM), *i.e.*, with unknown transition probabilities.

**Design of an FX trading system using
adaptive reinforcement learning**
M.A.H. Dempster
Carisma (2007)

Recurrent reinforcement learning (RRL), *i.e.*, a recurrent 1-layer neural network, can be used to turn returns time series into a buy/sell/wait order, so as to maximize a *moving-average Sharpe ratio*,

$$\frac{\text{EWMA}(\text{returns})}{\text{EWMA}(\text{returns}^2)}.$$

This used to work, one decade ago. One can try to improve the model as follows:

- Do not only consider past returns: add in technical indicators – actually, this does not add anything: RRL already extracts all the relevant information;
- Replace the transaction costs parameter by something larger than the bid-ask spread, so as to favour trades with larger returns;
- Fix the instability in the neural network weights by shrinking them;

- Update the weights twice at each step, *i.e.*, replace $w_t = f(x_t, w_{t-1})$ with $w_t = f(x_t, f(x_t, w_{t-1}))$.
- Add a risk and performance management layer in the algorithm, with a stop-loss and a shutdown procedure (to stop investing when the algorithm becomes unstable after a regime switch); the suggested risk measure takes into account both total loss and the size of the individual losses (this is similar to Omega):

$$\Sigma = \frac{\sum r_i^2}{\sum r_{i+}^2};$$

- Update the neural network weights at each step, but do not update the meta-parameters (transaction cost, trading threshold, etc. – there are five of them) that often;

The following improvements have not been tested yet:

- Add other information, such as the order flow or the limit order book;
- Use the algorithm on several currency pairs; generalize the risk control accordingly;
- Apply the algorithm to market making instead of trading.

Optimal liquidation against a markovian limit order book

**P. Hewlett
Carisma (2007)**

This technical talk combined limit order book models (cf. D. Farmer's work – I attended one of talks last month) with dynamic programming to find the optimal way of executing a trade; some of the tools required are similar to those used to price American options (?); the robustness of the resulting strategy could be examined as in D. Bienstock's talk.

Automated new content and algorithmic trading **P. Gagner (RavenPack) Carisma (2007)**

They turn news into numbers using a Bayesian spam filter – unconvincing.

Portfolio optimization with drawdown constraints

**S. Uryasev
Carisma (2007)**

Maximum drawdown, average drawdown and conditional drawdown at risk (CDaR) can be expressed using piecewise linear functions and can therefore be optimized with a linear program (scenario-based) solver. The actual risk measure is not that important.

His company (AOrDa) sells an optimizer and he claims to run his own money with it, using sample returns as an alpha (and Monte Carlo simulations to estimate the risk); surprisingly, he is aware that this momentum strategy does not perform that well because of reversal effects.

Applying stochastic programs to improve investor performance

**J.M. Mulvey
Carisma (2007)**

The title sounded interesting, but the talk was mostly empty:

- do not forget to rebalance (equal weights are good);
- look for volatility (or diversity);
- do not forget transaction costs;
- do not forget to diversify your portfolio (using *overlays*, if needed): with enough diversity and volatility, a *momentum* strategy can be quite successful.

The stressed difference between *dynamic stochastic control* (discretization of the state space, *i.e.*, of the investor's decisions) and *multi-stage stochastic program* (scenario tree) was not clear. The author suggests to analyze the result of those optimizations to derive *rules* that can then be back-tested.

Theory of acceptability indices

**D. Madan
Carisma (2007)**

To compare and choose among strategies, one can use *scale-free acceptability indices*, such as the Sharpe ratio and its generalizations: these are functions $\alpha(X)$ of the distribution of the returns X of the strategy. An acceptability index is *coherent* if it satisfies the following properties:

- convexity: $\alpha(X) \geq x, \alpha(Y) \geq x \implies \forall \lambda \in (0, 1) \alpha(\lambda X + (1 - \lambda)Y) \geq x$
- monotonicity, *i.e.*, compatibility with strong dominance: if $X \geq Y$ almost surely, then $\alpha(X) \geq \alpha(Y)$;
- scale invariance: $\forall \lambda > 0 \quad \alpha(\lambda X) = \alpha(X)$
- continuity: if $|X_n| \leq 1$, $\alpha(X_n) \geq x$ and X_n converges to X in probability, then $\alpha(X) \geq x$.

We would also like:

- second order monotonicity;
- arbitrage consistency: if $X \geq 0$ almost surely, then $\alpha(X) = \infty$
- expectation consistency: if $E[X] < 0$, then $\alpha(X) = 0$; if $E[X] > 0$, then $\alpha(X) > 0$.

Here are a few examples:

- The Sharpe ratio:

$$SR(X) = \frac{E[X]}{Sd(X)} \text{ if } E[X] > 0;$$

it is not monotonic and not arbitrage consistent;

- The gain-loss ratio:

$$GLR(X) = \frac{E[X_+]}{E[X_-]} - 1 \text{ if } E[X] > 0;$$

it is coherent, but small and large losses are considered equally bad;

- RAROC = $\frac{E[X]}{VaR(X)}$

- The *tilt coefficient* is the highest risk aversion that will say “yes” to the strategy (for the exponential utility):

$$TC(X) = \inf\{\lambda \geq 0 : E[Xe^{-\lambda X}] < 0\}$$

- The expected shortfall can be turned into a scale-free acceptability measure:

$$AIT(X) = \frac{1}{\inf\{\lambda \in [0, 1] : ES_\lambda(X) \geq 0\}} - 1$$

where the expected shortfall is

$$ES_\lambda(X) = E[X | X \leq F_X^{-1}(\lambda)]$$

and F_X^{-1} is the quantile function of X .

Actually, coherent acceptability measures can be characterized as follows (this is the same notion of coherence and the same characterization as for the coherent indices of satisfactions, see A. Meucci’s book, section 5.6): generalize the expected shortfall to

$$u(X) = \int_0^1 \psi'(s) F_X^{-1}(s) ds$$

where $\psi : [0, 1] \rightarrow [0, 1]$

is concave, non-decreasing, with $\psi(0) = 0$ and $\psi(1) = 1$; it can be seen as a deformation to be applied to the quantile function F_X^{-1} before computing the expected shortfall, equivalently, ψ' can be seen as weights (for the expected shortfall, the weight is constant on $[0, \lambda]$ and zero on $[\lambda, 1]$). To get the index of satisfaction, we actually need an increasing continuous family $(\psi_x)_{x \geq 0}$ of such functions ψ , with $\psi_0(y) = y$ and $\psi_x \rightarrow \delta_0$ when $x \rightarrow \infty$. The corresponding index of satisfaction is then (this is the same formula as for the expected shortfall, with $x = 1/\lambda - 1$):

$$AIW(X) = \inf\{x \geq 0 : u_x(X) < 0\}$$

For instance (these can be interpreted in terms of order statistics):

- MinVaR: $\psi(y) = 1 - (1 - y)^{x+1}$
- MaxVaR: $\psi(y) = y^{1/(1+x)}$
- MaxMinVaR: $\psi(y) = (1 - (1 - y)^{x+1})^{1/(1+x)}$
- MinMaxVaR: $\psi(y) = 1 - (1 - y^{1/(1+x)})^{x+1}$

Those results were applied to options and hedge funds; for the latter, the influence of the kurtosis was decomposed into *peakedness* and *tailweightedness*.

Algorithmic trading of hedge funds

N. Christofides
Carisma (2007)

A complete trading platform can be built as follows:

- Gather the data (some variables as daily, others monthly)
- Fill in the data, using the EM algorithm (contrary to what the speaker seems to think, this is *not* a data imputation algorithm: using it as such would lead to biased estimators, especially for dispersion estimators)

- Build a risk model, using independent component analysis (ICA) (principal component analysis (PCA) fails to get rid of cross-kurtosis)
- Model the (daily) time-series behaviour of the independent components (more complicated than that of the initial assets), using *neural networks* (fitted with *bionomic* (?) algorithm) or *wavelets*
- Discretize the market model into a *state transition graph* (STG); merge similar vertices to keep their number under control (but you can still have millions of them); make sure there are no arbitrage opportunities (it suffices to check for 1-period opportunities from each vertex);
- Proceed with dynamic programming (the model is daily but your investment horizon is longer); you may want to use a *state space relaxation* technique to replace this single large problem into several smaller ones.

The speaker also mentioned *real options*, but I still have no idea what it is.

Long-short portfolio optimization under the mean-variance-CVaR framework

G. Mitra
Carisma (2007)

Current optimizers are not limited to the variance as a risk measure: they can use mean absolute deviation (MAD), semi-variance, lower partial moments, value at risk (VaR), conditional value at risk (CVaR, also called expected shortfall (ES) or tail VaR (TVaR)) – the presenter gives more details as to how this can be expressed as a linear problem, provided you add more variables and stick to *scenario-based optimization*; he also explains how to write the long-short, leverage and number-of-assets constraints.

You can also use several risk measures, such as the variance and the CVaR: the efficient frontier is then 2-dimensional.

Independent component analysis

A. Robinson (APT)
Carisma (2007)

Principal component analysis (PCA) models data as a linear mixture of gaussian variables; the principal components are linear combinations (more precisely, rotations) of the observed variables that maximize the variance.

Independant component analysis (ICA) models the data as a linear mixture of independant non-gaussian variables: the independent components are linear combinations of the observed variables that maximize some measure of non-gaussianity, such as *kurtosis* or *negentropy* – a couple of years ago, APT were extremely careful never to use the “ICA” words when explaining their product.

Similarly, *second-order blind identification* (SOBI) models the data as a linear mixture of autocorrelated

variables – one could generalize this by considering the volatility process.

The audience raised a few questions:

- how robust is it?
- can we combine ICA and SOBI?

D. Madan raised a few objections:

- the assumption of a linear mixture of non-gaussian variables is not valid for financial data: it would create dependence between the necks, while we also/mainly observe (and worry about) dependence in the tails;
- furthermore, the independent components we get are not independent.

***Alpha budgeting
cross-sectional dispersion decomposed***
W. Yu and Y.M. Sharaiha
Journal of asset management (2007)

Anova (analysis of variance) can be used to decompose cross-sectional variance.

Improving returns-based style analysis
Daniel Mostovoy
(Northfield, 2007)

Returns-based style analysis (RBSA) tries to replicate the returns of a fund, or at least to explain its risk (for variance decomposition or to use it in a (fund-of-funds) portfolio optimization), from a handful of assets or *spanning indices*, in a linear way. The naive *constrained linear regression* (constrained because the weights have to be positive) can be improved:

- you can *compute confidence* intervals on the weights;
- for hedge funds, you can allow negative weights, add a cash asset and constrain on the leverage;
- you can allow regime shifts by choosing the estimation period using *CUSUM* – they have a CUSUM video on their website;
- plot the residuals against time (everyone should already be doing that) to spot slow style changes and use exponential weights to get rid of them; alternatively, use a *Kalman particle filter* (because of the constraints, you have to use Monte Carlo Markov Chain (MCMC) simulations)
- Correct for heteroskedasticity, lest the more volatile periods be counted more heavily: define the dispersion between the spanning indices, at a given date, as their (cross-sectional) average absolute returns difference; weigh the observations with the inverse of the square root of the dispersion;
- Be sure to include volatility-base indices; you can choose the spanning indices by *forward stepwise regression*;
- the proxy portfolio will be too diversified: replace it by its constituents and ask the optimizer to reduce the number of assets;
- You still cannot capture all the stock-specific risk: this can be fixed by adding cash and changing the

leverage; you will also have to tweak the systematic and unsystematic risk aversion parameters (RAP) to keep the same factor variances; you might also want to add a “pure stock-specific risk” asset to the risk model.

However, the more “hedged” the fund, the less it works.

Who should you listen to?
A sector decomposition of surprise stock returns
G. de Rossi (UBS) Northfield (2007)

A long-short strategy based on analysts’ earnings estimates upgrades and downgrades is profitable in some sectors but not in others, regardless of the quality of the forecasts (?). To explain this, one can start with a discounted cash flow model

$$\text{Price} = E \left[\sum_{t \geq 1} \frac{D_t}{1 + r_{0 \rightarrow t}} \right]$$

and try to separate the influence of the numerator (cash flow news) and the denominator (discount-rate news).

(I am not the best person to talk about discounted cash flow models: if you want more information, check the article itself.)

In a nutshell: in your models, use sector-specific weights.

Alpha scaling revisited Amish Shah
(Northfield, 2007)

The *Grinold formula* can be derived as follows: let

y :forward returns

g :investment signal (our alpha – or even its components)

\hat{g} :a realization of g

The ordinary least squares (OLS) estimate of y given $g = \hat{g}$ is

$$\begin{aligned} \hat{y} &= E[y] + \text{Cov}(y, g) \text{Cov}(g, g)^{-1} (\hat{g} - E[g]) \\ &= E[y] + \text{Cor}(y, g) \text{Sd}(y) \text{Sd}(g) \text{Sd}(g)^{-2} (\hat{g} - E[g]) \\ &= E[y] + \text{Cor}(y, g) * \text{Sd}(y) * (\hat{g} - E[g]) / \text{Sd}(g) \end{aligned}$$

Where

$\text{Cor}(y, g)$: information coefficient

$\text{Sd}(y)$: volatility

$\frac{\hat{g} - E[g]}{\text{Sd}(g)}$: score

This remains valid for time series regressions or cross-sectionnally (for the whole universe or within sectors).

The Northfield alpha scaling tool processes the client’s alpha as follows:

- gaussianize it to get a score
- use the cross-sectional Grinold formula:

$$\text{return forecast} = \text{IC} \times \text{volatility} \times \text{score}$$

The IC is provided by the user (perhaps on a sector basis); the volatility was not clearly explained (you could take the volatility from the risk model or compute a cross-sectional volatility for the whole market or for each sector).

This talk also mentioned the Black–Litterman framework. J. Sefton explained that this helps alleviate the “error maximization problem”: the risk factors used in the risk model are also present in the alpha and the optimizer is asked to minimize the former and maximize the latter – it ends up maximizing the misalignment between the two.

**Portfolio construction
in a regression framework
J. Sefton (formerly UBS)
Northfield (2007)**

Mean-variance optimization is often implemented as a 2-step process: first estimate the returns and the variance, then optimize. This can be replaced by a 1-step procedure, that goes directly from the data to the portfolio weights: constrained linear regression.

$$\begin{aligned}\gamma 1_T &= R w + \varepsilon \\ 1'_N w &= 1\end{aligned}$$

where

$$\begin{aligned}1_T &= (1 \cdots 1)' \\ 1_N &= (1 \cdot 1)' \\ R &= \begin{pmatrix} r_{11} & \cdots & r_{1N} \\ \vdots & & \vdots \\ r_{T1} & \cdots & r_{TN} \end{pmatrix}\end{aligned}$$

and γ is the risk appetite.

As a bonus, you get all the machinery surrounding regression: confidence intervals, robust regression, regression diagnostics (leverage, etc.) – the *audit trail* from data to weights is easier to follow.

For instance, looking at the *leverage* over time shows that, because of the recent drop in volatility, recent observations have a lower leverage, *i.e.*, a lower influence on the final weights, than older observations – this is not what you want.

Other example: the F-test can be used to test the difference between a portfolio P and an efficient portfolio E_γ ; it simplifies to

$$Z(\gamma) = \frac{\text{IR}(E_\gamma)^2 - \text{IR}(P)^2}{1 + \text{IR}(P)^2}$$

and the “distance” between portfolio P and the efficient frontier can be defined as

$$Z = \min_{\gamma} Z(\gamma).$$

I am not convinced that all the classical regression tools and formulas remain valid for constrained regression,

though. For confidence intervals, Dan di Bartolomeo wrote an article, 10 years ago.

The constrained regression can include priors for the returns and the risk matrix:

$$\begin{aligned}\gamma(1 \cdots 110 \cdots 0) &= \begin{pmatrix} R \\ \alpha_1 & \cdots & \alpha_N \\ V_{\text{prior}}^{1/2} \end{pmatrix} w + \varepsilon \\ \text{Var } \varepsilon &= \sigma^2 \text{diag}(1, t_0^{-1}, t_0^{-1})\end{aligned}$$

where t_0 is the “weight” (in days) of the prior.

**Distinguishing between being unlucky and
unskillful
Dan diBartolomeo (Northfield, 2007)**

Alpha or information ratios (IR) are rarely statistically significant, unless you have several centuries of data – and increasing the frequency of the data does not help: not only do the data become statistically more complicated (autocorrelation, kurtosis, jumps), but it does not increase the sample size, *i.e.*, the number of investment decisions taken. To account for regime switches, the size of the sample period can be estimated using the *CUSUM* method.

Grinold’s fundamental law of active management,

$$\begin{aligned}\text{IR} &= \text{IC} \sqrt{\text{breadth}} \\ \text{IR} &= \text{Information Ratio} = \frac{\alpha}{\text{tracking error}} \\ \text{IC} &= \text{Information coefficient} \\ &= \text{Cor}(\text{forecast, future returns}) \\ \text{breadth} &= \text{number of independent bets}\end{aligned}$$

makes unreasonable assumptions (no constraints, no transaction costs) and can be modified as

$$\text{IR} = \text{IC} \times \text{TC} \times \sqrt{\text{breadth}}$$

where the transfer coefficient $\text{TC} < 1$ measures portfolio construction efficiency.

Using the IR in the first place is not that good an idea: it only corresponds to a utility function if you are very, very risk averse – in which case, you should not approach stocks.

One can measure performance in a cross-sectional way (the sample size grows quickly) using the *effective information coefficient* (EIC, you can also see it as an *ex post transfer coefficient*): the correlation between the implied alpha (*i.e.*, the alpha for which the portfolio actually held would be optimal) and the realized returns.

Going the other way round, you can use the EIC to evaluate a risk model:

$$\text{excess returns} = \text{EIC} \times \text{dispersion} + \text{residuals}$$

where the dispersion is computed cross-sectionally and the dispersion of the residuals measures the quality of the risk model.

Good fund returns can have two causes: either a good *batting average* (the proportion of forecasts with the

correct sign) or a good *skew* (third moment of the product weights * returns), *i.e.*, larger gains than losses – the skew appears with trend-following strategies or portfolio insurance.

Someone remarked that those measures did not take *capacity* problems into account.

A market impact model that works
Dan diBartolomeo (Northfield, 2007)

Northfield now have a market impact model:

$$M = A + B * X + C * X^{1/2}.$$

Since large trades are extremely rare in the data (they are split into smaller trades), those model typically do not predict their impact well – the impact can exceed 100%. To avoid this, they add boundary constraints on the value of the coefficients, using a worst-case scenario (a takeover with information leakage). They also overweigh large trades (using their dollar value), in order to have better forecasts for them. Their current model works well for North America, but not for the UK or Japan – this may be due to a data problem.

In the Carisma seminar, Dan had more time and gave more details:

- When estimating the worst-case market impact, they take the liquidity into account
- Their market impact model has a liquidity exhaustion term

The market efficiency in stock markets
J.S. Yang et al.
arXiv:physics/0701179

Yet another econophysics article. For each asset of interest (here, indices: S&P 500 and Kospi) plot, over time (using high-frequency (1-minute) log-returns; only intraday to avoid discontinuities):

- The *tail index*;
- The “variance of the autocorrelation”, *i.e.*, the sum of the (day) 10 first autocorrelations, *i.e.*, the *Q-statistic* (used in the Ljung–Box test);
- The scaling property of the standard deviation, *i.e.*, μ in $\sigma(\Delta t) \sim (\Delta t)^\mu$.

Discretize the returns and compute:

- Their *entropy* $H(1) = \sum_i -p_i \ln p_i$;
- The entropy $H(L)$ of the sequences of L returns, or rather the marginal entropy $H(L) - H(L - 1)$;
- The *statistical complexity* (?) of the corresponding Markov chain (it will be zero if the data is either regular or completely random).

A valuation-based test of market-timing
W.B. Elliott et al.
Journal of corporate finance (2007)

When deciding whether to issue stock or debt, CFOs try to time the market. To test this hypothesis, one can

compute the correlation between the *leverage* (debt-to-equity ratio) and a misvaluation measure, such as the price-to-book ratio (P/B) – but the P/B contains more information than simple over-valuation: growth opportunities, asymmetric information, debt overhang, etc. Instead, the authors use the *residual income model* (RIM) to study the capital structure – CFOs do try to time the market.

CFA Institute magazine
March-April 2007

It does not make sense for a company not to pay dividends – it prevents investors from valuing it, unless you are satisfied with a null value.

Fat tails, power laws, drawdown can be used as a risk measure:

- APT models take fat tails into account;
- higher moments can be used in portfolio theory and lead to a *multi-moment efficient frontier*;
- The tails are different for market risk (thin) and credit and operational risk (fat); furthermore, they are not independent.

The article about the *quantitative investment process* (what we are doing) stressed the importance of sector-dependant, dynamic models; it also mentions *fundamental indices*, such as RAFI (Research Associates Fundamental Index), which weigh stock using (additive) variables other than market capitalization.

Fundamental indexation

Financial analysts journal (2005)

Extreme value problems in random matrix theory and other disordered systems
G. Biroli et al.
arXiv:cond-mat:0702244

There are several variants or generalizations of the central limit theorem:

- The asymptotic behaviour of $\sum_{i=1}^N x_i$ is gaussian if x is L^2 , stable (if defined) otherwise: only the tails matter;
- The asymptotic behaviour of $\text{Max}_{i=1}^N x_i$ is Weibull (if X is bounded), Gumbel (if X has thinner than power law tails) or Fréchet (if X has power law tails);
- The asymptotic behaviour of

$$S_q(N) = \sum_{i=1}^N x_i^q$$

- depends on $\mu = \sqrt{2 \ln N} / q\sigma$ and exhibit phase transition phenomena;
- etc.

The article examines what happens to the *Tracy–Widom distribution* (the distribution of the largest eigenvalue of a symmetric random matrix with gaussian entries) when the entries have power law tails.

On the distribution of the largest principal component
I.M. Johnstone (2000)

The largest singular of a random (gaussian) matrix (or the largest eigenvalue of a Wishart matrix) approaches the Tracy-Widom distribution, which is computable in terms of the Painlevé differential equation.

(Random matrix theory (RMT) is just a limit theorem for matrices, similar to other limit theorems (central limit, stable distributions, extreme distributions, large deviations, etc.)

Correlation functions, cluster functions and spacing distributions for random matrices
C.A. Tracy and H. Widom
arXiv:solv-int/9801004

Exponential weighting and matrix-based filtering of financial covariance matrices for portfolio optimization
S. Pafka et al.
arXiv:cond-mat/0402573

Random matrix theory (RMT) noise undressing can be combined with exponential weighting to account for heteroskedasticity.

Non-hermitian random matrices
B. Khoruzhenko (2001)

The tools used to study the (non-real) eigenvalues of non-hermitian matrices are very different.

Records in a changing world
J. Krug
arXiv:cond-mat/0702136

Records (*i.e.*, entries larger than all the previous ones) in a sequence of iid random variables asymptotically follow an extreme value theory (EVT) distribution and the distribution of record times do not depend on the distribution of the random variables.

One can also consider independant non-iid variables:

- $X_n = \text{Max}\{Y_{1,n}, \dots, Y_{N_n,n}\}$, with $Y_{i,j}$ iid, can be iused to mode sports records where N_n (usually increasing) is the population size;
- $X_n = Y_n + cn$;
- $X_n = \lambda_n Y_n$.

***Random but not so much
A parametrization for the returns and correlation matrix of financial time series***
A.C.R. Martins
arXiv:physics/0701025

Random matrix theory (RMT) can be seen as a statistical test of $H_0 : V = \mathbf{1}_{nn}$ using Spec \hat{V} , with no well-defined alternative hypothesis.

One can extend the Marčenko–Pastur model by:

- allowing for a more general variance matrix V , e.g., one with a handful of non-zero eigenvalues (this is how RMT is used, to compare $H_0 : \lambda_k = 0$ against $H_1 : \lambda_k \neq 0$; but people use results valid for $k = 1$ for any value of k , and feel free to perform as many tests as possible);
- allowing for non-stationarity effects (the subject of the article, but their model is not very clear).

***Stock market distributions:
from past to present***
S. Drożdż et al.
arXiv:0704.0664

Earlier studies claimed that market fluctuations had power laws with a scaling index $\alpha > 3$, regardless of the horizon. This index now depends on the horizon: 3 for high frequency data (minute), while weekly data are gaussian.

Mean-variance portfolio analysis under parameter uncertainty
T. Bodnar and W. Schmid

Going from sample returns to market parameters to the (minimum variance or tangency) efficient portfolio to an estimation of the portfolio return and risk are estimators.

Under gaussian assumptions, one can compute, in closed form, the distribution of those estimators, and perform *tests* on them.

Note that

$$E[|\hat{\mu}_{MV}|] = \infty$$

$$E[|\hat{\sigma}_{MV}^2|^{1/2}] = \infty.$$

The minimum variance portfolio is more robust.

SNP: a program for non-parametric time series analysis
A.R. Gallant and G. Tauchen (1990–2007)

Hermite probability distribution functions (pdf) generalize the gaussian distribution:

$$h(z) \propto P(z)^2 \phi(z)$$

where P is a polynomial and ϕ the (multivariate, standard) gaussian pdf.

Semi-non-parametric distributions are the distributions of affine transformations of Hermite random variables.

***Conditional properties of hedge funds:
evidence from daily returns***

Y. Li and H. Kazemi

European financial management (2007)

Non-parametric GARCH(1,1) (or more generally SNP models) can be used to model daily hedge fund returns and accounts for asymmetries.

***Investor attention
and time-varying comovements***

L. Pend et al.

European financial management (2007)

Comovement can be measures as

$$\frac{\text{stock-specific risk}}{\text{total risk}}.$$

The authors use realized log-volatility from 5-minute returns and regress stock returns against S&P 500 returns.

A comparative study of portfolio insurance
S. Basak (2001)

Portfolio insurance can be cast into a utility framework: as the wealth approaches the floor, the marginal utility tends to infinity, e.g., one can use

$$\frac{(\text{wealth} - \text{floor})^\gamma}{\gamma}$$

instead of $\text{wealth}^\gamma/\gamma$.

The article uses continuous-time processes

***A shrinkage approach to model uncertainty
and asset allocation***
Z. Wang (2003)

To account for model uncertainty, shrink stock returns and variance towards those implied by the CAPM or Fama–French model.

Valuation in US commercial real estate
E. Ghysels et al.

European financial management (2007)

Real estate (and real estate investment trusts (REIT)) is very similar to equity: properties (especially commercial properties) can be valued with the *discounted rent model*, analogue of the discounted cash flow model; the *cap rate* (rent-to-price ratio) is the analogue of the P/E, etc.

***Is coskewness a better measure of risk in the
downside that downside beta?***
Evidence in emerging market data
D.U.A. Galagedera and R.D. Brooks
Journal of multinational financial management
(2007)

The various *downside betas*

$$\beta^{\text{HW}} = \frac{E[(r - r_{\text{free}})(r_{\text{market}} - r_{\text{free}})_{-}]}{E[(r_{\text{market}} - r_{\text{free}})_{-}^2]}$$

$$\beta^{\text{HR}} = \frac{E[(r - \bar{r})(r_{\text{market}} - \bar{r}_{\text{market}})_{-}]}{E[(r_{\text{market}} - \bar{r}_{\text{market}})_{-}^2]}$$

$$\beta^{\text{E}} = \frac{E[(r - \bar{r})_{-}(r_{\text{market}} - \bar{r}_{\text{market}})_{-}]}{E[(r_{\text{market}} - \bar{r}_{\text{market}})_{-}^2]}$$

can be generalized into *downside skewnesses*:

$$\gamma^{\text{HW}} = \frac{E[(r - r_{\text{free}})(r_{\text{market}} - r_{\text{free}})_{-}^2]}{E[(r_{\text{market}} - r_{\text{free}})_{-}^3]}$$

$$\gamma^{\text{HR}} = \frac{E[(r - \bar{r})(r_{\text{market}} - \bar{r}_{\text{market}})_{-}^2]}{E[(r_{\text{market}} - \bar{r}_{\text{market}})_{-}^3]}$$

$$\gamma^{\text{E}} = \frac{E[(r - \bar{r})_{-}(r_{\text{market}} - \bar{r}_{\text{market}})_{-}^2]}{E[(r_{\text{market}} - \bar{r}_{\text{market}})_{-}^3]}$$

This is appropriate when the returns distribution is skewed.

Portfolio selection with higher moments
C.R. Harvey et al.

Traditional portfolio selection has two drawbacks:

- It assumes that the expected utility (the authors confuse utility and expected utility) only depends on the first two moments;
- It assumes that the market parameters are known, *i.e.*, that the *estimation risk* will remain negligible.

To tackle the first problem, one can:

- consider the expected utility as a function of the first three moments, leading to a 2-dimensional efficient frontier;
- replace the variance by an asymmetric measure of risk.

To tackle the second problem, one can:

- shrink the market parameters;
- use bayesian estimators of the market parameters (this is a non-linear shrinkage);
- use robust estimators of the market parameters;
- shrink the “optimal” portfolio (Black–Litterman);
- add constraints on the weights/

The authors use bayesian estimators from a multivariate *skew gaussian* (the sum of a truncated gaussian and a (smaller) gaussian, up to affine transformations) and a higher-dimensional efficient frontier to account for both skewness and estimation risk.

Their presentation of utility theory, with their undefined notion of *predictive utility* (something between utility and expected utility), is confusing.

As often, there is also some “resampled frontier bashing”.

Robust mean-variance portfolio selection **C. Perret-Gentil and M.P. Victoria-Feser (2003)**

“Robust portfolio construction” refers to two different notions:

- either a worst-case optimization;
- or a classical mean-variance optimization using robust estimates of the mean and variance matrices.

This article focuses on the latter and proves that it suffices to robustify the inputs of the mean-variance machinery to get a robust mean-variance portfolio.

However,

- it does not work complicated (non-convex) constraints – there are similar limitations to the equivalence between robust optimization (first sense) and bayesian optimization;
- in high dimensions (the article remains in dimension 3), robust variance matrices are not very robust.

Hedging predictions in machine learning **A. Gammernan and V. Vovk (2007)**

While statistical prediction procedures can provide confidence intervals (or, even better, full posterior distributions, for bayesian statistics), machine learning algorithms only provide a single, naked prediction.

- Find a measure of strangeness, using a machine learning (ML) algorithm, in an ad hoc way, e.g.:
 - absolute value of the residuals in a regression;
 - Lagrange multipliers in a support vector machine (SVM) (it is zero for non-support vectors);
 - for the k nearest neighbours,

$$\alpha = \frac{\sum_{j=1}^k d_{ij}^+}{\sum_{j=1}^k d_{ij}^-}$$

where d_{ij}^+ (resp. d_{ij}^-) is the j th shortest distance (euclidian or other) between i and the observations with the same (resp. a different) label (this can be seen as a “truncated anova”);

- The *empirical p-value* $p_{x,y}$ of an observation (x, y) is the proportion of observations stranger than it (this should remind you of bootstrap p -values);
- For regression problems, after choosing a confidence level ε , the prediction of x is the set

$$\{y \in Y : p_{x,y} > \varepsilon\};$$

- For classification problems,

$$\hat{y} = \underset{y}{\operatorname{Argmax}} p_{x,y}$$

$$\text{credibility}(\hat{y}) = p_{x,\hat{y}}$$

$$\text{confidence}(\hat{y}) = 1 - \underset{y \neq \hat{y}}{\operatorname{Max}} p_{x,y}$$

(this should remind you en *entropy-based estimators*: we are looking for the model under which the data looks as random as possible, *i.e.*, the model that removes as much regularity as possible from the data); the credibility should be high, unless the training set is not iid and/or not representative of the data and/or the new observation is an outlier.

More formally, the measure of strangeness α is called a *non-conformity measure* and is just a family of maps $(X \times Y)^n / \mathfrak{S}_n \rightarrow \mathbf{R}_+$.

The empirical p -value is an approximate *random test*: ideally, it should be a function $t : \mathbf{Z}^* \rightarrow [0, 1]$, where \mathbf{Z}^* is the set of all finite sequences of integers, such that for all $\varepsilon > 0$, for all $n \in \mathbf{N}^\times$, for all probability distribution P on \mathbf{Z}^n ,

$$P(\{z \in \mathbf{Z}^n : t(z) \leq \varepsilon\}) \leq \varepsilon.$$

The article mentions *ridge regression* but seems unaware of the fact that this is not a single estimator but a family of estimators (a *regularization path*), depending on the value of the ridge parameter.

The style consistency of hedge funds **R. Gibson and S. Gyger** **European financial management (2007)**

PAM (partitionning around medoids – this is similar to k -means clustering but the center of the clusters are chosen among the observations) can recognize hedge fund styles as well as principal component analysis (same R^2).

Fuzzy clustering algorithms find the clusters and assign a membership probability for each observation-cluster pair. The authors use an *entropy-based* fuzzy clustering:

- Entropy-based estimators find the probability distribution (p_1, \dots, p_n) that maximizes the entropy $H = -\sum p_i \ln p_i$, subject to all the information available expressed as constraints.
- The cost of a configuration (*i.e.*, a set of membership probabilities) is

$$\text{cost}(Y) = \sum_{ij} p_{ij} d(r_i, y_j)$$

where the r_i are the observations and the y_j the cluster centers. If the cost is known, we can find the membership probabilities that maximize the entropy under the constraint above.

- For the cost defined by each hard clustering configuration (yes, there are many of them), compute the entropy-maximizing membership probabilities and

average them all (*i.e.*, you have no prior preference on the hard clustering configurations).

- Finally, with those membership probabilities, find the cluster centers by maximum likelihood.

After fuzzy clustering, style consistency of hedge funds can be measured as *mean time consistency* (average (over time) membership probability), *consistency deviation* (standard deviation of time consistency) or their ratio (*consistency ratio*); style consistency does not affect returns.

Calibration risk for exotic options
K. Detlefsen and W.K. Härdle
Journal of derivatives (2007)

Derivative models have to be calibrated by minimizing some error function, but the calibration depends on the choice of this error function, leading to *calibration risk* – on top of *model risk*.

Popular error functions include:

- absolute price difference;
- relative price difference;
- absolute implied volatility difference;
- relative implied volatility difference.

This article compares them for the *Heston model*

$$\frac{dS_t}{S_t} = \mu dt + \sqrt{V_t} dW_t^1$$

$$dV_t = \xi(\eta - V_t)dt + \theta\sqrt{V_t}dW_t^2$$

(well-defined if $\xi\eta > \theta^2/2$, but in simulations, negative variances are truncated to zero) and the *Bates model*, which accounts for jumps in the stock prices,

$$\frac{dS_t}{S_t} = \mu dt + \sqrt{V_t}dW_t^1 + dZ_t$$

$$dV_t = \xi(\eta - V_t)dt + \theta\sqrt{V_t}dW_t^2$$

$$Z \sim \text{Poisson}(\lambda, k)$$

$$\log(1+k) \sim N\left(\log(1+\bar{k}) - \frac{\delta^2}{2}, \delta^2\right).$$

The models are calibrated with vanilla options (using the characteristic function of those models – yet another application of the characteristic function) and then used to price exotic options: barrier (un and out call)

$$\text{Payoff} = \mathbf{1}_{\text{Max } S < B}(S_T - K)^+$$

and cliquet

$$\text{Payoff} = \sum_{i=1}^N \frac{S_{t_i} - S_{t_{i-1}}}{S_{t_{i-1}}}$$

(the cliquet pays the sum of the *linear* returns; it is actually more complicated: in each period, the returns are truncated (above and below), and so is their sum).

The article suggests to calibrate with respect to absolute prices to mitigate model risk – or relative implied volatilities, if the model has already been chosen.

Hedge fund activism, corporate governance
and firm performance
A. Brav et al.

Some hedge funds can acquire more than 5% of a company (this has to be filed to the SEC (schedule 13D)) and ask it to change (e.g., sell part of its business, fire its CEO, accept a takeover). The following variables can help predict targeted companies:

- size:
 - market value;
- value:
 - $Q = \frac{\text{debt} + \text{market value}}{\text{debt} + \text{book value}}$;
 - book-to-market;
- performance:
 - sales growth;
 - $\text{ROA} = \frac{\text{EBITDA}}{\text{assets}}$;
- capital structure:
 - debt-to-capital;
 - new equity issuance;
 - dividend yield;
 - payout ratio = $\frac{\text{dividends}}{\text{net income before extraordinary items}}$;
- governance:
 - number of Ginex takeover defenses;
 - institutional ownership;
- liquidity:
 - Amihud illiquidity (daily values, averaged over 1 year):

$$E \left[0.001 \cdot \sqrt{\frac{\text{price} \cdot \text{volume}}{|\text{returns}|}} \right]$$

- idiosyncratic volatility: monthly standard deviation of the daily returns in excess of the industry mean.

A breakdown of the valuation effects of
international cross-listing

A. Bris et al.
European financial management (2007)

Cross-listing effects can be explained by:

- market segmentation;
- liquidity;
- bonding (differences in rights);
- signaling.

Acquisitions, overconfident managers
and self-attribution bias

J.A. Doukas and D. Petmezas
European financial management (2007)

Managers with more than 5 acquisitions in the past 3 years are overconfident.

***Do life insurance stocks
provide superior returns?***
M. Najand et al.

Journal of asset management (2007)

CAPM-GARCH (*i.e.*, CAPM with GARCH noise) is better than CAPM.

Managers with more than 5 acquisitions in the past 3 years are overconfident.

Risk and asset allocation
A. Meucci (2006)

Chapter 1: Univariate statistics

There are three equivalent ways of describing a univariate distribution: the probability distribution function (pdf, f_X), the cumulative distribution function (cdf, F_X) and the *characteristic function* ($\phi_X(\omega) = Ee^{i\omega X}$) – there is also the *quantile function* (F_X^{-1}), but it does not usefully generalize to higher dimensions.

A *location parameter* (mean, median, mode) is defined by affine equivariance; so are *dispersion parameters*: for instance, the standard deviation, the MAD, the interquartile range or the *modal dispersion*

$$\text{MDis} = \left(\frac{d^2 \ln f_X}{dx^2} \Big|_{x=\text{Mod } X} \right)^{-1}.$$

The *Z-score* for a location and a dispersion parameters is

$$Z = \frac{X - \text{Loc } X}{\text{Dis } X}.$$

The first chapter ends with a taxonomy of univariate distributions: uniform, gaussian, Cauchy, Student, log-normal, Gamma (a generalization of the χ^2 distribution, often used as a prior for variance).

Chapter 2: Multivariate statistics

In a multivariate setting, there are still three ways of representing a distribution: pdf, cdf and characteristic function. A multivariate distribution can be factored into 1-dimension distributions (the marginals) and a “purely joint component” – the *copula*, defined as the joint definition of its grades (the *grade* of a univariate distribution being its uniformization).

The book fails to give a taxonomy of copulas, but provides a few examples:

- The copula of a log-normal distribution is a gaussian copula;
- The Student T copula is not independant;
- The copula between prices and log-prices, or between ratio-returns and log-returns, is trivial;
- The copula between a call option and its underlying is trivial.

The copula is invariant under monotonic increasing transformations – e.g., replacing a stock by a call option has no effect.

A *location parameter* (mean, mode) is characterized by

affine equivariance:

$$\text{Loc}(a + BX) = a + B \text{Loc } X$$

for all invertible affine transformations $x \mapsto a + Bx$.

In dimension greater than 1, the median is not a location parameter: it depends on a choice of coordinates.

A *dispersion matrix* is a symetric, positive matrix satisfying the affine equivariance property:

$$\text{DisSq}(a + Bx) = B \text{DisSq}(X) B'$$

for all invertible affine transformations $x \mapsto a + Bx$, such as the covariance matrix or the *modal dispersion*:

$$\text{MDis } X = - \left(\frac{\partial^2 \ln f_X}{\partial x \partial x'} \Big|_{x=\text{Mod } X} \right)^{-1}.$$

The *Z-score* is then:

$$Z = \sqrt{(X - \text{Loc } X)' (\text{DisSq } X)^{-1} (X - \text{Loc } X)}.$$

Any measures of location and dispersion define a family of *location-dispersion ellipsoids* – for non-elliptical distribution, this information is far from sufficient.

For a more empirical/non-parametric/procedural analogue of the location-dispersion ellipsoid, check the notions of *bag plot* and *half-space depth*.

The expected value and the variance are equivariant with respect to not-necessarily invertible transformations: you can obtain the location-dispersion ellipsoid of a portfolio from that of the market.

Higher-order statistics (HOS) can also be defined in the multidimensional case, but they are *tensors*; however, the *coskewness* and the *cokurtosis* tensors can be summarized in one overall index of symmetry (for coskewness) or tail thickness (for kurtosis) – but the book does not tell us how...

The *Schweizer–Wolff* measure of *dependence* of two (univariate) random variables is the L^p distance between their copula and the independant copula, normalized to take values in $[0, 1]$; it is invariant under monotonic (increasing or decreasing) transformations.

Measures of *concordance*, such as *Kendall's* τ or *Spearman's* ρ are only invariant under increasing transformations and take values in $[-1, 1]$; they change sign

under decreasing transformations; furthermore, being zero is only a necessary condition for independence.

Correlation mixes marginal and joint features: it is only an “affine measure of concordance”, it is changed by monotonic transformations of the marginals: “One might wonder why correlation is such a popular tool: (...) for an important class of distributions [elliptical distributions], the correlation completely defines the dependance structure.”

The taxonomy of multivariate distributions includes: matrix-variate gaussian and T distributions, Wishart (generalization of the χ^2 : it is the distribution of $X_1 X_1' + \dots + X_\nu X_\nu'$, where $X_i \sim N(0, \Sigma)$ with $\nu \geq n$).

Elliptical distributions are affine transformations of spherically symmetric distributions, which can be described by a single univariate function: $X \sim \text{El}(\mu, \Sigma, g)$ has density

$$f(x) = |\Sigma|^{-1/2} g((x - \mu)' \Sigma^{-1} (x - \mu))$$

where g is a *probability density generator*: $g \geq 0$ and $\int_0^\infty v^{N/2-1} g(v) dv < \infty$. For instance:

$$g(z) \propto e^{-z/2} \quad (\text{gaussian})$$

$$g(z) \propto (1+z)^{-(1+N)/2} \quad (\text{Cauchy})$$

$$g(z) \propto \left(1 + \frac{z}{\nu}\right)^{-(\nu+N)/2} \quad (\text{Student})$$

(Notice that the gaussian pdf has an exponential decay, while the Student or Cauchy pdf have a *power law* decay.)

Alternatively, elliptic distributions can be recognized from their characteristic function, $\phi(\omega) = e^{i\omega' \mu} \psi(\omega' \Sigma \omega)$, for some suitable real-valued function ψ .

When a *stable distribution* describes a phenomenon (log-returns, risk, etc.) at horizon T , the compounded distribution at horizon $2T$, $3T$, etc. is still in the same family. *Symmetric-alpha-stable* (sas) distributions, $X \sim \text{SS}(\alpha, \mu, m_\Sigma)$, are defined as

$$\phi_X(\omega) = e^{i\omega' \mu} \exp \left(- \int_{\mathbf{R}^N} |\omega' s|^\alpha m_\Sigma(s) ds \right)$$

where m_Σ is a symmetric measure on the ellipsoid $s' \Sigma^{-1} s = 1$.

Beware, stable distributions are dangerous: they violate the central limit theorem (they have no second moment).

When an *infinitely divisible* distribution describes some phenomenon at horizon T , you can (under an independence assumption) get the distribution at horizons $0 < t < T$.

Chapter 3: Market invariants

To model a market, the author suggests to:

- Look for *market invariants*, *i.e.*, iid random variables built from market data (if you see the market

as a machine to produce prices from iid noise, the noise is a market invariant – some people speak of *innovations*), recognized by looking (graphically) at their autocorrelation and comparing their distribution in the first and last half of the sample; examples include: log-returns for the equity market, changes in yield to maturity for the fixed income market, changes in (ATMF) implied volatility for the options market;

- Model their distribution;
- Project their distribution to the investment horizon (e.g., we could use daily data to invest on a monthly horizon) – this can be done using the *characteristic function* and is even easier with additive invariants (such as log-returns);
- Transform the projected market invariant distribution into a market price distribution – even if that transformation is not analytically tractable, one can easily get the moments of the distribution of prices – but be sure to keep track of the propagation of estimation errors.

The quest for market invariants can involve *dimension reduction* or *variable selection*, but this part of the book is a bit confusing and the author fails to warn the reader of the dangers of model selection.

Cointegration is mentioned, for the equity and fixed income markets, but not detailed.

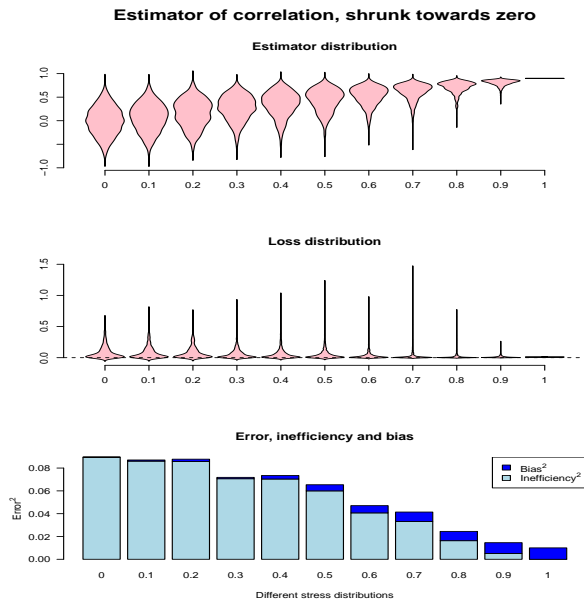

Chapter 4: Estimators

Depending on the amount of information available, you will prefer shrinkage or bayesian estimates (very little data), maximum likelihood estimators (MLE) (more data) or non-parametric estimators (a lot of data).

The quality of an estimator can be measured as its *error* (mean square error, MSE), its *bias* (average distance to the correct value) and its *inefficiency* (standard deviation, *i.e.*, dispersion around its expected value):

$$\text{Error}^2 = \text{Bias}^2 + \text{Inefficiency}^2.$$

One can also consider the *loss*, *i.e.*, the squared distance to the correct value (with respect to some quadratic form) – contrary to the error, the bias or the inefficiency, this is not a number but a random variable. One can look at these quantities and distributions for a family of “stress-test distributions”, to gauge estimation risk.

The *Glivenko–Cantelli* theorem states that the empirical cumulative distribution function (ecdf) is a consistent estimator of the cdf; this yields the *benchmark (non-parametric) estimator*: just replace the cdf in the definition of the quantity of interest by the ecdf; those estimators are often a good starting point and can be improved on (e.g.: sample mean and OLS benchmark estimators are non-biased, while the variance benchmark estimator is).

Kernel estimators are obtained from the benchmark estimators by replacing the Dirac masses in the epdf by gaussian kernels – *i.e.*, we use a smoothed estimator of the pdf.

MLE relies on the assumption that the distribution from which the data is drawn is in a very small set of (known) distributions (sometimes called the *stress distributions*): the MLE is the mode of the distribution of the parameters given the data; it is asymptotically unbiased, asymptotically gaussian, and asymptotically attains the Cramer–Rao bound (*i.e.*, it is the best unbiased estimator – the book assumes you are already familiar with those notions).

The MLE of the parameters of an elliptic distribution (with a known probability density generator g) is a weighted mean and weighted variance; the weights can be computed (iteratively) using the Mahalanobis distance and the density generator. The book does not consider the (semi-parametric) situation of an elliptic distribution with an unknown probability density generator. Linear regression or principal components are still amenable in the case of elliptic distributions.

In the gaussian case, the *condition number*, *i.e.*, the ratio of the smallest to the largest eigen value, measures how close to a sphere the cloud of points is: if it is close to 1, the problem is *well-conditionned*, if it is close to 0, it is *ill-conditionned*.

An estimator is *admissible* if there does not exist another estimator with a lower error for all the stress-test distributions. Benchmark estimators or MLE estima-

tors tend not to be admissible: their bias is low but their inefficiency large (especially when the condition number is close to one); shrinkage estimators have a larger bias and often a much smaller inefficiency, resulting in a lower error.

For instance, the sample mean, with gaussian data, in dimension at least 2, is not admissible: the *James–Stein shrinkage estimator*

$$\hat{\mu}^{\text{Stein}} = (1 - \alpha)\hat{\mu} + \alpha\mathbf{b}$$

$$\alpha = \frac{1}{T} \frac{N\bar{\lambda} - 2\lambda_1}{(\hat{\mu} - \mathbf{b})'(\hat{\mu} - \mathbf{b})}$$

where T is the number of observations, N the dimension, λ_1 the largest eigenvalue (we do not know it: it will have to be computed from an estimator of the variance matrix), $\bar{\lambda}$ the average eigen value and \mathbf{b} any vector, is admissible. The prior \mathbf{b} can be chosen arbitrarily (e.g., 0), or using “prior” information, or as the *grand mean*

$$\mathbf{b} = \frac{\mathbf{1}'\hat{\mu}}{N}\mathbf{1}$$

or as the volatility-weighted grand-mean (*Jorion estimator*)

$$\mathbf{b} = \frac{\mathbf{1}'\hat{\Sigma}^{-1}\hat{\mu}}{\mathbf{1}'\hat{\Sigma}^{-1}\mathbf{1}}\mathbf{1}.$$

(Strictly speaking, this is not prior information, since it is extracted from the same data set; but it is much less volatile.)

Dispersion estimators can be assessed with the *Frobenius loss*

$$\text{Loss}(\hat{\sigma}, \sigma) = \text{tr} \left(\hat{\Sigma} - \Sigma \right)^2.$$

The sample covariance matrix scatters the eigen values away from $\bar{\lambda}$ (this is easily seen when the true eigen values are all equal: the sample eigen values will be more dispersed, the largest eigen values will be too large and the smallest eigen values too small): it squeezes and stretches the location-dispersion ellipsoid; the estimation worsens the condition number of the market invariants. One can shrink the eigenvalues towards their mean (Ledoit):

$$\hat{\Sigma}^s = (1 - \alpha)\hat{\Sigma} + \alpha\hat{C}$$

$$\hat{C} = \frac{1}{N} \sum_{n=1}^N \hat{\lambda}_n$$

$$\alpha = \text{Min} \left(1, \frac{\frac{1}{T} \sum_t \text{tr}(x_t x_t' - \hat{\Sigma})^2}{\text{tr}(\hat{\Sigma} - \hat{C})^2} \right)$$

Ledoit shrinkage also works for regression.

Robustness

Here are a few measures of robustness:

- the *leave-out-one Jackknife*;
- the *sensitivity curve* (add an observation instead of removing it; this is a function of the added observation; in particular, we are interested whether this function is bounded);

- the *influence function* (the infinite-sample limit of the sensitivity curve): generalize your estimator so that it be a function of a distribution:

$$\hat{G} = G\left[\sum_t \delta^{(x_t)}\right]$$

and consider its *Gâteaux derivative* (or *directional derivative*: contrary to the usual (Fréchet) derivative, we do not require it to be linear, *i.e.*, the derivative in the direction $\vec{u} + \vec{v}$ need not be the sum of the derivatives in the directions \vec{u} and \vec{v}):

$$\text{IF}(x, f, \hat{G}) = \lim_{\varepsilon \rightarrow 0} \frac{1}{\varepsilon} \left(\hat{G}[(1 - \varepsilon)f + \varepsilon \delta^{(x)}] - \hat{G}[f] \right).$$

For maximum likelihood estimators (MLE), one can show that

$$\text{IF}(x, f, \hat{\theta}) = A \left. \frac{\partial \ln f_{\theta}}{\partial \theta} \right|_{\theta=\hat{\theta}[f]}$$

$$A = - \left[\int \left. \frac{\partial^2 \ln f_{\theta}(x)}{\partial \theta \partial \theta'} \right|_{\theta=\hat{\theta}[f]} f(x) dx \right]^{-1}.$$

The influence functions of the gaussian MLE of location and dispersion are not bounded: they are not robust; for other elliptical distribution, they are.

More generally, *M-estimators* (or *generalized MLE*) are obtained by modifying the log-likelihood so that the influence be bounded; M-estimators of location and dispersion are actually weighted means and variances.

Outliers

The *breakdown point* of an estimator is the proportion of outliers it can sustain while maintaining a bounded influence function.

The *minimum volume ellipsoid* (MVE: find the smallest ellipsoid containing $x\%$ of the data, for various values of x ; if there is a jump in the volume, we know there are outliers and we know how many) and the *minimum covariance determinan* (MCD: the minimum value of the determinant of the sample covariance matrix containing $x\%$ of the data) have a high breakdown point and are usually computed in a greedy and approximate way, by discarding the observations one at a time.

Missing data

To compute location and dispersion parameters in presence of *missing values*, one can do better than discarding incomplete observations. In dimension 2, if the time series are complete but have different lengths, there is an explicit formula (Stambaugh). In the general case, use the *expectation-maximization* (EM) algorithm.

Beware: the EM algorithm is not a data imputation algorithm. Indeed, since the values are replaced by their expected values, they will have a much lower dispersion; in particular, you cannot naively use them to compute a dispersion parameter (the EM algorithm explains how to compensate for that in the case of the variance – some books forget that compensation in their presentation of the algorithm).

Weighted estimates

Since more recent observations contain less stale information, they can be given a linear weight, either with a *moving window* or *exponential smoothing* – to find the *decay factor*, just put it in the log-likelihood formula for $\hat{\mu}$ and $\hat{\Sigma}$ – this is actually consistent with a GARCH model.

If the location is known to be close to zero (with respect to the dispersion), you can assume it actually is zero: this is a *shrinkage estimator*.

One can also estimate location, dispersion or any other parameter using a *pricing model*, *i.e.*, choosing the parameters so that the model-implied price be as close as possible from the market price.

Chapter 5: Evaluation allocations

The *investor's objective* can be expressed in monetary terms: usually the final wealth or the change in wealth (when the absolute value of wealth does not matter) or the difference between the final wealth and a benchmark.

Dominance

An allocation α *strongly dominates* an allocation β if $\Psi_{\alpha} \geq \Psi_{\beta}$ a.s, where Ψ_{α} is the investor's objective coming from allocation α (it is a random variable). Strong dominance (also called *zeroth-order dominance*) rarely happens and relies on the *join* distribution $(\Psi_{\alpha}, \Psi_{\beta})$.

Weak dominance (or *first-order dominance*) is defined as

$$\forall \psi \in \mathbf{R} \quad F_{\Psi_{\alpha}}(\psi) \leq F_{\Psi_{\beta}}(\psi)$$

where F is the cumulative distribution function.

Equivalently:

$$\forall p \in [0, 1] \quad Q_{\Psi_{\alpha}}(\psi) \geq Q_{\Psi_{\beta}}(\psi)$$

where Q is the quantile function.

Second-order stochastic dominance (SSD) is defined as

$$\forall \psi \in \mathbf{R} \quad E[\Psi_{\alpha} - \psi]^{-} \geq E[\Psi_{\beta} - \psi]^{-},$$

i.e., for every benchmark ψ , the underperformance of α is not as bad as that of β . Equivalently:

$$\forall \psi \in \mathbf{R} \quad I^2[f_{\Psi_{\alpha}}](\psi) \geq I^2[f_{\Psi_{\beta}}](\psi)$$

where

$$I^2[f_{\Psi}](\psi) = I[F_{\Psi}](\psi) = \int_{-\infty}^{\psi} F_{\Psi}(s) ds.$$

These definitions can be generalized to *order-q dominance* – but these are not easily interpretable and still fail to yield a total order.

Satisfaction

Instead of trying to assess the whole distribution of the investor's objective Ψ_α , one can try to summarize an allocation α into a single number $S(\alpha)$, an *index of satisfaction*. We might want it to satisfy some of the following properties:

- money-equivalence: it should be measured in units of money;
- sensibility, *i.e.*, consistence with strong dominance;
- consistence with stochastic dominance;
- constancy: if the distribution of the investor's objective is concentrated in a single point, $\Psi_\alpha = \delta_\psi$, then $S(\alpha) = \psi$;
- positive homogeneity of degree 1 (the investor's objective already is):

$$\forall \alpha \quad \forall \lambda > 0 \quad S(\lambda \alpha) = \lambda S(\alpha)$$

in particular, this gives the *contribution* of each asset (Euler's formula):

$$S(\alpha) = \sum_{n=1}^N \alpha_n \frac{\partial S(\alpha)}{\partial \alpha_n}$$

- translation invariance (translation by a deterministic allocation): if $\Psi_b = \delta_{\psi_b}$, then $S(\alpha + b) = S(\alpha) + \psi_b$;
- super-additivity (if you focus on risk and not satisfaction, you will call this *subadditivity*):

$$\forall \alpha, \beta \quad S(\alpha + \beta) \geq S(\alpha) + S(\beta)$$

- comonotonic additivity (two allocations α and β are *comonotonic* if their objectives are increasing functions of one another, for instance a stock and a call option on it): if α and β are comonotonic, then $S(\alpha + \beta) = S(\alpha) + S(\beta)$, *i.e.*, the index of satisfaction is option-proof;
- concavity (results from homogeneity and superadditivity), *i.e.*, the index of satisfaction promotes diversification;
- risk aversion: if $\Psi_b = \delta_\psi$ and $E\Psi_\alpha = 0$ then $S(b) \geq S(b + \alpha)$.

Examples include:

- the expected value of the objective, $S(\alpha) = E\Psi_\alpha$;
- the *Sharpe ratio*

$$SR(\alpha) = \frac{E\Psi_\alpha}{Sd\Psi_\alpha}$$

(it is not expressed in monetary units; it is homogeneous of degree 0, not 1);

- the certainty-equivalent;
- the value at risk;
- expected shortfall.

Certainty-equivalent

Given a (continuous) increasing *utility function* u , the *certainty equivalent* is

$$CE(\alpha) = u^{-1}E[u(\Psi_\alpha)];$$

this is the value of the investor's objective of a deterministic investment having the same expected utility as α – *i.e.*, this is the expected utility expressed in monetary units thanks to the (inverse of the) utility function:

- it is only homogeneous for *power utility*, $u(\psi) = \psi^{1-1/\gamma}$, $\gamma \geq 1$;
- it is not comonotonic additive (except for a linear utility);
- it is not superadditive (except for a linear utility);
- in general, it is neither nor convex (in particular, the convexity of the utility function is not linked to the convexity of the certainty equivalent);
- if the utility is concave, it is risk-averse.

For theoretical purposes, the utility function can be written

$$u(\psi) = \int g(\theta) H^{(\theta)}(\psi) d\theta, \quad g \geq 0, \quad \int g = 1$$

where H is the Heaviside function (this generates all increasing functions) or

$$u(\psi) = \int g(\theta) \text{Min}(\psi, \theta) d\theta, \quad g \geq 0, \quad \int g = 1$$

(which generates all concave functions).

(I do not understand the explanations about the investor's *subjective probability*.)

A utility function is entirely determined (up to a positive affine transformation) by its *Arrow-Pratt absolute risk aversion*,

$$A(\psi) = -\frac{u''(\psi)}{u'(\psi)}.$$

The *Pearson specification* includes the following particular cases:

- hyperbolic absolute risk aversion (HARA, always concave):

$$A(\psi) = \frac{1}{\gamma\psi + \zeta}$$

- exponential utility: $u(\psi) = -\exp -\frac{\psi}{\zeta}$
- quadratic utility (beware, it is not sensible for $\psi > \zeta$):

$$u(\psi) = \psi - \frac{\psi^2}{2\zeta}$$

- power utility: $u(\psi) = \psi^{1-1/\gamma}$
- logarithmic utility: $u(\psi) = \ln \psi$
- linear utility: $u(\psi) = \psi$.

The Arrow-Pratt risk aversion also yields approximations of the certainty equivalent and the *risk premium*:

$$CE(\alpha) \approx E\Psi_\alpha - \frac{1}{2}A(E\Psi_\alpha) \text{Var} \Psi_\alpha$$

$$\begin{aligned} RP(\alpha) &= E[\Psi_\alpha] - S(\alpha) \\ &= E[\Psi_\alpha] - CE(\alpha) \\ &\approx \frac{1}{2}A(E\Psi_\alpha) \text{Var} \Psi_\alpha \end{aligned}$$

In *prospect theory*, utility functions are S-shaped: concave (risk-averse) for profits and convex (risk-prone) for losses.

Quantile (VaR)

The *value at risk* (VaR), defined as

$$Q_c(\alpha) = Q_{\Psi_\alpha}(1 - c),$$

is

- not consistent with second-order dominance (the definitions of second-order dominance and of the expected shortfall are very similar);
- consistent with first-order dominance;
- not super-additive: it fails to promote diversity;
- comonotonic additive (it is not fooled by derivatives);
- positive homogeneous;
- neither concave nor convex;
- not risk-averse.

The VaR can be computed with: a lot of data, or a gaussian assumption, or the *Cornish-Fisher expansion* (which is an approximation of the quantile function, but it need not be particularly accurate for the extreme values we are interested in), or *extreme value theory* (EVT) (which requires enough data in the tails – but in the 1% tail, you only have 1% of your data).

Coherent indices, spectral indices, expected shortfall

An index of satisfaction is *coherent* if it is

- consistent with strong dominance;
- positive homogeneous;
- translation invariant;
- superadditive.

This implies money-equivalence and concavity. The *one-sided moments* are coherent (but they are not comonotonic additive).

A coherent index of satisfaction is *spectral* if it is estimable (?) and comonotonic additive. This implies weak stochastic dominance and risk aversion.

Spectral indices are of the form

$$\text{Spc}_\phi(\alpha) = \int_0^1 \phi(p) Q_{\Psi_\alpha}(p) dp$$

where ϕ , the *spectrum*, is decreasing, $\phi(1) = 0$ and $\int_0^1 \phi = 1$.

Chapter 6: Optimizing allocations

Portfolio construction proceeds as follows:

- Define the investor's objective;
- Define his index of satisfaction;
- Model the market invariants;
- Project the market invariants to the investment horizon;
- Gather other information: legal constraints, transaction costs;
- Maximize the investor's satisfaction – if there are

several indices of satisfaction, maximize the first subject to bounds on the others.

The author details an example with a closed form solution: total wealth, certainty equivalent for the exponential utility, gaussian prices (the certainty equivalent is then quadratic), linear transaction costs, constraint on the value at risk.

The classes of optimization problems that can be efficiently solved include, from the most specific to the most general:

- Linear programming (LP);
- Quadratic programming (QP);
- Quadratically-constrained linear programming (QCLP);
- Second-order cone programming (SOCP: the *ice cream* constraints);
- Semi-definite programming (SDP);
- Cone programming (up to here, interior point methods are available);
- Convex programming.

Most of the time, e.g., with value at risk or certainty equivalent, we are not that lucky: the optimization problem is not convex. The *mean-variance approximation* can make this problem amenable:

- Express the satisfaction as a function of the moments of the market distribution,

$$S(\alpha) = H(E[\Psi_\alpha], \text{CM}_2(\Psi_\alpha), \text{CM}_3(\Psi_\alpha), \dots)$$

(this is obtained from a Taylor expansion of the utility function or the Cornish–Fisher expansion of the value at risk); the problem is now infinite-dimensional:

$$\begin{array}{ccc} \mathbf{R}^n & \xrightarrow{\quad} & \mathbf{R}^N \xrightarrow{\quad} \mathbf{R} \\ \alpha \mapsto & (E[\Psi_\alpha], \text{CM}_2(\Psi_\alpha), \dots) \mapsto & S(\alpha) \end{array}$$

- Assume that the index of satisfaction is well approximated by the first two moments

$$S(\alpha) \approx \tilde{H}(E[\Psi_\alpha], \text{CM}_2(\Psi_\alpha))$$

- Since the index of satisfaction is consistent with weak stochastic dominance, the optimal allocation is on the *efficient frontier*

$$\alpha(v) = \underset{\substack{\alpha \in \mathcal{C} \\ \text{Var } \Psi_\alpha = v}}{\text{Argmax}} E[\Psi_\alpha], v \geq 0$$

- You now just have to maximize the index of satisfaction on the efficient frontier.

The approximation of $S(\alpha)$ from the first two moments is valid in the following cases:

- The market prices Ψ_α are elliptical (e.g., gaussian), so that their distribution is entirely determined by the first two moments (regardless of the index of satisfaction); this is wrong for derivatives and even for stock prices (it has to be prices, not their logarithms) – but for short horizons, this is good enough an approximation;

- The index of satisfaction really depends only on the first two moments (regardless of the distribution of the market invariants).

Contrary to what many people believe, the risk aversion parameter λ in $E[\Psi_\alpha] - \lambda \text{Var} \Psi_\alpha$ is not a feature of the investor and it does not define an index of satisfaction: its value also depends on the market – in some extreme cases, it only depends on the market and not on the investor; choosing it beforehand yields allocations inconsistent with strong dominance.

The mean-variance approximation is a two-step process: first compute the (approximate) efficient frontier, then maximize the index of satisfaction on this frontier. The one-step mean-variance approximation, *i.e.*, fixing the “Lagrange multiplier” λ , is only valid under very strong assumptions, *e.g.*, gaussian prices and exponential utility.

The following problems are usually considered equivalent, but this is only the case for affine constraints:

$$\begin{aligned} &\text{Maximize } E[\Psi_\alpha] \text{ such that } \text{Var} \Psi_\alpha = v \\ &\text{Maximize } E[\Psi_\alpha] \text{ such that } \text{Var} \Psi_\alpha \leq v \\ &\text{Minimize } \text{Var} \Psi_\alpha \text{ such that } E[\Psi_\alpha] \geq e. \end{aligned}$$

Chapter 7: Bayesian estimators

Bayesian statistics differs from classical inference in two regards:

- we provide some *prior* information as input;
- the output is not a single number or vector but a whole distribution – the *posterior*.

A *classical-equivalent* estimator is the single number (or vector) obtained as a location parameter of the posterior distribution – *e.g.*, *maximum a posteriori* (MAP) estimators, Bayes–Stein estimators, shrinkage estimators.

For some prior and model distributions (called *conjugate distributions*), the posterior is computable in closed form; for instance, the *normal inverse Wishart* distribution specifies the joint distribution of (μ, Σ) as

$$\begin{aligned} \mu | \Sigma &\sim N\left(\mu_0, \frac{\Sigma}{T_0}\right) \\ \Sigma^{-1} &\sim W\left(\nu_0, \frac{\Sigma_0^{-1}}{\nu_0}\right) \end{aligned}$$

and the data is

$$X_t | \mu, \Sigma \sim N(\mu, \Sigma).$$

Similar computations can be performed with factor models.

The prior distribution (or its location parameter) can be defined by

- inverting the unconstrained allocation function $\theta \mapsto \alpha(\theta) = \text{Argmax} S_\theta(\alpha)$, *i.e.*, finding the θ for which the market weights maximize the satisfaction index (the Black–Litterman prior is of this kind) – you might want to add a few constraints, though;

- a (constrained) maximum likelihood estimator.

Chapter 8: Evaluating allocations under uncertainty

An *allocation* is not a single set of weights but a function (a random variable)

$$\text{available information} \mapsto \text{weights}.$$

The *cost of randomness* is the difference between the satisfaction of the best portfolio given perfect insight, *i.e.*, the portfolio with the highest ex-post returns (it is likely to contain a single security) and the optimal (diversified) portfolio.

The *opportunity cost* (OC) is the difference between the satisfaction of the optimal allocation (assuming perfect knowledge of the market distribution) and that of the allocation actually chosen; constraint violations should be expressed in monetary terms (often in an ad hoc way).

Cost of randomness and opportunity cost are random variables.

Prior allocation, *i.e.*, allocation that does not use the information available, is the analogue of a fixed estimator: it is extremely biased.

Sample-based allocations are not too biased but have a very scattered opportunity cost (they are inefficient): the optimal allocation function is very sensitive to its inputs and *leverages* estimation error.

Chapter 9: Shrinkage allocation decisions

Bayesian allocation maximizes the expected utility of the investor’s objective, but the expectation is computed with respect to the posterior distribution; this is the analogue of a classical-equivalent bayesian estimator and the opportunity costs are less scattered than with sample-based allocation. Bayesian methods are *non-linear shrinkage* methods.

Black–Litterman allocation shrinks, not the market parameters, but the market distribution, towards the investor’s prior. The investor provides a random variable V that depends on the as-yet unknown market invariants X , for instance, $V \sim N(w'X, \phi^2)$, where X are the market returns, w' a portfolio on which the investor has a view and ϕ^2 the confidence of this view. Given a realization v of V and the knowledge of the distribution of $V|X$, we can compute the Black–Litterman distribution $X|V = v$ and then the corresponding Black–Litterman allocation decision. The prior X need not be the market invariants, but can be an “official” model. In the gaussian, linear case, the computations are straightforward.

The Mahalanobis distance between the market expectations μ and the Black–Litterman expectations μ_{BL} follows a χ^2 distribution, which can be turned into a p -value, to spot views in contradiction with the prior. To identify which view is responsible, just differentiate this p -value with respect to each view.

Resampled allocation proceeds as follows:

- Estimate the market parameters $\hat{\theta}$ from the data;
- Create new samples, by parametric bootstrap;
- For each sample q , estimate the market parameters θ_q and the corresponding optimal allocation α_p ;
- Average those optimal allocations.

However, resampled allocation can violate investment constraints (e.g., the maximum number of securities) and are difficult to stress-test – see Scherer’s book for more arguments against it.

Robust allocation replaces point estimates of market parameters by *uncertainty regions*: $\text{Argmax}_{\alpha} S(\alpha, \theta)$ becomes

$$\text{Argmax}_{\alpha} \text{Min}_{\theta \in \Theta} S(\alpha, \theta).$$

This depends on the choice (size, shape) of the uncertainty regions; with elliptical uncertainty regions, the problem is a second order cone program (SOCP).

Since bayesian methods output a whole distribution instead of a single value, *robust bayesian allocation* uses the corresponding location-dispersion ellipsoids as uncertainty sets; the radius of the chosen ellipsoid is the investor’s aversion to estimation risk. Under gaussian assumptions, the robust, bayesian, (two-step) mean-variance framework is amenable to explicit computations.

***Beyond Black–Litterman:
views on non-normal markets***
**A. Meucci
Risk (2006)**

The Black–Litterman framework can be generalized to a non-gaussian framework using the *copula-opinion pooling* (COP) methodology:

- Choose a prior distribution (e.g., by an equilibrium argument, as in the traditional BL framework, or by backward-looking estimation, or with forward-looking market-implied values – the prior could be a company-wide model on which individual managers would add their views),

$$V \sim (f_M, F_M, \phi_M)$$

(f_M is the probability distribution function (pdf), F_M the cumulative distribution function (cdf), ϕ_M the characteristic function);

- Choose the views $V = PM$ (each row of P is a portfolio; those portfolios should be independent) and the (marginal) distribution of each of them,

$$\hat{V}_k \sim (f_{\hat{V}_k}, F_{\hat{V}_k}, \phi_{\hat{V}_k})$$

- Blend these distributions with those, ($f_{V_k}, F_{V_k}, \phi_{V_k}$) induced by the market (separately for each view):

$$\tilde{V}_k \sim f_{\tilde{V}_k} = (1 - c_k)f_{V_k} + c_k f_{\hat{V}_k}$$

- Compute the joint posterior distribution of the views, by combining the marginal posterior distribution with the copula induced by the market distribution;

- Complete P into a basis:

$$\begin{pmatrix} V \\ W \end{pmatrix} = \begin{pmatrix} P \\ P^\perp \end{pmatrix} M \quad \text{or} \quad M = \begin{pmatrix} P \\ P^\perp \end{pmatrix}^{-1} \begin{pmatrix} V \\ W \end{pmatrix}$$

and compute the posterior distribution

$$\tilde{M} = \begin{pmatrix} P \\ P^\perp \end{pmatrix}^{-1} \begin{pmatrix} \tilde{V} \\ W \end{pmatrix}.$$

The computations can be carried out explicitly with a skewed T prior and uniform views; the result can be used in an expected shortfall optimization.

Beyond Black–Litterman in practice
**A. Meucci
Risk (2006)**

The COP approach can be applied even if the prior is not amenable to computations, by representing it by a large number (100,000) of Monte Carlo simulations:

- Generate Monte-Carlo samples from the market prior: M ;
- Turn those samples into marginal view priors: $V = PM$;
- Compute the view posterior distributions, using the cdf of the investor’s views;
- Compute the market copula;
- Combine the view posterior marginal distributions with the market copula;
- Compute the market distribution:

$$M = \begin{pmatrix} P \\ P^\perp \end{pmatrix}^{-1} \begin{pmatrix} \tilde{V} \\ P^\perp M \end{pmatrix}.$$

Convex vs concave dynamic allocation
A. Meucci (2002)

In a 2-asset world (cash and a stock), the author compares

- a buy-and-hold strategy;
- a call option (or the corresponding replicating portfolio);
- portfolio insurance (CPPI – the article clearly explains what it is);
- a power-utility maximizing strategy.

Portfolio insurance and call options yield a very similar payoff (indeed, the strategies are almost identical), while the power-utility maximizing strategy has a concave payoff (you would prefer a convex one).

The plots of the payoff of those four strategies are impressive – if you want to promote CPPI or badmouth portfolio optimization (but the results are specific to power-utility).

Broadening horizons
**A. Meucci
Risk Magazine (2004)**

Care should be taken when estimating the market distribution at a short (1 month) horizon and using it

at a longer (several years) one: use the characteristic function. The article details this switch between logarithmic and linear returns in a gaussian world and applies the results to portfolio optimization.

Robust bayesian allocation
A. Meucci

Robust bayesian allocation yields an efficient frontier parametrized by 3 parameters: the target variance, the size of the confidence ellipsoid on the mean, the size of the confidence ellipsoid on the variance matrix – but the efficient frontier is actually 1-dimensional, those 3 parameters, mixing market risk and estimation risk, can be combined in a single parameter.

Bayesian diagnostics for portfolio allocation
F. Corielli and A. Meucci

To decide whether to or how much to rebalance your portfolio towards the optimal portfolio, do not compare the composition of the portfolios (this is not robust) but their utility.

This article actually compares the investor's views and the equilibrium portfolio, in the Black–Litterman framework, and gauges how far from the equilibrium one can go; this will be different for each view: check the derivative of the utility wrt the confidence in each view.

***A common pitfall
in mean-variance asset allocation***
**A. Meucci
Wilmott (2001)**

When using mean-variance asset allocation, investors often mix linear returns and log-returns: the risk matrix is estimated using log-returns (the variance of the ratio returns is then:

$$\mu_{\text{ratio}} = \exp(\mu + \frac{1}{2} \text{diag } \Sigma) - 1$$

$$\Sigma_{\text{ratio}} = \exp(\mu + \frac{1}{2} \text{diag } \Sigma)' (\exp \Sigma - 1) \exp(\mu + \frac{1}{2} \text{diag } \Sigma)$$

but people rarely bother computing it – furthermore, the mean-variance framework assumes that the ratio returns follow an elliptical distribution), the forecasted alphas are ratio returns but are projected to a longer horizon as if they were log-returns. In the short term, those mistakes are harmless, but lead to very different allocations for long-term strategies – the author suspiciously finds that long-term investors should prefer less volatile assets.

Assessing views
G. Fusai and A. Meucci
Risk (2003)

When using the Black–Litterman framework to blend a general model (usually, universal equilibrium) with views, you may want to check how far from the model those views are: this can be measured with the Mahalanobis distance between the model alpha and the

Black–Litterman alpha (they use a RiskMetrics variance matrix, *i.e.*, an exponentially-weighted sample non-central variance matrix). The distance can be brought back to $[0, 1]$ assuming a χ_N^2 distribution (N is the number of assets). If the distance is too large and has to be reduced, you can choose which view to alter by differentiating the distance with respect to the returns of the views and selecting the view with the highest derivative.

Pitfalls in linear models for style analysis
F. Corielli and A. Meucci
Statistical methods and applications (2004)

Debunking bad econometrics (a case study for an econometrics (OLS) course): it is usually a bad idea to consider returns and is preferable to use prices and numbers of shares; some models that are often assumed linear are actually not linear and should be tackled with non-linear regression. There is no loss of parsimony: this is simply “the model you had in mind”, with exactly the same parameters, instead of an approximation. Using non-linear regression might not be that good an idea if you want reliable estimates, but is preferable if you want to compare models.

***Anomalies in the foundations
of ridge regression***
D.R. Jensen and D.E. Ramirez
arXiv:math.ST/0703551

Many people claim, without proof, that *ridge regression*, *i.e.*, replacing the ordinary least squares (OLS) estimator

$$\hat{\beta} = (X'X)^{-1}X'Y$$

by the biased estimator

$$\hat{\beta} = (X'X + \lambda I)^{-1}X'Y$$

is equivalent to a constrained regression

$$\begin{aligned} &\text{Minimize } (Y - X\beta)'(Y - X\beta) \\ &\text{such that } \beta'\beta \leq c^2 \end{aligned}$$

or

$$\begin{aligned} &\text{Minimize } (Y - X\beta)'(Y - X\beta) \\ &\text{such that } \beta'\beta = c^2. \end{aligned}$$

This is actually wrong.

***Forecasting the CATS benchmark with the
double vector quantization method***
G. Simon et al.
arXiv:math.ST/0703143

Double vector quantization (DVQ) can be used to predict a time series (the data comes from the competition on artificial time series (CATS) of the IJCNN 2004 (international joint conference on neural networks)):

- The data is modelled as a non-linear auto-regressive (NAR) time series whose order is computed from the *correlation dimension*

$$p = 2D_{\text{cor}} + 1$$

$$D_{\text{cor}} = \lim_{r \rightarrow 0} \frac{\ln C(r)}{\ln r}$$

$$C(r) = \lim_{n \rightarrow \infty} \frac{2}{n(n-1)} \sum_{1 \leq t < t' \leq n} \mathbf{1}(\|x_t - x_{t'}\| < r);$$

$C(r)$ is the (normalized) number of points in a hypersphere of radius r centered on x_t ; D_{cor} can be estimated by plotting $C(r)$ versus r and looking at the slope of the curve in the middle of the plot;

- Compute a self-organizing map (SOM – any other *quantization* algorithm would do) for the $\mathbf{x}_t = (x_t, \dots, x_{t-p+1})$ and another one for the *deformation regressors* $\mathbf{y}_t = \mathbf{x}_t - \mathbf{x}_{t-1}$;
- Compute the transition probabilities from the cells of the first map to those of the second; use them to *simulate* (do not just take the most probable values) the missing values.

***Measuring financial contagion:
a copula approach***
J.C. Rodriguez

Journal of empirical finance (2007)

You can model pairs of exchange rates, around crises, using switching copulas:

- the marginals are SWARCH (switching ARCH) models;
- the copula is a mixture of Frank, Clayton and Gumbel copulas; the parameters do not depend on the state variable but the weights do.

The model is compared with a switching Student copula with SWARCH marginals using the AICC (the AIC corrected for small sample size; this is better than the BIC is you are more interested in model selection than actual forecasts). Tests are then performed on the upper (and lower) *tail dependence*:

$$\lambda_u = \lim_{u \rightarrow 1} P[Y > G^{-1}(u) | X > F^{-1}(u)]$$

$$= \lim_{u \rightarrow 1} \frac{1 - 2u + C(u, u)}{1 - u}$$

$$\lambda_l = \lim_{u \rightarrow 0} P[Y < G^{-1}(u) | X < F^{-1}(u)]$$

$$= \lim_{u \rightarrow 0} \frac{C(u, u)}{u}$$

where F and G are the cdf of X and Y and C their copula.

Asian currency crises exhibit tail dependance and asymetry, while latin American ones do not.

***Specification and estimation of discrete time
quadratic stochastic volatility models***
H. Kawakatsu
Journal of empirical finance (2007)

The log-quadratic stochastic volatility model is:

$$y_t = \sigma_t u_t$$

$$\ln \sigma_t^2 = a_0 + a_1 x_t + a_2 x_t^2$$

$$x_{t+1} = \phi x_t + \sqrt{1 - \phi^2} v_{t+1} \begin{pmatrix} u_t \\ v_{t+1} \end{pmatrix} \sim N \left(0, \begin{pmatrix} 1 & \rho \\ \rho & 1 \end{pmatrix} \right)$$

***A closed form approach to the valuation and
hedging of basket and spread options***
S. Borovkova et al.
Journal of derivatives (2007)

Option pricing often relies on a log-normal distribution. When the underlying is a linear combination of assets, sometimes with negative coefficients (*commodity basket options*, e.g., *spread options*: spark spread (difference between electricity and gas price), crack spread (difference between crude oil and refined products), soybean crush spread), this no longer works: instead, one can use a shifted and/or reflected log-normal distribution.

***An algorithm for simulating bermudan option
prices on simulated asset prices***
B.N. Hugel and N. Rom-Poulsen
Journal of derivatives (2007)

How to price options when the underlying (e.g., an already complicated option) has itself to be priced by Monte Carlo simulation – in particular, the simulated prices will be too volatile and this bias should be corrected.

Algebraic statistical models
M. Drton and S. Sullivant
arXiv:math.ST/0703609

An *algebraic exponential family* is a semi-algebraic subset (up to diffeomorphism) of a regular exponential family. It is “well-behaved”: its maximum likelihood estimators are asymptotically gaussian.

Using *semi-algebraic sets*, i.e., allowing for inequalities, has applications in phylogenetics with *conditional independance models*, e.g., $X \perp\!\!\!\perp Y | Z \vee U \perp\!\!\!\perp Z$.

The article is very abstract: for instance, regular algebraic families are defined in a non-constructive way, using the Laplace transform.

***Transitional densities of diffusion processes:
a new approach to solving
the Fokker–Planck equation***
A.S. Hurn et al.
Journal of derivatives (2007)

Numerically computing the transition probability distribution function (pdf) of a diffusion process via the Fokker–Planck PDE is tricky: the initial condition is a Dirac measure. Instead, one can consider the cumulative distribution function (cdf) and numerically differentiate it.

***The implied volatility term structure
of stock index options***

S. Mixon

Journal of empirical finance (2007)

$\left(\frac{\partial \text{implied volatility}}{\partial \text{maturity}}\right)_{\text{ATM}}$ can help predict future implied volatility.

When is inter-transaction time informative?

C. Furfine

Journal of empirical finance (2007)

Faster arriving trades move prices more than slower ones; the effect is weaker for actively traded stocks; faster arriving stocks in the same direction are more informative.

***The performance of hedge fund strategies and
the asymmetry of return distributions***

B. Ding and H.A. Shawky

European financial management

To study hedge funds, do not use returns but residual returns, *i.e.*, remove the effect of the market, the Fama-French factors and the square of the market (the corresponding coefficient of the regression is the *coskewness*: that added term yields a higher-moment CAPM).

***Risk measures for hedge funds:
a cross-sectional approach***

B. Liang and H. Park

European financial management

To measure risk, prefer expected shortfall (ES) or *tail risk* (TR) (*i.e.*, $E[(X - \bar{X})^2 | X < \text{VaR}]$) to value at risk or semi-variance.

The Cornish-Fisher expansion is preferable to a non-parametric estimation of ES or TR – the authors do not consider parametric (extreme value theory, EVT) estimation – the non-parametric approach should become preferable with more (daily) data.

***Hedge fund indices:
reconciling investability and representativity***

F. Goltz et al.

European financial management

It is possible to build investable and representative hedge fund indices (classical HF indices are not investable).

***Sources of contrarian profits
in the Japanese stock market***

P.-H. Chou et al.

Journal of empirical finance (2007)

Reversal (with short (1 month) or long (2 years) horizons) works in Japan, because of the *lead-lag* effect, *i.e.*, because of *cross-correlations* between the stock returns.

***Industry information diffusion and the
lead-lag effect in stock returns***

K. Hou (2007)

The *lead-lag* effect (past large-firm returns and future small-firm returns are related) is an intra-industry phenomenon, more pronounced in small (size, volume, market share), less competitive and neglected (analyst coverage, analyst dispersion) industries (institutional ownership also plays a role).

Portfolio selection with heavy tails

N. Hyung and C.G. de Vries

Journal of empirical finance (2007)

For portfolio construction, first order tail expansions are not precise enough: they lead to extreme allocations, with all the weight in the asset with the thinnest tail – in fact, the tail thickness of a portfolio is well approximated by that of its component with the fatest tail.

The article derives asymptotic expansions of $P(X_1 + X_2 > s)$ assuming that X_1 and X_2 are independent and satisfy

$$P(X > s) = As^{-\alpha} (1 + Bs^{-\beta} + o(s^{-\beta})).$$

Are IPOs really overpriced?

S.X. Zheng

Journal of empirical finance (2007)

Studies claiming that IPOs are overpriced often overlook their growth potential (omitted variable problem).

***Interaction of stock return momentum
with earnings measures***

I. Figelman

Financial analysts journal (2007)

Among companies with poor past returns, companies with high ROE or low quality (accruals) underperform.

Migration

E.F. Fama and K.R. French

Financial analysts journal (2007)

The size premium can be explained by small caps becoming large caps and conversely. This remains valid for the value premium – but these are ex post explanations.

***Bayesian learning in financial markets:
testing the relevance of information precision
and price discovery***

N. Hautsch and D. Hess

**Journal of financial and quantitative analysis
(2007)**

Investors are not blind to heteroskedasticity: use a “quality” factor in your models.

Small-world MCMC and convergence to multi-modal distributions: from slow-mixing to fast mixing

Y. Guan and S.M. Krone
arXiv:math.PR/0703021

To reduce mixing time in an MCMC (Markov Chain Monte Carlo) simulation on a multimodal space, you can use, as a proposal distribution, a mixture of a thin-tailed and a fat-tailed distribution. This can be interpreted in graph-theoretic terms as a small-world effect – some people will also see a Levy process.

The article also contains a theoretical (functional analysis) presentation of continuous Markov chains.

A generative model for feedback networks
D.R. White et al. (2005)

There are many models of *random networks*, but not is satisfactory. Here is yet another one, that mimicks kinship or corporate alliances networks:

- Select a node i ,

$$P(i) \propto \text{degree}(i)^\alpha$$

- Select a distance d ,

$$P(d) \propto d^\beta$$

- Generate a search path, from i , of length d , iteratively, randomly choosing a neighbour l , without going through the same node twice,

$$P(l) \propto 1 + u(l)^\gamma$$

where $u(l)$ is the unused degree of l

- If this works (we do find a path), then we add an edge between i and the end of the path; otherwise, we add a new node and link it to i .

Times-series behavior of share repurchases and dividends

B.S. Lee and O.M. Rui
Journal of financial and quantitative analysis
(2007)

The authors compare two hypotheses to explain the fall in the number of companies paying dividends and the rise of buy-backs: either taxes or temporary cash flows – the latter is more likely.

Giving content to investor sentiment: the role of media in the stock market

P.C. Tetlock
Journal of Finance (2007)

The author processes a daily Wall Street Journal editorial over 16 years through a *content analysis* software (General Inquirer, non-free, non-commercial – check <http://www.wjh.harvard.edu/~inquirer/inqtabs.txt> and <http://textanalysis.info>), counting the words in 100 predefined categories;

a principal component analysis (PCA) of the result yields a *pessimism measure*.

It predicts volume, volatility, depth, but not returns – though it is correlated with downwards pressure followed by a reversal.

An examination of alternative portfolio rebalancing strategies applied to sector funds
Journal of asset management (2007)

You should rebalance your portfolio (to make it equal-weighted), if only to limit the effect of bubbles, but there are no significant differences between rebalancing on a trigger or at regular intervals (once a year on average for a portfolio made of index funds).

Event studies with a contaminated estimation period
N. Aktas et al.
Journal of corporate finance (2007)

In event studies, the learning period can be contaminated, *i.e.*, can already contain events (e.g., if you are looking for potential M&A bidders). This can be taken into account with *Markov switching models*, distinguishing between high and low periods.

The article also reviews the tests classically used in event studies.

All events induce variance: analyzing abnormal returns when effects vary across firms
S.E. Harrington and D.G. Shrider
Journal of financial and quantitative analysis
(2007)

Beware of heteroskedasticity in event studies – prefer robust tests.

A theory for long-memory in supply and demand
F. Lillo et al. (2005)

The long memory of the sign of trades can be explained by *market clearing* and hidden orders.

Statistical mechanics of liquidity providers and liquidity takers
J.D. Farmer
Barclays Capital (2007)

The *market impact* is not a “second order effect” as some claim, but the main price formation mechanism (buyer-initiated trades raise the price, seller-initiated ones lower it).

The statistical properties of the price impact can be examined as follows: plot the price impact (logarithm of the ratio of prices) aggregated over 2 (resp. 4, 8, 16, ..., 1024) trades versus the corresponding aggregated signed volume. After rescaling, you get:

This shape can be explained by the following model:

- the volume follows a power law: $p(v) = 1/v^{\alpha+1}$;
- the impact is $f(v) = \text{sign } v \cdot |v|^\beta$

which also gives the slope of the limiting curve:

$$\frac{\text{aggregated returns}}{\text{aggregated signed}} \sim N^{-\kappa}$$

where N is the number of aggregated transactions and κ depends on α and β .

However, this does not give the whole picture: it does not account for the following two facts:

- the orders that arrive are not iid;
- the volume sign has *long-memory*: if you plot the log autocorrelation versus the log of the lag, you get a line, *i.e.*, the autocorrelation decreases very slowly: even after two weeks (remember, these are high-frequency data), autocorrelation is still statistically significant. (As far as statistical estimation is concerned, this is bad news: the error of most estimators decrease as $1/N^{1-H}$, where H is the *Hurst exponent* (expect it to be around 3/4), instead of the usual $1/\sqrt{N}$.)

The main cause of this long memory seems to be, not herding, but the slicing of large trades into smaller ones: indeed, the autocorrelation of the volume signs is more persistent if you restrict the data to a single

broker and the long memory disappears if you consider different brokers.

Long memory does not contradict market efficiency thanks to the following (equivalent) phenomena:

- the price impact is temporary and cancels the long memory;
- there is liquidity imbalance.

One can model the non-iid nature of the orders by assuming that:

- large, *hidden orders* are split into smaller ones;
- large orders follow a power law;
- the market participants know when a large order starts but not when it stops – because of the power law, the probability that the next order will be of the same sign increases with the size of the hidden trade);
- the market is efficient.

This suffices to show that

$$\text{impact} \sim \log N$$

where N is the number of chunks (their size is fixed). This is confirmed by the data – on the other hand, the hypothesis that order flows are anonymized (market participants do not know when a hidden trade starts) do not fit the data.

The life of a hidden order looks like this (the model also predicts clustered volatility; it can take more than four transactions for the market participants to realize that the hidden trade has ended):

In a nutshell:

- power laws are everywhere
- they can be explained by the slicing of large (hidden) orders
- the market participants can recognize those hidden orders, but they do not immediately notice when they have stopped
- the logarithm law, $\text{impact} \sim \log N$ suggests that the *capacity* of your strategy could be higher than you think.

The speaker likens the financial world to an *ecosystem*, with *competition* (if A grows bigger then B loses money; if B grows bigger, then A loses money) and *prey/predator* relations (if A grows bigger, then B earns money; if B grow bigger, then A loses money) – you can also imagine relations not encountered in wildlife ecosystems.

The key role of liquidity fluctuations in determining large price changes

F. Lillo and J. D. Farmer

Fluctuation and noise letters (2005)

In a *double continuous auction market*, such as the LSE (London stock exchange) or the NYSE (New York Stock Exchange), impatient traders send *market orders*, to be executed immediately, at the best possible price, while patient investors send *limit orders* or *quotes*, to be executed at a given price, which are stored in a (publicly visible) queue, the *limit order book*. (At the beginning and the end of the day, there is also an auction, where everyone sends quotes for 10 minutes, and they are only matched at the end. And this is only the *on-book market* (SETS in London, downstairs market in New York): there is an *off-book market* (SEAQ, upstairs market), where trades are decided bilaterally, on the phone, and only made public afterwards.)

Large price changes are determined by holes in the order book and can be triggered by small volumes. Not only the first *gap* (the closest to the best price) matters, but also the others – *sparse* order books call for large price changes.

(The gap size or the sparsity of the book can be measured from the tick data we already have.)

There's more to volatility than volume

L. Guillemot et al. (2005)

Volatility clustering cannot be explained by a change-of-time either using the volume clock or the number-of-transactions clock.

An empirical behavioral model of price formation

S. Mike and J. D. Farmer (2005)

An *agent-based model* of price formation, comprised of

- An order placement model, using a Student T distribution with fewer than 2 degrees of freedom;
- A cancellation model, taking order imbalance and the position wrt the best price

can reproduce the observed distributions of returns and bid-ask spreads.

International bond market cointegration using regime switching techniques

A. Davies

Journal of fixed income (2007)

There is *cointegration* (“integration”) between national bond markets; the common trend presents structural changes.

Simple forecasts and paradigm shifts

H. Hong et al.

Journal of finance (2007)

The following agent-base model:

- A and B are two independant AR processes (think of A as value and B as growth);
- (Log-)dividend payments are given by a linear regression: $D_{t+1} = A_t + B_t + \text{noise}$;
- Investors choose between the two incorrect models $D_{t+1} = A_t + \text{noise}$ and $D_{t+1} = B_t + \text{noise}$; they change their model when the difference in log-likelihood exceeds a certain threshold (this is the confidence level of the statistical (LR) test); that threshold varies from investor to investor;
- The combined behaviour of those investors drives the prices

explains the stylized facts:

- book-to-market effect;
- volatility and skewness are stochastic.

How to make better choices

K. Douglas and D. Jones

New Scientist 2602, May 2007, p.35–43

This article lists several *behavioural biases* that could be applied to bahavioural finance:

- loss aversion
- information overload; to many choices (e.g., in a supermarket, when faced with two queues, you have a 50% chance of chosing the fastest one; with 100 queues, this probability drops to 1%)

- emotions (anger or disgust are bad, depression is good)
- confirmation bias
- anchoring effect (*i.e.*, bayesian shrinkage with a meaningless prior)
- sunk cost
- framing effect (the half full/empty glass)
- social (or peer) pressure.

See also: *Intuition, its powers and perils* (D.G. Myers), *The paradox of choice* (B. Schwartz), *Why choose this book?* (R. Montague), *Why smart people make big money mistakes and how to correct them* (G. Belsky and T. Gilovich).

A tale of two anomalies: the implication of investor attention for price and earnings momentum
K. Hou et al. (2007)

This article examines interactions between:

- investor *attention* (they use the volume as a proxy for it; one could also use analysts' coverage): excessive attention can lead to over-confidence and explain price momentum while lack of attention could lead to post earnings announcement drift (PEAD);
- market direction
- price momentum
- earnings momentum (*standardized unexpected earnings* or SUE).

For instance: price momentum is profitable in up markets; earnings momentum is profitable in down markets.

Liquidity aggregation: what institutional investors need to know
G. Butler
Algorithmic trading (2007)

Presentation of *alternative trading systems* (ATS), *i.e.*, brokers' internal crossing engines, *ATS aggregators* and *electronic communication networks* (ECN) (network between the ATS).

Shedding light on Dark liquidity
J. Suryawanshi and J. Fox (2007)
Algorithmic trading (2007)

(Empty article)

More and more shares are crossed outside the displayed markets (ATS, ECN).

A boosting approach for automated trading
G. Creamer and Y. Freund
Algorithmic trading (2007)
Journal of trading (2007)

The authors implemented the following strategy for the *Penn-Lehman automated trading* (PLAT) competition (a competitor of the university of Michigan's *trading agent competition* (TAC)), that simulates ISLAND, one of the majors ECNs:

- Using Rmetrics, compute technical indicators over the past 90 days (they are detailed in an appendix);
- Apply *boosting* on the trading rules (*decision trees*) derived from those indicators;
- Use a constantly rebalanced portfolio (50% cash, 50% long; or 125% cash, 25% short); peek into the *limit order* book and add limit orders just beyond the best ones; only use *market orders* if this fails.

Stupid data miner tricks: overfitting the S&P 500
D.J. Leinweber
Journal of investing (2007)

Data mining, *i.e.*, the extraction of patterns from large data sets, can go awry and become *data snooping*. To prevent this, the authors suggest to use:

- temporal and cross-sectional out-of-sample;
- a measure of data snooping, such as *White's reality check*;
- random data.

This sounds outdated: no mention of the bootstrap as an alternative to the in- and out-of-sample splitting; no mention of sensitivity measures (influence function, etc.) to measure how dependant on data variations the results are or robust methods to reduce this dependence; no mention of procedures that can cope with an excess of predictive variables (shrinkage, support vector machines (SVM), etc.).

Value and growth, theory and practice
J.S. Brush
Journal of portfolio management (spring 2007)

Value (V) and growth (ΔV) are two (negatively correlated but) different signals, measuring *static* and *dynamic* value. Growth beats value in the short term, while value persists for years. Thanks to the negative correlation, combining them lowers volatility (plot various blends of value and growth in the returns×volatility plane).

The author uses the following value factors:

- dividend to price;
- earnings to price;
- cash flow to price;
- expected earnings to price;
- book value to price

and the following growth factors:

- short-term change in earnings-to-price
- long-term change in earnings-to-price
- estimate revisions (number of upwards revisions, minus number of downwards ones, divided by the total number of revisions, time-weighted);
- earnings surprises (reported earnings minus consensus predicted earnings, at the time of the last earnings report);
- price momentum.

***Should owners of Nasdaq stocks
fear short-selling?***

S.E. Christophe et al.

Journal of portfolio management (spring 2007)

Short selling is not detrimental to stock returns:

- only extreme short selling (over 10%) has a negative impact on stock returns, but only 5 basis points per percentage point;
- dealer short-selling has a positive impact on returns: market makers only short when they receive many buy orders.

The article did not study the effect of short-selling on volatility or during a crash.

***Analysis of the interest rate sensitivity
of common stocks: empirical equity
duration is a useful measure***

F.K. Reilly et al.

Journal of portfolio management (spring 2007)

Equity duration (you might already be familiar with the notion from fixed income), defined from a regression

$$\Delta \text{price} \sim \Delta \text{IR}$$

or

$$\Delta \text{price} \sim \text{market returns} + \Delta \text{IR}$$

is very unstable and depends on the industry and the period (e.g., it changed in 2001).

Clarifications on “Beyond Markowitz”

A.B. Chhabra

Journal of wealth management (summer 2007)

Discussions on what to do with investors who have several goals, do not understand mean-variance optimality and prefer buckets: WAF (wealth allocation framework), DWH (discretionary wealth hypothesis) or HOG (holistic goal optimization).

***How to generate random matrices
from the classical compact groups***

F. Mezzadri

Notices of the AMS, May 2007

To get a random unitary matrix (since $U(N)$ is a compact group, we use its Haar measure), one could think of using the *Gram–Schmidt orthonormalization* – but it is numerically unstable. Instead, one can use the *QR decomposition*, accounting for its non-uniqueness, as follows:

- Take a random, gaussian, complex matrix Z (this probability space is called the *Ginibre ensemble*);
- Compute the *QR decomposition*: $Z = QR$;
- Set $Q' = Q \cdot \text{diag} \left(\frac{r_{11}}{|r_{11}|}, \dots, \frac{r_{NN}}{|r_{NN}|} \right)$

The article gives actual code (in Python, using *scipy*) and examples from applications of random matrix theory (RMT) in quantum mechanics, approximating infinite-dimensional operators with large matrices.

***Enhanced index investing
based on goal programming***

L.-C. Wu et al

Journal of portfolio management (2007)

Goal programming can be used to tackle dual-objective problems, such as active management (*i.e.*, follow the market and beat it, *i.e.*, have a low tracking error with the market and high expected returns): just set a goal for each objective (say, 3% tracking error and 7% returns) and minimize the sum of the distances to those goals.

The authors fail to see that the objectives should be expressed in the same (monetary) unit, lest the user want to tweak the weight given to each.

***Robust portfolio optimization:
recent trends and future directions***

F.J. Fabozzi et al.

Journal of portfolio management (2007)

The article is an informal presentation of robust optimization – or an advert for the authors’ forthcoming book.

Robust optimization provides more stable weights and a better use of the turnover budget than classical mean-variance optimization.

Robust optimization is only equivalent to shrinkage towards the minimum variance portfolio in some very special cases (no uncertainty on the variance matrix, stock variance and estimation variance are proportional, no constraints).

Robust portfolio optimization can also be used to find a portfolio “statistically equivalent” to the optimal one that minimizes transaction costs.

Robust portfolio optimization is essentially a worst-case optimization: *zero net alpha adjustment* changes the shape of the uncertainty set to reflect the fact that estimation errors are not systematically in the wrong direction.

Robust *multi-period* problems can surprisingly prove more tractable than their non-robust analogues.

Robust optimization is not limited to portfolio construction, but also has applications in optimal trading, optimal hedging, econometric model estimation, model selection, etc.

***Does size matter? Assets under management
a questionable question***

G.C. Allen

Journal of portfolio management (2007)

Funds with large AUM (assets under management) are less risky but have lower returns; the effect is less marked with large capitalizations.

**Optimal execution for portfolio transitions:
minimizing opportunity cost**

M. Kritzman et al.

Journal of portfolio management (2007)

To find the best trade order for a *portfolio transition* (i.e., a drastic rebalance), look at the partial derivative of the tracking error (TE) (the distance between the current and desired portfolios) and choose trades that reduce the TE most. (Generally, people use any order that preserves sector neutrality.) You can also add *market impact*, proportional to

$$\sqrt{\frac{\text{trade size}}{\text{average daily volume}}}$$

to the TE.

**Measuring portfolio performance
using a modified measure of risk**

C. Adcock

Journal of asset management (2007)

The *Rubinstein-Leland beta*, defined as

$$\beta^{\text{RL}} = \frac{\text{Cov}(r, -(1+r_m)^{-b})}{\text{Cov}(r_m, -(1+r_m)^{-b})}$$

(where r are the portfolio ratio-returns, r_m the market ratio-returns, the investor's utility is $U(x) \propto x^{1-b}/(1-b)$ and b can be estimated as $b = \frac{1}{2} + (E \ln(1+r_m) - \log(1+r_f))/\sigma_m^2$) does not seem to add anything to the CAPM beta: this can be proven for elliptical distributions, and empirically tested for asymmetric ones.

**Can robust portfolio optimization help
to build better portfolios?**

B. Scherer

Journal of asset management (2007)

Robust optimization is no better than bayesian shrinkage – it actually is a shrinkage towards the minimum variance portfolio, with a difficult-to-interpret-and-predict coefficient. Furthermore, it decouples model uncertainty and risk, while they are inseparable.

(“Robust optimization” is actually a misnomer: it should be called “worst case optimization”.)

Modeling asset characteristics as portfolios

R. Grinold

Journal of portfolio management (2006)

The author explains how to analyze a portfolio using only covariances between portfolio returns.

Let X be the random variable of stock returns, with $EX = \alpha$, $\text{Var } X = V$; let p be the portfolio weights and $P = p'X$ its returns. The ideal portfolio has weights $q = \lambda^{-1}V^{-1}\alpha$ and returns $Q = q'X$, where λ is the

risk aversion. One then has:

$$\alpha_P = \lambda \text{Cov}(P, Q)$$

$$\text{IR}_P = \frac{\alpha}{\text{Sd } P} = \lambda \text{Sd}(Q) \text{Cor}(P, Q)$$

$$\text{TC}_P = \frac{\text{IR}_P}{\text{IR}_Q} = \text{Cor}(P, Q)$$

$$U_Q - U_P = \frac{\lambda}{2} \text{Var}(Q - P)$$

(The transfer coefficient (TC) is a measure of implementation efficiency.)

By decomposing the portfolio weights into several explanatory portfolios (it is up to you to define them),

$$p = \sum_j \beta_j p_j + \varepsilon$$

(in case of multicollinearity problems, you might want to use some shrinkage; also not the absence of intercept: if some relevant factors are missing, they will be spread out over all the terms instead of being put in the residual portfolio), you can decompose the alpha (it is linear in p) into contributions for each source.

For an ex post analysis, just replace the alphas by realized returns.

The article suggests a report as follows:

- Portfolio IR: $\lambda \text{Sd } Q \text{Cor}(P, Q)$
- Portfolio risk: $\text{Sd } P$
- Portfolio alpha: $\lambda \text{Cov}(P, Q)$
- Portfolio TC: $\text{Cor}(P, Q)$
- For each explanatory portfolio:
 - Exposure: $\psi_j = \beta_j \frac{\text{Sd } P_j}{\text{Sd } P}$
 - Risk: $\psi_j \text{Cor}(P_j, P)$?
 - TC: $\text{Cor}(P_j, Q)$
 - IR Sd PTC_j
 - Contribution: $\psi_j \cdot \text{IR} \cdot \text{Sd } P \cdot \text{TC}_j$
- Residual exposure: $\text{Cor}(P, E)$
- Residual risk: $\text{Cor}(E, P)^2$?
- TC_{residual}: $\text{Cor}(E, Q)$
- Residual alpha: $\text{IR} \cdot \text{Sd } P \cdot \text{Cor}(P, E) \cdot \text{Cor}(E, Q)$

**Portfolio constraints and the fundamental law
of active management**

R. Clarke et al. (2002)

(Another article on the transfer coefficient.)

Maximize the Sharpe ratio

Axioma Advisor Newsletter, March 2007

The problem

$$\text{Maximize } \frac{w' \alpha}{\sqrt{w' Q w}}$$

$$\text{such that } w' 1 = 1$$

$$w \geq 1$$

$$\forall i \quad l_i \leq w' s_i \leq u_i$$

can be replaced by

$$\begin{aligned} & \text{Minimize } w'Qw \\ & \text{such that } w'\alpha = \bar{\alpha} \\ & w \geq 1 \\ & \forall i \quad \tau l_i \leq w's_i \leq \tau u_i \end{aligned}$$

The unknowns are w and τ and the desired weights are w/τ , but since you do not know $\bar{\alpha}$, you will have to perform several iterations to fine-tune it. This does not easily generalize to more complicated constraints or penalties (transaction costs, etc.)

Database cracking
S. Idreos et al
CIDR 2007

Database optimizations are usually done by means of indices or partitioning (*i.e.*, prescribing the order in which the data should be stored on the disk): this article suggests that the DBMS should dynamically reorder the data on disk in order to speed queries up.

This is already implemented in MonetDB, a (mainly) main-memory column-oriented DBMS, with SQL and XQuery interfaces.

An anthological review
of research utilizing MontyLingua:
a Python-based end-to-end text processor
M.H.T. Ling
The Python Journal

There are two natural language processing (NLP) Python libraries: NLTK (targeted at NLP teaching) and MontyLingua. This article reviews 19 articles using the latter.

Econometrics
B. Hansen (2000–2007)

There are several differences between econometrics and mainstream statistics:

- The use of *observational data* means that one cannot redo an experiment after changing something: *causality* cannot be inferred;
- Econometricians make as few hypotheses as possible, in particular, they rarely assume that the distributions are gaussian (or even known) or that the variables of interest are independant;
- They do not only want forecasts from their models, they also want inferences on the parameters of those models.

One can consider several *regression models*:

- *Linear regression*:

$$\begin{aligned} y &= x'\beta + e \\ E[e|x] &= 0 \end{aligned}$$

- *Homoskedastic linear regression*:

$$\begin{aligned} y &= x'\beta + e \\ E[e|x] &= 0 \\ E[e^2|x] &= \sigma^2 \end{aligned}$$

- *Linear projection* (we assume that the formula for the coefficient of the regression is valid at the population level and we try to see what we can say from a sample):

$$\begin{aligned} y &= x'\beta + e \\ E[e|x] &= 0 \\ \beta &= E[xx']^{-1}E[xy] \end{aligned}$$

- Homoskedastic linear projection;
- Gaussian linear regression.

The following estimators coincide:

- Take the formula for the linear projection model and replace expectations by means (this is called a *moment*);
- Minimize $\|y - x'\beta\|^2$: this is the *ordinary least squares* (OLS or LS) estimator;
- Assume that the predictors x and the noise e are independant, that the noise is iid gaussian and maximize the likelihood: this is the *maximum likelihood estimator* (MLE);
- Assume that (x, y) only take a finite number of values and compute the corresponding (multinomial) MLE;
- Maximize the R^2 (not mentioned in this book).

In the linear projection model, the LS estimator is the *best linear unbiased estimator* (BLUE) and *semi-parametric efficient* (*i.e.*, it has the smallest mean square error (MSE) among the feasible estimators; a *feasible* estimator is an estimator that does not use parameters we do not know, e.g., it cannot use σ).

The regression can be done in two steps:

$$\text{res}(y \sim x_1 + x_2) = \text{res}(\text{res}(y \sim x_2) \sim \text{res}(x_1 \sim x_2)).$$

In case of *multicollinearity*, *i.e.*, redundant predictive variables, it will be difficult to disentangle the effects of the predictors.

To measure the influence of isolated observations, you can compute their *leverage*, the *leave-out-one* (LOO) $\hat{\beta}$ and residuals.

The quality of a regression model can be measured by estimators of $\rho^2 = 1 - \sigma^2/\sigma_y^2$:

$$\begin{aligned} R^2 &= 1 - \frac{\hat{\sigma}^2}{\hat{\sigma}_y^2} \\ R_{\text{adj}}^2 &= 1 - \frac{s^2}{\hat{s}_y^2} \end{aligned}$$

where

$$\begin{aligned}\hat{\sigma}^2 &= \frac{1}{n} \sum \hat{e}_i^2 \\ s^2 &= \frac{1}{n-k} \sum \hat{e}_i^2 \\ \hat{\sigma}_y^2 &= \frac{1}{n} \sum (y_i - \bar{y})^2 \\ \hat{s}_y^2 &= \frac{1}{n-1} \sum (y_i - \bar{y})^2\end{aligned}$$

The least squares estimator is *consistent*: it converges, in probability, to the true value of the parameter. More precisely, $\sqrt{n}(\hat{\beta} - \beta) \xrightarrow{d} N(0, V)$ where

$$\begin{aligned}Q &= E[xx'] \\ \Omega &= E[(x_i e_i)(x_i e_i)'] = E[x_i x_i' e_i^2] \\ V &= Q^{-1} \Omega Q^{-1}.\end{aligned}$$

For the homoskedastic projection model, the variance is $V^0 = Q^{-1} \sigma^2$.

Since the true value of V is not knowable, we estimate it:

- Traditional: $\hat{V}^0 = \hat{Q}^{-1} s^2$;
- Heteroskedasticity-robust covariance matrix:

$$\hat{V} = \hat{Q}^{-1} \hat{\Omega} \hat{Q}^{-1};$$

- MacKinnon–White jackknife estimator:

$$\hat{V}^* = (n-1) \sum (\hat{\beta}_{(-i)} - \bar{\beta})(\hat{\beta}_{(-i)} - \bar{\beta})';$$

- Andrew’s cross-validation estimator.

The *t*-statistic

$$t_n(\theta) = \frac{\hat{\theta} - \theta}{s(\hat{\theta})},$$

with $\theta = h(\beta)$ some function of the parameters,

$$\begin{aligned}s(\hat{\theta}) &= n^{-1/2} \sqrt{\hat{H}'_{\beta} \hat{V} \hat{H}_{\beta}} \\ H_{\beta} &= \frac{\partial h}{\partial \beta}(\beta),\end{aligned}$$

converges in distribution to $N(0, 1)$ (it is asymptotically *pivotal*, *i.e.*, the limit distribution no longer depends on the parameters) and can be used for (asymptotic tests) or (asymptotic) confidence intervals.

The *Wald test* is a higher-dimensional analogue:

$$W_n = n(h(\beta) - \theta_0)(\hat{H}'_{\beta} \hat{V} \hat{H}_{\beta})^{-1}(h(\beta) - \theta_0)';$$

it converges in distribution to χ_q^2 where $q = \text{rank } H_{\beta}$.

The *F*-test is a special test of the Wald test where one checks if one or several of the parameters is zero.

With gaussian linear model, one knows the distribution of the *T*-statistic and can replace the Wald test by a more precise *likelihood ratio* (LR) test – the former is a first-order approximation of the latter.

The *T*- and Wald tests do not work well with non-linear hypotheses – in that case (if you cannot transform the

hypothesis into a linear one), or if the sample is small prefer Monte Carlo simulations,

OLS is efficient in the projection model (and in the gaussian one, of course), but not in the linear regression model. However, the *generalized least squares* (GLS) estimator is efficient:

$$\begin{aligned}\tilde{\beta} &= (X' D^{-1} X)^{-1} (X' D^{-1} y) \\ D &= \text{diag}(\sigma_1^2, \dots, \sigma_n^2) \\ \sigma_i^2 &= \sigma^2(x_i) = E[e_i^2 | x_i].\end{aligned}$$

If you want a feasible estimator, replace σ_i^2 by some estimator $\hat{\sigma}_i^2$, *e.g.*, from a *skedastic regression* $\sigma_i^2 = \alpha' z_i$.

GLS is less robust than OLS: only use it if you really, really need it.

Heteroskedasticity can be tested with a Wald test on the skedastic regression; the White and Breusch–Pagan tests actually test for more: second-order independence (the z_i include the x_i , their squares and cross-products).

I have not read section 5.3 on forecast intervals.

Non-linear least squares estimate a (prescribed) non-linear expression for the conditional mean, still minimizing the sum of squared errors. Non-linear models need not be *identifiable*: *e.g.*, if $y = \beta x^{\gamma}$ and $\beta = 0$, then γ is not identified.

Least absolute deviations (LAD) minimizes the sum of the absolute values of the errors:

$$\theta_0 = \underset{\theta}{\text{argmin}} E |y - \theta|;$$

equivalently:

$$P(y \leq \theta_0) = P(y \geq \theta_0) = \frac{1}{2}$$

or

$$E[\text{sgn}(y - \theta_0)] = 0.$$

LAD works better when there are many observations bear the median, *i.e.*, when $f(0)$ is large. This is the case with many skewed distributions (there are more observations around the median than around the mean) and fat-tailed distributions (they are “pointy”).

LAD is a special case of *quantile regression*, usually implemented as a linear problem.

To test for non-linearity, just add non-linear functions of the regressors and perform a Wald test: the *RESET test* uses $\hat{y}^2, \hat{y}^3, \dots, \hat{y}^m$ and is particularly powerful at detecting *single-index models*: $y = G(x' \beta) + e$.

Omission of a relevant variable leads to the *omitted variable bias*. When the error is conditionally heteroskedastic, $E[e_i^2 | x_i] = \sigma^2$, the inclusion of irrelevant correlated variables reduces efficiency; without homoskedasticity, there is no clear rule.

Statistical tests do not help for *model selection* (they are not symmetric); AIC (an estimator of the Kullback–Leibler distance) selection is inconsistent (it overfits): prefer the BIC.

A statistic can be written as $T_n(F)$ where F is the (population) distribution function of the data and n the number of observations. To estimate the cumulative distribution function (cdf) $G_n(u, F) = P(T_n \geq u | F)$, the *non-parametric bootstrap* makes two approximations:

- Use a consistent estimator of the cdf F , such as the *empirical distribution function* F_n ;
- Use a Monte Carlo simulation to estimate $G_n^*(u) = G_n(u, F_n)$ – in other words, we sample *with replacement* (to simulate the multinomial distribution F_n) from the sample.

The *bias-corrected* bootstrap estimator is $\hat{\theta} - (\bar{\hat{\theta}}^* - \hat{\theta}) = 2\hat{\theta} - \bar{\hat{\theta}}^*$ where $\hat{\theta}$ is the value of the estimator T on the sample, $\hat{\theta}^*$ is the value of T on a bootstrap sample, $\bar{\hat{\theta}}^*$ is the average value value of T on the bootstrap samples, $(\bar{\hat{\theta}}^* - \hat{\theta})$ is an estimator of the bias.

Variance estimators are not very useful for the bootstrap: prefer *confidence intervals*:

- The oft-used *Efron percentile interval*, $[\hat{\theta} - q(\alpha/2), \hat{\theta} - q(1 - \alpha/2)]$, where q are the quantiles of $\hat{\theta}^* - \hat{\theta}$, is biased (unless the distribution of symmetric) and should be avoided;
- The *percentile interval*, $[\hat{\theta} - q(1 - \alpha/2), \hat{\theta} - q(\alpha/2)]$, is preferable;
- The *percentile-t interval* uses the quantiles of

$$\frac{\hat{\theta}^* - \hat{\theta}}{s(\hat{\theta}^*)};$$

- The *symmetric percentile-t interval* uses the quantiles of

$$\frac{|\hat{\theta}^* - \hat{\theta}|}{s(\hat{\theta}^*)};$$

The convergence of bootstrap estimates is $O(n^{-1/2})$, but the $n^{-1/2}$ term is even and the n^{-1} term odd: this can lead to cancellations in certain situations – notably, the percentile-t interval is in $O(n^{-1})$ and the the symmetric percentile-t interval is in $O(n^{-3/2})$.

To bootstrap a regression $y = x'\beta + e$, sample the noises e_i^* from the residuals \hat{e}_i and resample the predictors (or leave the predictors as-is) – but this assumes that predictors x and noise e are independent.

The *wild bootstrap* uses a 2-point distribution for each e_i^* so that the first three (conditional) moments of e_i^* coincide with those of \hat{e}_i :

$$P \left[e_i^* = \frac{1 \pm \sqrt{5}}{2\sqrt{5}} \right] = \frac{1 \mp \sqrt{5}}{2\sqrt{5}}.$$

Empirical likelihood (EL) maximizes the likelihood of the sample, seen as a multinomial model, $\sum \log p_i$, subject to $\sum p_i = 1$ and all the *estimating equations* you

have. For instance:

$$\begin{aligned} &\text{Maximize } \sum \log p_i \\ &\text{such that } \sum p_i = 1 \\ &\quad y - x'\beta = 0 \end{aligned}$$

The actual optimization requires *Lagrange multipliers* and is not straightforward. The EL estimator is asymptotically efficient and can be used to perform likelihood ratio (LR) tests.

The rest of the book is less clear and/or more superficial.

The presentation of the *generalized method of moments* (GMM) (B. Hansen invented it in the 1980s) is by far the least readable chapter.

An *endogeneous* model is a model $y = z'\beta + e$ with $E(ze) \neq 0$. For instance:

- You want to estimate β in $y = x'\beta + e$ but you only observe the predictor x with noise: $z = x + u$ (with OLS, the forecasts of y will be fine, but the estimation of β will be biased);
- There is a *feedback* in the system you are modeling:

$$\begin{aligned} q &= \beta_1 p + e_1 \\ p &= \beta_2 q + e_2; \end{aligned}$$

naive projection then suffers for the *simultaneous equations bias*: $\beta_1^* = (\beta_1 - \beta_2)/2$

One solution to the endogeneity problem is to add variables for which $E(xe) = 0$ – these are called *instrument variables* (IV). The estimation can be done by GMM or EL.

The presentation of the *IV estimator* and the *indirect least squares* (ILS) is confusing.

In case of homoskedasticity, $E(e_i^2 | x_i) = \sigma^2$, one can use the *two-stage least squares* (2SLS) estimator: regress z on x , then y on \hat{z} . The 2SLS bias increases with the number of IV and decreases with sample size.

The time series chapters are too superficial but cover AR, unit roots, cointegration and Granger causality.

Limited dependant variables (LDV), i.e., binary (logit, probit; which can be interpreted as a *latent variable model*), multinomial, integral (Poisson regression), censored are mentioned, but only estimated with parametric maximum likelihood, even though semi-parametric methods are superior.

The *Tobit model* is the censored regression

$$\begin{aligned} y_i &= (y_i^* > 0) ? y_i^* : 0 \\ y_i^* &= x_i'\beta + e_i \\ e_i &\sim N(0, \sigma^2) \end{aligned}$$

The *sample selection* problem is similar:

$$\begin{aligned} y_i &= x_i'\beta + e_i \\ T &= \mathbf{1}(z_i'\gamma + f_i) \end{aligned}$$

and y is only observed when $T = 1$. Since $E[e | T = 1] = \rho\lambda(z'\gamma)$, where $\rho = \text{Cov}(e, f)$, $\lambda = E[\varepsilon | \varepsilon > -x] = \phi(x)/\Phi(x)$, $\varepsilon \sim N(0, 1)$ (λ is called the *Mills ratio*), it is natural to estimate β and ρ using

$$y = x'\beta + \rho\lambda(z'\gamma) + u$$

$$E[u | T = 1] = 0$$

where γ is estimate with a probit model – this 2-step procedure is the *Heckit estimator* and it has a few robustness problems.

Only two *panel* data models are presented:

$$y \sim (1 | \text{subject}) + x$$

$$y \sim (1 | \text{subject}) + \text{lag}(y) + x$$

The quality of a *kernel density estimation* can be measured by the bias, the variance, their sum (asymptotic MSE or AMSE) (but all this depends on the point) or the integral of that sum (integrated AMSE or AMISE)

$$\text{Bias}(x) = \frac{1}{2}f''(x)h^2\sigma_K^2$$

$$\text{Var} \hat{f}(x) \approx \frac{f(x)R(K)}{nh}$$

$$\text{AMSE}(x) = \text{Bias}(x) + \text{Var} \hat{f}(x)$$

$$\text{AMISE}(x) = \int \text{AMSE}(x) dx$$

where K is the kernel, $R(K) = \int K^2$ its *roughness* and h the bandwidth. This can be used to choose the bandwidth.

Bootstrap methods and permutation tests **T. Hersterberg et al.**

This is part of the S-Plus documentation but remains software agnostic. It gives some good advice (use bootstrap confidence intervals corrected for bias and skewness; permutation tests are not valid if, under the null hypothesis, the two samples do not have the same spread and shape), but fails to give any technical detail (you will not know how *BCa* and *tilting* confidence intervals are computed).

Developing time-oriented database applications in SQL **R.T. Snodgras** **Morgan Kaufman (2000)**

This is an SQL cookbook for temporal problems. Its examples are complicated, anti-pedagogic (lots of numeric magic numbers, numeric codes, abbreviations and cryptic acronyms as column names, only chunks of the database at a time so as to prevent a global view of the data, examples intentionally “quite difficult to decipher”, etc.) and dusty (some references to Cobol).

There are three temporal types (instants, intervals and periods (anchored intervals)); three types of times (user-defined (a normal piece of data), valid time

(time in the real world), transaction time (time in the database)); three types of statements (current, sequenced, non-sequenced). Time in SQL is *granular* (i.e., discrete, e.g., with a 1-day or 1-minute precision).

NOW is an unsolved problem in SQL: you can either use NULL, but this has side effects for comparisons and clashes with other uses of NULL or use a magic value far in the future, which, besides its arbitrariness, leads to a confusion between “until further notice” and “forever”.

A temporal table is a table with **start** and **end** columns. A *temporal partition* splits this table into current (the **end** column contains NOW) and past tables (this is actually a solution to the NOW problem). A *snapshot table* is a slice of a temporal table, at a given date. A *transaction table* contains a log of the changes to a table (similar to a set of patches in a version control system). You might want to vacuum transaction tables or even temporal tables, if old data becomes irrelevant.

A *bitemporal table* contains both valid time and transaction time: there are two **start** and two **end** columns. A bitemporal table can be partitionned along valid time, transaction time or both.

Most of the book is devoted to the handling, in SQL, of temporal or bitemporal tables: sequenced JOIN,

```
SELECT A.x, B.y, ...
      last(A.start, B.start) AS start,
      first(A.end, B.end) AS end
FROM A, B
WHERE ...
AND last(...) < first(...);
```

sequenced EXCEPT, sequenced DISTINCT (trickier: procedural), sequenced PRIMARY KEY, sequenced UPDATE, etc. – if in doubt, draw all the possible relative positions of the intervals and write a huge query full of UNION or CASE.

Bitemporal tables complicate things, but not as much as one would fear. Bitemporal diagrams are bidimensional.

The recipe to build a temporal database goes as follows:

- Build a non-temporal ER (entity-relation) model;
- Add time;
- Convert it into a relational model (no more entities, only relations);
- Convert it to a physical model (with tables, taking into account efficiency problems, e.g., temporal partitioning).

To deal with time in an application using the database, choose among:

- Avoid time;
- Write unreadable SQL code;
- Use a middleware to convert SQL/Temporal (a rarely implemented part of the SQL standard) to SQL.

The book ends with a presentation of SQL/Temporal: it adds a PERIOD data type,

```
PERIOD '[2001-01-01 2002-01-01]';
```

with a few operators (OVERLAPS, PRECEDES, SUCCEEDS, MEETS, BEGIN, END, LAST, PRIOR, NEXT, P_UNION, P_INTERSECT, P_EXCEPT, CAST (to change the granularity)), a VALIDTIME keyword to handle temporal tables

EXPAND and NORMALIZE (for sets of potentially overlapping or abutting periods) operators and a NORMALIZE ON construct (similar to GROUP BY).

You may note that SQL/Temporal fails to address the NOW problem.

***The statistical bootstrap
and other resampling methods***
P. Burns (2007)

A short introduction to the bootstrap.

Dart to the heart
P. Burns (2007)

A advert for random portfolios, comparing them to benchmarks and peer groups.

***Total return strategies
for multi-asset portfolios:
dynamically managing portfolio risk***
U. Herold et al.
Journal of portfolio management (2007)

This article review various dynamic asset allocation (DAA) strategies:

- Portfolio insurance (stop loss, synthetic put, CPPI);
- Rainbow options (best-of-two, best-of- n plus floor);
- Optimization with a constraint on the value at risk (VaR) or the expected shortfall (ES, CVaR), e.g., require that the probability of going below a pre-determined floor be below 1%.

The VaR-based strategies seem preferable, provided one controls the turnover.

***A Cardan's discriminant approach
to predicting currency crashes***
S.K. Koh, W.M. Fong and F. Chan
Journal of international money and finance
(2007)

The *generalized normal* (GEN) distribution,

$$f(u) \propto \exp \left(\theta_1 u + \theta_2 \frac{u^2}{2} - \frac{u^4}{4} \right),$$

allows for bimodality and can be used to model large jumps. Bimodality can be measured with *Cardan's determinant*

$$CD = \frac{\theta_1^2}{4} - \frac{\theta_2^3}{27}$$

which can help predict currency crises – both type I and type II error rates are low.

The same idea could be generalized to any other jump prediction situation.

Towards reliable efficient frontiers
K. Schöttle and R. Werner
Journal of asset management (2006)

One could use *robust optimization*:

- For the portfolio to change slowly with time, when the inputs are changed;
- For the portfolio to change slowly when changing the risk target;
- To account for parameter estimation error.

Robust optimization outperforms *Michaud's resampled portfolio*, which outperforms classical mean-variance optimization.

***Incorporating estimation errors into portfolio
selection: robust portfolio construction***
S. Ceria and R.A. Stubbs
Journal of asset management (2006)

The list of alternatives to mean-variance portfolio optimization:

- *James–Stein estimators* shrink the expected returns of each asset to the average expected returns, depending on the volatility of the asset;
- *Jorion estimators* shrink the expected returns estimate towards the minimum variance portfolio;
- The *Black–Litterman* model blends views on some portfolios to implied market returns;
- *Michaud's resampled portfolios* are computed as follows: on bootstrap samples, estimate average returns and variance matrix, compute the optimal portfolio, average those portfolios;
- Adding constraints might improve (or worsen) the sensitivity of the portfolio to parameter changes;
- Robust optimization, where we only give the optimizer intervals containing the alpha;

the authors add a new one.

One can estimate the error on the expected returns of the portfolio and maximize this return with a penalty for the estimation error:

$$\begin{array}{ll} \text{Maximize} & \mathbf{w}'\boldsymbol{\alpha} - \lambda \left\| \Sigma^{1/2} \mathbf{w} \right\| \\ \text{st} & \mathbf{w}'V\mathbf{w} \leq v \\ & \mathbf{w}'\mathbf{1} = 1 \\ & \mathbf{w} \geq 0 \end{array}$$

where λ is the penalty for the estimation error, Σ is the variance matrix of the estimation errors, V is the variance matrix of the returns, $\boldsymbol{\alpha}$ are the forward returns, v is the risk target and \mathbf{w} are the portfolio weights the optimizer should find.

This is not a quadratic problem, but a *second-order cone program*.

***Improving investment performance
for pension plans***
J.M. Mulvey et al.

Journal of asset management (2006)

We do not live in a one-period world; traditional risk-reward measures such as the Sharpe ratio are not directly applicable to a multi-period setup; one should consider multi-period strategies, stochastic programming, etc.

***Investing in hedge funds: adding value through
active style allocation decisions***

L. Martellini et al. Edhec, SGAM (2005)

The Black–Litterman framework can be generalized to allow views on higher moments; the optimization can then use a fourth-order approximation of the utility function and the (Cornish-Fisher) VaR as a risk measure.

***An analysis of performance measures
using copulae***

S. Hwang and M. Salmon (2001)

The following performance measures

- *Jensen's alpha*, i.e., the intercept in the regression of the returns (we always consider the returns minus the risk-free rate) against the market returns (this is the alpha in the CAPM);
- The *Treynor and Mazuy measure*, the intercept and the quadratic term in a quadratic CAPM,

$$\begin{aligned} r_t &= \beta_1 r_t^{\text{market}} + \beta_2 (r_t^{\text{market}})^2 + \varepsilon_t \\ \text{TM} &= \alpha + \beta_2 E[(r_t^{\text{market}})^2] \end{aligned}$$

- The higher moment performance measure (?)

$$\begin{aligned} \text{HM} &= \mu + \lambda_1 \mu_M + \lambda_2 (\beta_{P,M} - \gamma_{P,M}) \\ \mu &= E[r_t] \\ \mu_M &= E[r_t^{\text{Market}}] \\ \sigma_M^2 &= \text{Var}(r_t^{\text{Market}}) \\ \gamma_M &= \frac{\text{Cov}(r_t^{\text{Market}}, r_t^{\text{Market}}, r_t^{\text{Market}})}{\sigma_M^4} \\ \theta_M &= \frac{\text{Cov}(r_t^{\text{Market}}, r_t^{\text{Market}}, r_t^{\text{Market}}, r_t^{\text{Market}})}{\sigma_M^4} \\ \beta_{P,M} &= \frac{\text{Cov}(r_t, r_t^{\text{Market}})}{\sigma_M^2} \\ \gamma_{P,M} &= \frac{\text{Cov}(r_t, r_t^{\text{Market}}, r_t^{\text{Market}})}{\sigma_M^3} \\ \lambda_1 &= \frac{\gamma_M^2 \gamma_{P,M} - \theta_M}{\gamma_M^2 - (\theta_M - 1)} \\ \lambda_2 &= \frac{\gamma_M \sigma_M}{\gamma_M^2 - (\theta_M - 1)} \end{aligned}$$

- The positive weighted weighting (PPW) measure (?)

The Sharpe ratio is very different from the others and, worryingly, for extreme positive values, those performance measures are *asymptotically independent*.

To this end, the article reviews various measures of tail or asymptotic dependence, around

$$\lambda = \lim_{u \rightarrow 1} P[Y > F_Y^{-1}(u) | X > F_X^{-1}(u)].$$

To obtain a more reliable measure of performance, one can use a *copula*, describing the relation between those measures, to combine them, yielding the following distribution (the choice of the copula is left to the reader, e.g., a gaussian copula to simplify the computations):

$$f(x|f1, f2) = f_1(x)f_2(x)c(1 - F_1(x), 1 - F_2(x)).$$

***Stock returns and volatility:
pricing the short-run and long-run
components of market risk***

T. Adrian and J. Rosenberg (2006)

Volatility can be modeled by a GARCH-like model where $\log v_t$ is the sum of two AR(1) processes.

***Market reactions to tangible
and intangible information***

K. Daniel and S. Titman
Journal of finance (2006)

The *intangible return*, i.e., the component of the past returns unexplained by the firm's past performance, defined as the residuals of the regression (over 5 years; the book-value growth is actually corrected for dividend payments)

$$\text{forward returns} \sim \log(B/P) + \text{growth}(B)$$

is negatively related to future returns.

The article also explains why the B/P helps predict future returns: it can be written as

$$\log(P/B)_{\text{now}} = \log(B/P)_{\text{before}} + \text{growth}(B) - \text{growth}(P)$$

(where $\text{growth}(x) = \log(x_{\text{now}}/x_{\text{before}})$) and only $\text{growth}(B) - \text{growth}(P)$ has a predictive power.

Predicting the time-varying covariance matrix of electricity forwards

K. Aas and K.F. K arsen (2003)

The ARCH model can be generalized to describe the covariance between similar, short-lived, overlapping time series (forwards).

Trimability and fast optimization of long-short portfolios

B.I. Jacobs et al.

Financial analysts journal (2006)

The authors explain how to transform most long-short optimization problems into a long-only problem, suitable for long-only optimizers.

Feedback and the success of irrational investors

D. Hirshleifer et al.

Journal of financial economics (2006)

It is good to be an early irrational investor and bad to be a late one – provided many share your irrationality. Early irrational investors have private information about the future order flow of investors with similar biases. This effect causes prices to follow a random walk...

A comparison of financial duration models via density forecasts

L. Bauwens et al. (2000)

Duration data are irregular time series represented as bidimensional time series, $(x_n, t_n - t_{n-1})$, where x_n is the value measured at time t_n . Examples include price or volume in high-frequency financial data. They exhibit properties similar to those of GARCH data, such as *duration clustering*: hence, one can model them along the same lines by replacing the (unobserved) volatility by the (observed) duration – GARCH becomes ACD (autoregressive conditional duration), T-FARCH becomes TACD (threshold ACD), log-GARCH becomes log-ACD and stochastic volatility models become SVD (stochastic volatility duration).

The authors compare those methods using *density forecasts*: prediction methods do not simply provide a forecast value \hat{x}_i , but a whole forecast distribution \mathcal{F}_i : for each observation i , you can compute $p_{\mathcal{F}_i}(x_i)$, where x_i is the actual observation and $p_{\mathcal{F}_i}$ is the p -function (cumulative distribution function) of the predictive distribution. If the forecasts are correct, the $p_{\mathcal{F}_i}(x_i)$ should be uniformly distributed – this can be tested. This method accounts for models that change over time.

Equity style timing using support vector regressions

G. Nalbantov et al.

Support vector machines (SVM) can be used to *time* growth vs value and large vs small strategies.

The variables used are: value-growth spread, small-large spread, S&P 500 volatility, 12-month forward S&P 500 P/E, 6-month S&P 500 momentum, EPS change over the past year in the S&P 500, P/E differences between value and growth, P/E differences between large and small caps, dividend yield difference between value and growth, dividend yield difference between large and small caps, yield spread Baa vs Aaa, 12-month change in the US CPI (consumer price index), difference between the forward E/P of the S&P 500 and the 10-year T-bond yield, yield spread between 10-year T-bonds and 3-month T-bills, 10-year T-bond yield adjusted for the inflation rate, seasonally-adjusted US industrial production, and a couple more.

Applying financial statement analysis to forecast earnings growth and evaluate P/E ratios

S. Li (2003)

If investors buy future earnings, the P/E should be explained by the earnings (or operating income) growth, which can be obtained by a big cross-sectional regression with the variables from the financial statement. The author suggests to combine this estimate with that from the analysts.

Essential portfolio theory

J. Mulvey

Rydex investments (2005)

Empty article: it just reminds us that we do not live in a long-only, equity-and-bonds-only, 1-period, static, unleveraged world.

You want to diversify risk? Consider economic derivatives

R. Dubil

Journal of wealth management (2007)

Individual investors should use *economic derivatives* (consumer inflation, currencies, real estate prices, gas-at-the-pump, etc.) to hedge their non-stock assets (house, purchasing power, etc.).

Contrary to derivatives with a tradable underlying, economic derivatives are valued with *probabilistic insurance pricing*.

An introduction to differential geometry in econometrics

P. Marriott and M. Salmon

in *Applications of differential geometry to econometrics*, Chapter 1 (CUP, 2000)

A parametric (exponential) family of probability distributions can be seen as a manifold (generalizations

to the manifold of “all” distributions are possible, but infinite-dimensional manifolds pose further theoretical problems) and statistical properties of distributions, tests or estimators can be translated into geometric properties, for instance:

- The *score* statistic is the length of a certain cotangent vector measured with respect to the metric defined by the expected Fisher information;
- The Kullback–Leibler divergence defines a (non-metric) *connection*;
- The *curvature* of the manifold is linked to information loss (on a flat statistical manifold, expected and observed information coincide).

The authors do not mention the interpretation of *robust* estimators as continuous functions on a statistical manifold.

***Region vs industry effects
and volatility transmission***

**P. Soriano and F. Climent
Financial analysts journal (2006)**

This article studies *volatility transmission* (anova) between regions, between industries, between regions within industries, between industries within regions, and confirms the dominance of region effects over industry effects.

***Common failings:
how corporate defaults are correlated***
S.R. Das et al. Journal of finance (2007)

Defaults cluster in time, but this cannot be explained only by the exposure to common risk factors (the authors develop a test for this): *contagion* plays a role.

***Cluster analysis:
two macro themes dominate Eurozone markets***
**A. Harmstone
Bear Stearns (2005)**

One can cluster stocks (with the PAM algorithm) using their exposure to risk factors and then use the resulting (two) groups as *macro themes* (depending on the market conditions, these could be value and growth, or something entirely different).

***Information transmission
across global markets***
**P. Singh
Bear Stearns (2006)**

Uncertainty (volatility) is transmitted both ways between Asia (Japan, Hong Kong, Taiwan, South Korea) and the West (US and Europe), while returns are mainly transmitted from Asia to the West with a surprising 1-day lag. As a result, intra-day US strategies should use Asian information.

***Implied macro returns:
profiting from over-reaction***
**A. Harmstone
Bear Stearns (2006)**

Yet another article advocating the use of cumulated (time series) residuals.

***Multilayer modeling of
a market covariance matrix***
**R. Staub
Journal of Portfolio management (2006)**

Rolling (or weighted rolling) volatility is a bad estimate of future volatility: prefer GARCH modeling.

One can generalize strict factor models (“risk models”) in a multilayer way: estimate the covariance between asset groups; then, within each group, between the subgroups; etc..

***Liquidity and stock returns:
evidence from a pure order-driven market
using a new liquidity proxy***
**B.R. Marshall
International review of financial analysis
(2006)**

The *weighted order value* (WOV) is a new liquidity proxy: in 30-minute windows, bin the bids (and asks) with respect to the best one (e.g., 1% from the best, 2%, 5%, 10%, etc.); compute the bid (resp. ask) execution rate (number of executed orders divided by the number of orders) in each bin; pool the bids in each bin to get the bid order value (the sum of the bid prices times the bid volumes); pool the bins: the weighted bid value is the sum of the products of the bid order values and the bid execution rates; the WOVI is then the geometric mean of the bid and ask weighted values.

Sharpening Sharpe Ratios
W. Goetzmann et al. (2004)

Sharpe ratios are amenable to manipulations, with options (non-linear payoffs), dynamic strategies (that also modify the distribution of returns: truncate it on the right and fatten the left tail to the mean to the right) or smoothed returns.

***Futures trading volume as a determinant of
prices in different momentum phases***
**A. Hodgson et al.
International review of financial analysis
(2006)**

Options trading volume has predictive power on the short-term (15 minutes) stock price; this effect changes with the current price trend.

***Advanced frequency and time domain filters
for currency portfolio management***
**C. Dunis and J. Miao
Journal of asset management (2006)**

Many FX traders use a combination of several MACDs (say, 1 and 32 days, 1 and 61 days, 1 and 117 days, equal-weighted), but this strategy does not perform well.

Spectral analysis (the periodogram) can help identify cyclical spells in FX time series (you can try to use it as a trading strategy, but it will not work).

The article suggests to follow the MACD strategy but to modify it in cyclical and/or volatile (as measured by the RiskMetrics model, *i.e.*, an exponentially-weighted non-central variance) periods, by not trading or trading in the opposite direction.

***On the maximum drawdown
of a brownian motion***
M. Magdon-Ismail et al. (2003)

The (asymptotic) expected maximum drawdown (MDD) of a brownian motion is

$$\begin{aligned} X(t) &= \sigma W(t) + \mu t \\ E[D] &= \sqrt{\frac{\pi}{2}} \sigma \sqrt{T} && \text{if } \mu = 0 \\ E[D] &\sim_{T \rightarrow \infty} \frac{\sigma^2}{2\mu} \log T && \text{if } \mu > 0 \\ E[D] &\sim_{T \rightarrow \infty} -\mu T && \text{if } \mu < 0. \end{aligned}$$

Maximum drawdown
M. Magdon-Ismail et al. (2003)
Risk (October 2004)

Using the previous article, one can study the term structure of the *Calmar* or *Sterling* ratios.

$$\begin{aligned} \text{Calmar} &= \frac{\text{returns on } [0, T]}{\text{MDD on } [0, T]} \\ \text{Sterling} &= \frac{\text{returns on } [0, T]}{\text{MDD on } [0, T] - 10\%} \end{aligned}$$

The misuse of expected returns
E. Hughson et al.
Financial analysts journal (2006)

Yet another article against ratio returns...

At the very least, if you have to deal with ratio returns, prefer their median to their mean.

***Portfolio selection with parameter and model
uncertainty: a multi-prior approach***
L. Garlappi et al.
Review of financial studies (2007)

The article interprets the robust portfolio optimization framework

$$\begin{aligned} &\text{Maximize} && \min_{\alpha} w' \alpha - \lambda w' V w \\ &\text{st} && \alpha_{\min} \leq \alpha \leq \alpha_{\max} \end{aligned}$$

in a bayesian setting, as a generalization of the Black–Litterman model, in terms of *uncertainty aversion*.

***Common and country-specific components
in national stock prices***
O. Hu
Journal of multinational financial management
(2006)

Market integration can be measured by cointegration – more precisely, the presence of a *single* cointegration relation.

G7 countries are not integrated: diversification benefits still exist.

***Testing for multiple regimes in the tail
behavior of emerging currency returns***
B. Candelon and S. Straetmans
Journal of international money and finance
(2006)

The *tail index* of a distribution is the parameter α such that

$$\forall x > 0 \quad \lim_{t \rightarrow \infty} \frac{1 - F(tx)}{1 - F(t)} = x^{-\alpha},$$

i.e., such that the tail of the distribution be a first order approximation of a Pareto distribution ($F_{\text{Pareto}}(x) = 1 - ax^{-\alpha}$).

The *Hills estimator* of the tail index in a sample of size n is

$$\hat{\alpha} = \left(\frac{1}{m} \sum_{j=0}^{m-1} \log \frac{X_{(n-j)}}{X_{(n-m)}} \right)^{-1}$$

where the $X_{(k)}$ are the order statistics and m is chosen so that m/n be small (the estimator has good asymptotic properties for $m/n \rightarrow 0$ and $n \rightarrow \infty$).

The authors then perform *recursive tests for structural breaks*: when you find a break, split the sample in two and look for new breaks in each chunk.

There are structural breaks in the tail index of emerging market currency returns.

***Are international value premiums driven by
the same set of fundamentals?***
A.J. Black et al.
International review of economics and finance
(2007)

Yet another article that gauges the benefits of diversification (of a value strategy, across G7 countries) using cointegration: cointegration is present.

***Using dynamic programming
to optimally rebalance portfolios***
W. Sun et al.
Journal of trading (2006)

Dynamic trading strategies include: periodic rebalancing, *tolerance band rebalancing*, *no trade zone* (identical to the tolerance band rebalancing, but the band is not arbitrarily defined and we do not rebalance all the way to the optimal portfolio but just back into the band).

The authors measure, in USD, the tracking error of a portfolio as the risk-free return giving the same utility (*certainty equivalent*) and use this measure in a dynamic program to control rebalancing – this can be seen as a dynamic equivalent of tolerance band rebalancing. The problem is amenable up to 8 or 9 assets.

***Forecasting online auctions
using dynamic models***

W. Jank et al.

**KDD 2006 Workshop on Data mining
for Business Applications**

The authors use *functional data analysis* (FDA) to forecast irregular time series (ebay auction prices) taking into account the influence of opening bid, auction length and seller's reputation on the price dynamics (acceleration, velocity and eventually final price).

***Data mining in the real world:
what do we need and what do we have?***

F. Fogelman Soulié

**KDD 2006 Workshop on Data mining
for Business Applications**

Data mining is widely used for CRM (client relation management), fraud detection, credit scoring, etc. and *extreme data mining*, *i.e.*, data mining with databases beyond 10 TB is starting to emerge. It is characterized by:

- Heterogeneous data;
- poor data quality (outliers, missing data and even *unlabelled data*, *i.e.*, “massively missing values”);
- Large volumes (millions of rows, thousands of variables) that prevent the user from hand-chosing the variables and calls for *data duplication avoidance*;
- Fast model calibration (hours; linear in the number of rows or columns);
- Automated model quality assessment (they use a *robustness indicator*, KR , from Vapnik's *structural risk minimization theory*);
- Real-time model application;
- Industrialization (“productionalization”) within the same project, not as a separate, long project;
- Model control (checks deviations in the data distribution);
- Data export using data mining standards (JDM, PMML);
- Process control and workflow;
- Exploratory modeling (the end-user needs to understand the model);
- Predictive modeling (the end-user want accurate forecasts);
- Unskilled users.

The article failed to mention the following:

- Asynchronicity (we might want real-time results even though some data sources might not be real-time; bursts of data may delay the delivery of the results);
- Distributed analysis (the volume and location of the

data, with the requirement that the data should not be duplicated, will call for the computations to be run where the data is, possibly in different locations).

***The landscape of parallel computing research:
a view from Berkeley***
2006

The next big thing in computer science could be *distributed computing*: this article enumerates benchmarks (called “*dwarfs*”) or challenges for such systems.

Among the potential “next big thing”, one could add, in no particular order: declarative programming, functional languages, virtualization, virtual machines.

DNA computers, quantum computers are still decades (or centuries) away, though programming paradigms are already being developed for those architectures.

Concurrency and Erlang
A. Pang

Another article about distributed programming and the need for adequate tools – not threads: in the hands of most programmers, they make $i = i + 1$ non-deterministic...

On the same subject:

- Some real-time systems already use lock-free programming, *e.g.*, the Jack audio server, as explained in the Linux Audio Conference 2005.
- Software Transactional Memory (STM) is getting more widely discussed, and is already in the Haskell libraries.

***Robust moving least squares fitting
with sharp features***
S. Fleishman et al.
SIGGRAPH 2005

This article applies an *outlier detection* algorithm (the *forward search algorithm paradigm*: start with a small set of robustly chosen points, progressively add more points, while monitoring some statistic) for *surface reconstruction*, accounting for noise and singularities (*i.e.*, sharp edges).

***Everything you know about
dynamic time warping is wrong***
C.A. Ratanamahatana and E. Keogh
SDM 2005

This article disspsells a few DTW myths:

- DTW's ability to deal with sequences of different lengths is not an advantage (but not a disadvantage either): you would get the same results after resampling the sequences;
- The 10% constraint on warping paths inherited from the speech processing community is not too low but actually much too high for most data mining applications;
- As a result, DTW is essentially $O(n)$.

Portfolio selection in stochastic environments

J. Liu

Review of financial studies (2007)

The *dynamic portfolio choice* problem can be expressed as a partial differential equation (Merton, 1971), which does not lead to a general, amenable solution. This article derives an explicit solution in the case of *quadratic returns*, generalizing similar results for *Ornstein–Uhlenbeck processes*.

Emergent effective collusion in an economy of perfectly rational competitors

R.K. Standish and S. Keen

arXiv:nlin.AO/0411006

Some agent-based models predict the emergence of monopolies; irrational agents or delays can help avoid them.

Portfolio optimization with drawdown constraints

A. Chekhlov et al. (2003)

In portfolio optimization, one can replace the standard deviation by other risk measures such as the expected shortfall (ES, conditional value at risk, CVaR) or the conditional drawdown at risk (CDaR).

Investor sentiment and the cross-section of stock returns

M. Baker and J. Wurgler

Journal of finance (2006)

You might want to completely reverse your trading strategy (usually: large, mature, low-volatility, profitable, dividend-paying, non-distressed, value stocks) when the investor sentiment is low.

The *investor sentiment* can be computed from the following (annual) proxies (do not forget to remove the systematic risk):

- Opposite of the closed-end fund discount (CEFD), *i.e.*, the average difference between the net asset value (NAV) of closed-end stock funds shares and their market prices;
- Detrended NYSE share turnover (or any measure of liquidity);
- Number of IPOs;
- Average first-day returns on IPOs;
- Equity share in new issues;
- Dividend premium, *i.e.*, difference of the P/B of dividend payers and non-payers.

Re-examining the profitability of technical analysis with White’s reality check and Hansen’s SPA test

P.H. Hsu and C.M. Kuan (2005)

To avoid data snooping, one can:

- Claim it is not a problem (but it is!);
- Split the data into in- and out-of-sample (but this is arbitrary and discards part of the data);

- Explicitly test all the models and correct the p -values accordingly (but when there are too many tests, the power of the corrected tests drops);
- Use the bootstrap to compute the p -value:
 - Build a universe of all trading strategies you might be interested in;
 - Choose a performance measure (White uses the annualized returns, Hansen uses the information ratio or 0 when it is negative);
 - Estimate the distribution of the maximum performance on bootstrap samples;
 - Compare the performance of your model with the distribution of the best performing model.

The article applies this methodology to technical analysis (TA): it works, and works better in less mature markets.

Data Envelopment Analysis

G.N. Gregoriou and J. Zhu

Journal of portfolio management (2007)

The notion of *efficient frontier* can be generalized to higher dimensions: several risk measures or inputs (standard deviation, downside deviation, maximum drawdown), several outputs (returns, proportion of profitable months, maximum consecutive gain).

If you have enough data points, they provide an approximation of the efficient frontier (?).

The *efficiency* (closeness to the efficient frontier) can be defined as the solution of a linear problem:

Minimize θ such that

$$\sum_k \lambda_k x_{ik} \leq \theta x_{ik_0}$$

$$\sum_k \lambda_k y_{jk} \geq y_{jk_0}$$

$$\sum_k \lambda_k = 1$$

$$\lambda_k \geq 0$$

i : input

j : output

k : funds

k_0 : fund whose efficiency is being computed

x_{ik} : input i of fund k

y_{jk} : output j of fund k .

See <http://people.brunel.ac.uk/~mastjjb/jeb/or/dea.html> for a picture.

Optimization of the largest US mutual funds using data envelopment analysis

G.N. Gregoriou

Journal of asset management (2006)

Another article on data envelopment analysis (DEA, sometimes also called *frontier analysis*). It defines the

classical efficiency as

$$CCR_{k_0} = \text{Max} \left\{ \frac{\sum_j \mu_j y_{jk_0}}{\sum_i \lambda_i x_{ik_0}} \text{ st } \forall k \frac{\sum_j \mu_j y_{jk}}{\sum_i \lambda_i x_{ik}} \leq 1 \right\}$$

and the *super-efficiency* (which is no longer bounded by 1) as

$$CCR_{k_0} = \text{Max} \left\{ \frac{\sum_j \mu_j y_{jk_0}}{\sum_i \lambda_i x_{ik_0}} \text{ st } \forall k \neq k_0 \frac{\sum_j \mu_j y_{jk}}{\sum_i \lambda_i x_{ik}} \leq 1 \right\}$$

They also mention the *cross-efficiency model*, but not clearly.

Asset allocation for robust portfolios

T. Farrelly

Journal of investing (2006)

This article is a variation on Michaud's *resampled portfolios*:

- Start with your risk model and your alpha; choose a risk threshold and a “sensitivity to underperformance” λ ;
- Compute $N = 500$ simulated returns from $N(0, V)$ (or $N(\alpha, V)$, the article is not clear) and let

r_{ij} = return of stock i in situation j
 w_{ij} = weight of stock i in
the efficient portfolio ($r_{\bullet, j}, V$)

(the article is not clear here either: there sometimes seems to be one optimal portfolio per scenario, sometimes one for the set of all scenarios)

- Minimize

$$\sum_{ij} |(w_{ij} - w_i) r_{ij}|^\lambda$$

under the condition that the risk be below the threshold.

Automatic bayesian model averaging for linear regression and applications in bayesian curve fitting

F. Liang et al.

Statistica Sinica 11 (2001) 1005–1029

The article suggests an “automatic prior” for bayesian model average (BMA) – in situations where it has an edge on model selection, BMA is sensitive to the prior, for instance, to the expected number of factors in the model.

The inclusion probability still has to be provided by the user; the authors only provide a prior for β and σ (equations 10 and 11).

Evolutionary Monte Carlo: applications to C_p model sampling and change point problem

F. Liang and W.H. Wong

Statistica Sinica 10 (2000) 317–342

Check *Monte Carlo Strategies in Scientific Computing*, J.S. Liu, Springer Verlag, 2002, for a 1-page summary of this article.

Are alternatives the next bubble?

J. Loeys and N. Panigirtzoglou

Journal of alternative investment (2006)

One can use high returns, expensive valuation (low risk premium), speculative activity (trading volume, credit, leverage) as a bubble indicator.

Profitability of price momentum strategies: surprising evidence from Pacific-Bassin countries

P. Ryan and R. Curtin

Journal of investing (2006)

Momentum does not work in Asia – but have a look at reversal.

Do asset prices reflect fundamentals?

Freshly squeezed evidence from the orange juice market

J. Boudoukh et al.

Journal of financial economics (2006)

Example of the misuse of linear regression to study a non-linear phenomenon.

Mean-variance versus full-scale optimisation: in- and out-of-sample

T. Adler and M. Kritzman

Journal of asset management (2007)

The authors suggest to replace quadratic utility (or even power utility: $U(x) = x^\gamma/\gamma$, which translates *constant relative risk aversion* (CRRA)) by *kinked utility* (for investors wishing to breach a threshold, e.g., the minimum level of wealth to maintain a certain standard of living) or *S-shaped utility* (to reflect asymmetric risk behaviour).

$$\begin{aligned} U_{\text{kinked}}(x) &= \ln(1+x) & \text{if } x \geq \theta \\ &= 10(x-\theta) + \ln(1+\theta) & \text{if } x < \theta \\ U_{\text{S-shaped}}(x) &= -A(\theta-x)^{\gamma_1} & \text{if } x \leq \theta \\ &= -B(x-\theta)^{\gamma_2} & \text{if } x > \theta \end{aligned}$$

***Forecasting financial time series
using artificial market models***

N. Gupta et al.
arXiv:physics/0506134

Stock market simulations by *agent-based models* suggest there are *pockets of predictability*; once one such pocket is closed, investment strategies trained on previous data become worthless.

In other words: agent-based market simulations confirm the predictability of stock markets and the presence of structural breaks.

***Are you about to handcuff
your information ratio?***

R. Staub
Journal of Asset Management (2007)

If you want yet another explanation/application of the FLAM (fundamental law of active management)...

***Alphas with attitude:
revving up your factor model***

B. Lau and G. Platt
Macquarie Research Equities (2007)

Yet another article promoting dynamic, IC-based weights: $w = (\text{Var IC})^{-1} \cdot \text{IC}$, using an expanding window and imposing constraints on the weights ($0 \leq w \leq 0.5$).

Do industries lead stock markets?

H. Hong et al.
Journal of Financial Economics (2007)

One can predict market returns from lagged industry returns; this is due to the *bounded rationality* of investors: they cannot process all the information about all the stocks immediately when they receive it; the effect is present in all developed markets; the predicting power is comparable to that of inflation, default spread and dividend yield.

Others had already noticed that large or liquid stocks lead small or illiquid ones.

***Noise trader risk:
evidence from the Siamese twins***

J.T. Scruggs
Journal of Financial Markets (2007)

Identical stocks on different exchanges do not move in parallel: up to half the weekly volatility is due to noise trading.

Thus, arbitrage is limited and the risk of pairs trading is high.

***Behavioral finance: frame-dependant
decision making and factor anomalies***

T. Suwabe et al.
Goldman Sachs (2006)

Investors look at their *unrealized gains* when deciding to leave a position: this can be exploited by comparing the current price of a stock with its average buying price

$$R_{t+1} = V_t P_t + (1 - V_t) R_t$$

where P_t is the price and V_t the turnover.

This is actually a momentum computed with an exponential moving average of the price (instead of the lagged price), where the coefficient depends on the volume.

Profiting from momentum

R. de Souza
Macquarie Research, Equities (2006)

Another article on the same subject, under the name *capital gains overhang*.

***Alpha repair: a factor competition
approach to stock selection***

J.J. Mezrich and J. Feng
Nomura (2007)

To select the factors to put in your model, regard them as assets, evaluate their long-term (5-year) returns, their variance matrix, and feed them to your preferred optimizer to find an optimal “portfolio of 5 factors” (you can fine-tune the number of factors).

***Refinements to the Sharpe ratio:
comparing alternatives for bear markets***

H. Scholz
Journal of Asset Management (2007)

Sharpe ratios (excess returns divided by risk) cannot be used to compare funds when the returns are negative (they rarely give the right order).

The *normalized Sharpe ratio* tries to correct this. The Sharpe ratio can be computed as

$$\begin{aligned} \text{er}_t &= \text{excess returns} \\ \text{mer}_t &= \text{market excess returns} \\ \text{er}_t &= \alpha + \beta \text{mer}_t + \varepsilon_t \\ \text{SR} &= \frac{\alpha + \beta \overline{\text{mer}}}{\sqrt{\beta^2 + \sigma(\text{mer})^2 + \sigma(\varepsilon)^2}} \end{aligned}$$

The authors simply use 20 years for $\overline{\text{mer}}$ and $\sigma(\text{mer})$.

***Momentum, reversal
and the trading behaviors of institutions***

R.C. Gutierrez and C.A. Prinsky
Journal of Financial markets (2007)

Cumulated residual returns (for a 5-year CAPM model) can help devise a long-term strategy, while the other component of the momentum (“relative momentum”) reverts after one year.

More precisely, the article builds a strategy from the signal :

$$\alpha = \frac{\text{cumulated residual returns}}{\text{cumulated variance of the residuals}}$$

This effect is linked to institutional ownership.

Countries versus industries in emerging markets: a normative portfolio approach
J. Estrada et al., Journal of investing (2006)

The authors compare dispersion, information ratio ($IR = \mu/\sigma$), utility ($U = \log(1+\mu) - \frac{1}{2}\sigma^2/(1+\mu)^2$), option price (an option that allows its owner to swap the performance of the top (or bottom) quartile with the median performance) of random country portfolios and random industry portfolios and conclude that country effects prevail.

On the use of hypothesis testing and other problems in financial research
F. Gómez-Bezares et al.
Journal of investing (2006)

The authors notices the following problems:

- Not enough “case studies” – *i.e.*, you should look at the data;
- Unnecessary mathematical formulation;
- Rarely applicable results: when they become familiar with a method (say, regression), researchers try to apply it everywhere;
- Bad null hypothesis: it may even overlap with the alternative hypothesis – the use of *confidence intervals* besides tests would mitigate the problem.
- Data snooping: be extremely suspicious of “tables of *p*-values”;
- Publication bias, *i.e.*, unpublished “tables of *p*-values”;
- Errors in the data – you should look at the data and use *robust methods*;
- Simplifying hypotheses (no transaction costs, no bid-ask spread, etc.);
- Insufficient data (sample too small);
- Non-parametric tests – only use them when needed: their power is much lower;
- Some studies turn qualitative variables into quantitative ones in a rather arbitrary way.

The authors fail to notice the following problems:

- Unnecessary data binning;
- Use of linear or gaussian methods without checking if it makes sense.

Theory and techniques of Electronic Music
M. Puckette (2007)

A hands-on digital signal processing (DSP) book, covering, among other things, filters and Fourier analysis.

Divergence of opinion and equity returns under different states of earnings expectations
J.A. Doukas et al.
Journal of financial markets (2006)

The interaction between analysts estimates and analysts divergence is non-linear.

Was there a Nasdaq bubble in the late 1990s?

L. Pástor and P. Veronesi
Journal of financial economics (2006)

The Nasdaq bubble can be explained by uncertainty about future profitability which, by Jensen’s formula, increases a firm’s value:

$$\frac{\text{Price}}{\text{Dividends}} = \frac{1}{\text{discount rate} - \text{growth}}$$

$$E[P/D] > \frac{1}{\text{discount rate} - E[\text{growth}]}$$

Analysts’ selective coverage and subsequent performance of newly public firms
S. Das et al.
The journal of finance (2006)

Initial public offerings (IPO) followed by many analysts outperform those followed by fewer analysts over three years.

Earnings and price momentum
T. Chordia and L. Shivakumar
Journal of financial economics (2006)

The momentum effect can be explained by *earnings surprises*.

Decomposing the price-earnings ratio
K. Anderson and C. Brooks
Journal of asset management (2006)

The authors suggest to correct the P/E for sector and size.

Conditional skewness in asset pricing tests
C.R. Harvey and A. Siddique
Journal of finance (2000)

Systematic skewness commands a risk premium, on average 3.6% per year; the momentum effect is related to systematic skewness.

On the aggregation of local risk models for global risk management
G. Anderson et al. (2005)

To build an integrated risk model, *i.e.*, a risk model covering several markets, from a model for each market and a global model, with the drill-down property, *i.e.*, such that the restriction of the integrated model be the local ones, one can write the global risk model as $V = BB'$ and replace B by LB where L is to be determined.

The possible values are $L = \bigoplus_i \tilde{\Theta}_i^{1/2} O_i \tilde{\Theta}_i^{-1/2}$ with $O_i \in O(n_i)$, the Θ_i are the diagonal blocks of the global model and $\tilde{\Theta}_i$ are the desired diagonal blocs – the local risk models.

Choose the O_i to minimize $\|BB' - LBB'L'\|^2$ – or rather, the distance between the corresponding correlation measures.

This is the *double Procrustes problem*.

***On pricing derivatives in the presence
of auxiliary state variables***
J. Lin and P. Ritchken
Journal of derivatives (2006)

The pricing of certain options requires a path-dependant auxiliary variable (e.g., the volatility when the underlying follows a GARCH model). This can be implemented on a lattice (often improperly called a “binomial (or trinomial) tree”) by storing an array of values at each node. The article explains that keeping a single value, viz. the expectation of the auxiliary variable, is actually sufficient, and details the Heath-Jarrow-Merton (HJM) model.

***Using order statistics to estimate confidence
intervals for probabilistic risk measures***
K. Dowd, Journal of derivatives (2006)

The α -VaR is the α th quantile: it is an order statistic. If F is the cumulative distribution function of your random variable, the r th order statistic $X_{(r)}$ of a sample of size n has the cumulative distribution function

$$G_{r,n}(x) = \sum_{i=r}^n \binom{n}{i} F(x)^i (1 - F(x))^{n-i}.$$

From there, just estimate F from the data you have (parametrically or not) and estimate the confidence interval $[x_1, x_2]$ by solving $G_{r,n}(x_1) = 0.05$ and $G_{r,n}(x_2) = 0.95$.

The author claims that the same approach applies to the expected shortfall.

***The information content
of the FOMC minutes***
E. Boukus and J.V. Rosenberg (2006)

Latent semantic analysis (LSA) goes as follows:

- Convert the texts to *bags of words*, i.e., remove the *stop words*, *stem* the words, forget their order but not their number;
- Form the *term-document matrix* X : one row per term, one column per document, the term frequency x_{ij} is the number of occurrences of term i in document j divided by the number of terms in document j ;
- Compute the singular value decomposition (SVD) of X : $X = USV'$, the columns of U are “virtual documents” that can be interpreted as the *themes* of the corpus.

There are variants for the construction of the term-document matrix:

- One can forget the number of occurrences;
- One can use *global weights*, such as *TFIDF* (term frequency inverse document frequency), which replaces the term frequency x_{ij} by

$$x_{ij} \cdot \log \frac{1}{y_i}$$

where y_i is the document frequency, i.e., the number of documents containing term i divided by the number of documents.

***Order book characteristics
and the volume-volatility relation:
empirical evidence from a limit-order market***
R. Næs and J.A. Skjeltorp
Journal of financial markets (2006)

The *order book slope* influences volume, volatility and their interactions; it is a proxy for *disagreement among investors*.

Subordinated binomial option pricing
C.W. Chang et al.
Journal of financial research (2006)

Binomial trees can easily be generalised to account for stochastic volatility, by describing the price evolution with successive binomial trials up/down and trade/non-trade (this is a *trinomial tree*, the spot price S becoming uS , S or dS with probabilities gh , $1 - g$ and $g(1 - h)$), corresponding to a time change from calendar time to operational time.

***Individual equity return data from
Thomson DataStream: handle with care!***
O.S. Ince and R.B. Porter
Journal of financial research (2006)

Beware of your data source (CRSP vs TDS): clean before use.

***Momentum: does the database
make a difference?***
B. Chakrabarty and C. Trzcinka
Journal of financial research (2006)

Statistical and real profits might or might not coincide, depending on your data source (CRSP or TAQ).

Downside risk
A. Ang et al. Review of Financial Studies (2006)

Stocks with a high sensitivity to downside market movement (β_-) have higher returns.

This effect does not (entirely) come from stock with high coskewness risk having higher returns.

Downside beta can be used as an alpha, but not for high-volatility stocks.

***Transmission of information
across international equity markets***
J. Wongswan
Review of Financial Studies (2006)

Macroeconomic announcements in the US or Japan have short-lived (30 to 60 minutes) effects on volatility and volume (not returns) in Korea and Thailand.

Lehman suite of PCA risk models
J. Ruiz-Mata (2006)

They provide statistical risk models, for Europe, US, developed Asia and emerging markets, built as follows:

- Using daily (or weekly, monthly) *excess returns* over 40 (long-only) to 60 (long-short) days, they perform a factor analysis with 4 to 8 factors;
- The number of factors is determined by *random matrix theory* (RMT), *i.e.*, by comparing the distribution of the eigenvalues with that of the variance matrix of iid gaussian variables (they do not seem to realize that RMT uses principal component analysis (PCA), not factor analysis, *i.e.*, it assumes there is no stock-specific risk: this might bias the methodology towards an unduly high number of factors – they are lucky to have so few); they fail to note that the number of factors to retain also depends on the size of the universe: 4 or 5 factors might be necessary if you have several thousand US stocks, but with just 100, one might be sufficient;
- The training period is determined by computing the distance between the factor model variance matrix and the *forward* sample variance matrix (they do not use the distance between those matrices, by the difference between the forecasted risk and the realized risk, for a large number of long-short portfolios – this is very similar to the definition of a *matrix norm*, but we do not need to have time series of forward returns, one forward return for each stock suffices).

Is fundamental analysis effective for growth stocks?
P.S. Mohanram (2003)

This article lists financial variables likely to help predict future returns for growth stocks. There are classical fundamental variables:

- ROA
- ROA growth
- Cash flow ROA
- Cash flow – Net income
- Asset turnover (sales / beginning-of-period assets) growth
- Operating margin (gross margin / sales) growth
- Leverage reduction
- Current ratio (?) growth
- Equity issuance in previous year

and growth-specific variables (all sectorwise):

- Earnings stability: 5-year ROA variance
- Growth stability: 5-year sales growth variance
- Earnings growth – Sales growth
- R&D / Beginning-of-period assets
- Capital expenditures / Assets
- Advertising / Assets

Price-to-earnings ratio and expected earnings growth rate in global equity markets

G. Bakshi and A. Chan (2000)

Expected earnings growth rate have a predictive effect on P/E variations.

Rewriting history
A. Ljungqvist et al. (2006)

Some estimates in the IBES database are anonymized (when the analysts ask for it). You would expect that: either all the estimates of an analyst are anonymized, or only the most recent (so that only his direct clients have access to the complete information). This article remarked that past forecasts are also anonymized, especially bad forecasts, thereby invalidating the use of the database to rank analysts.

Using Economic and financial information for stock selection
I. Roko and M. Gilli (2006)

Instead of building a model using linear regression on a moving window, they use a *classification tree*.

They do not produce a single tree, but a set of trees (a *bag*, a *forest*), each estimated on a bootstrap sample, to lower the variance of the predictor – this should be reminiscent of the set of models produced by bayesian model averaging.

They do not predict the future returns of the stocks but just whether they outperform, underperform or remain neutral – but the method can be generalized to *regression trees* (and forests).

They discretize the predictive variables, thereby discarding information: this is a mistake.

Dynamic market intelligence
M. Krause (2006)

The author suggests using an alpha (valuation, sentiment, quality, risk) to build a portfolio, by investing in the top stocks (his portfolio has the same capbin and sector composition as the market and is equal-weighted in each sector×capbin).

Investment strategies using options on ETFs
A. Seddik Meziani (2006)

On the use of *covered calls* (calls written when you own the underlying, as opposed to *naked calls*): if you think the price will drop for a stock you own, you can write a call: if the price goes up, you just fail to cash on it, if it goes down, you do not lose anything and even pocket the option price.

The author also mentions *short straddles* (write a put and a call, if you think the price will not move) and *long straddles* (buy a call and a put, if you think the price will move but have no view on its direction).

The other January effect
M.J. Cooper et al.
Journal of Financial Economics (2006)

The *January Effect* states that small and low-priced stocks that lose a lot at the end of the year rebound in January.

The (completely unrelated) *Other January Effect* states that January returns help predict the returns of the remaining 11 months. The article confirms this effect, for capitalization-weighted or equal-weighted portfolios, large or small stocks, value or growth stocks.

***Applied Functional Data Analysis
Methods and Case Studies***
J.O. Ramsay and B.W. Silverman
Springer Verlag (2002)

One can reliably smooth a function, defined by a noisy set of points, by expanding it over a basis (e.g., splines – in case of periodic phenomena, you can also consider a Fourier expansion) and by adding a penalty: if you want the k th derivative to be smooth, add a penalty on the $(k + 2)$ th derivative. The smoothing parameter can be estimated by *cross-validation*.

The principal component analysis (PCA) of smoothed data is still noisy and not interpretable: *functional PCA* (fPCA) solves the problem by putting the smoothing inside the PCA algorithm – e.g., for the first component, you maximize a penalized variance. More precisely, the usual conditions

$$\begin{aligned} \forall i & \int \xi_i^2 = 1 \\ \forall i \neq j & \int \xi_i \xi_j = 0 \end{aligned}$$

become

$$\begin{aligned} \forall i & \int \xi_i^2 + \lambda \int \xi_i''^2 = 1 \\ \forall i \neq j & \int \xi_i \xi_j + \lambda \int \xi_i'' \xi_j'' = 0. \end{aligned}$$

Thanks to the use of basis functions, the computations boil down to linear algebra.

To plot and interpret the principal components, just plot the mean function plus and minus some multiple of those components.

The book uses fPCA to study crime careers – but the same ideas could be applied to parallel plots.

Classical methods (e.g., Linear Discriminant Analysis (LDA)) can either be applied on the first functional principal components or “penalized” as PCA was.

A *phase-plane plot*, i.e., a plot of the acceleration against the velocity (since you want to use the second derivative, use a penalty on the fourth), can be interpreted in terms of energy and momentum; one should look for cycles, their radius, their center, changes in their shape, etc. The book examines a consumption index phase plane plot.

To expand plane curves (here, bone shapes) over a basis of functions, one can use *landmarks* or parametrize the curves with *arc-length*.

If the principal components are not directly interpretable, you can perform a *varimax rotation*: this is a rotation in the subspace spanned by the first few principal components that maximizes the variance of the coordinates (“loadings”); it makes the loadings either large or close to zero and therefore eases the interpretation of the components. With the *promax rotation*, one first performs a varimax rotation, takes the power 2 or 4 of the loadings, so as to simplify them further, and looks for an invertible (not necessarily orthogonal) matrix Q that approximates those loadings: $Qb \approx (R_{\text{varimax}}b)^2$. (In R, check the `varimax` and `promax` functions.) This sounds like a poor man’s *independent component analysis* (ICA).

One can use the same ideas to study families of sample distributions, by smoothing the sample distribution functions. Those distributions can then be used in, say, hierarchical models.

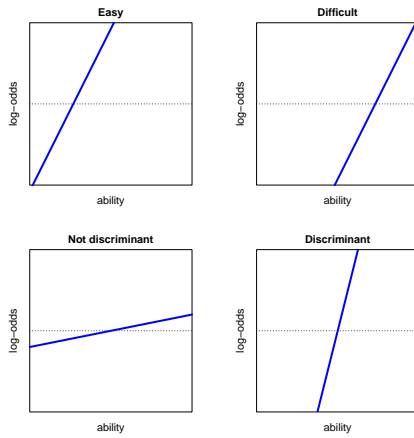

The mean curve may fail to exhibit the features of the individual curves, especially if (as in the example of human growth) they differ in location – they are averaged out. Before computing the mean, you can align the functions: this is called *registration* or (*dynamic*) *time warping*. This accounts for phase changes – but one can also allow for amplitude changes – this can be expressed and implemented as an eigenvalue problem.

Registration transforms the set of curves to study into a set of pairs of curves: the aligned curves and the warping functions $h(t)$ (or the *time deformation functions* $h(t) - t$).

Depending on the data, you may want to register the functions themselves of their first derivative.

Monotone curve smoothing (e.g., human growth or time warping functions) can be performed as follows: instead of looking directly for a smooth increasing function H , look for the *relative acceleration* $w = H''/H'$, i.e., look for a differential equation $H'' = wH'$. As usual, smooth w using a penalty on $\int |w''|$.

Item Response Theory (IRT) studies answers to ability tests. The *ability curve* is a curve in $[0, 1]^N$, where N is the number of questions, whose k th coordinate is the probability of correctly answering the k th question – we assume that the test allows us to rank the candidates, i.e., that they are indeed described by a 1-dimensional subspace, i.e., that the test only measures one thing –, it goes from **0** (bad candidate) to **1** (excellent candidate) and wriggles in between depending on the *difficulty* and *discriminability* of the questions.

The arclength on that curve can be used as a measure θ of *ability*.

IRT models the probability of a correct answer to question i as a function of the ability θ : logistic regression measures difficulty and discriminability, but one can also devise models that account for a non-negligible probability of right answer at low ability (the candidate can answer at random). The picture is complicated by the fact that the ability θ is unknown.

Functional PCA allows more freedom in the modeling of the success probabilities.

A *functional linear model* is a continuous analogue of a regression of a time series versus another, including lags:

$$y_i(t) = \alpha(t) + \sum_{s=t-k}^t \beta_s(t)x_i(s) + \varepsilon_i(t)$$

$$y_i(t) = \alpha(t) + \int_{t-k}^t \beta(s,t)x_i(s) ds + \varepsilon_i(t).$$

The data can be visualized by a *cross-correlation matrix*, the model can be fitted after discretization by *finite elements*, the fit can be assessed by looking at the MSE (mean square error) as a function of time.

$$\text{SSE}(t) = \sum_{i=1}^N (y_i(t) - \hat{y}_i(t))^2$$

$$\text{SSM}(t) = \sum_{i=1}^N (y_i(t) - \bar{y}_i(t))^2$$

$$R^2 = 1 - \frac{\int \text{SSE}(t)dt}{\int \text{SSM}(t)dt}$$

One can characterize a family of functions (here, handwritten letters) by a differential equation

$$D^3 f_i = \alpha + \beta_0 f_i + \beta_1 D f_i + \beta_2 D^2 f_i + \varepsilon_i$$

which can then be used for supervised classification: *Principal Differential Analysis* is a functional analogue of LDA.

This differential equation can actually be a vector one, that allows for *coupling* between the coordinates – especially when there is no canonical coordinate system (here, the hand movements of a juggler).

Those differential equations can be seen as a continuous analogue of regression and the coefficients can be estimated by *integrated least squares*.

Stock market diversity **R. Fernholz, Intech (2005)**

Studying portfolios in a 1-period world can be misleading: by modeling them as stochastic processes (with time-varying, *i.e.*, stochastic, weights), one can decompose the portfolio returns into the contribution of its constituents and the contribution (*excess growth rate*) of the volatility and the correlation of those constituents, accounting for rebalancing and diversification – this is called *stochastic portfolio theory*.

The distribution of the capitalization in the market changes over time; one can measure the *diversity* of this distribution with the *entropy*

$$S = \sum_i -w_i \log w_i$$

where w_i are the market capitalization weights, or with

$$D_p = \left(\sum_i w_i^p \right)^{1/p}$$

(people suggest $p = 0.5$ or $p = 0.76$). Each such diversity measure is canonically associated with a *diversity-weighted portfolio* (in our examples, its weights would be $1/N$ or (proportional to) $w_i^{1/p}$).

One can note that when market diversity rises, active strategies outperform passive ones and conversely.

Diversity measures are linked to the performance of “size” factors.

Diversity-weighted indexing **R. Fernholz, et al., JPM (1998)**

Capitalization-weighted indexes are never rebalanced, except when stocks enter or leave the index, *i.e.*, stocks with a historically high or low price are bought or sold – the opposite of what you should be doing.

Diversity-weighted indexes mitigate this problem: the weights are proportional to some power, $p \in [0, 1]$, of the market capitalization (e.g., $p = 0.76$).

The returns of a diversity-weighted portfolio can be decomposed into a contribution of the variation in the distribution of the capitalization of the stocks and a contribution of the changes in stock rankings (“kinetic differential” – strictly speaking, this component also accounts for dividend payments and stocks leaving and entering the index). The former is noisy and mean-reverting, the latter brings the returns.

Volatility capture as an alpha source **L. Vasquez, SEI (2005)**

Rebalancing a portfolio so that its weights remain constant is better than a buy-and-hold strategy.

“Volatility capture” is also sometimes called *compound growth* or *diversity-weighted indexing*.

Diversification returns and asset contributions
D.G. Booth and E.F. Fama
Financial Analysts Journal (1992)

A portfolio rebalanced so as to keep its weights constant performs better than a non-rebalanced one. More precisely, the returns of a buy-and-hold strategy are:

$$\begin{aligned}\sum_i w_i \left(\prod_t (1 + r_{it}) - 1 \right) &\approx \sum_i w_i (E[r_{i.}] - \frac{1}{2} \text{Var}[r_{i.}]) \\ &\approx \sum_i w_i r_i - \frac{1}{2} \sum_{ij} w_i \sigma_{ii}\end{aligned}$$

while those of a rebalanced one are

$$\begin{aligned}\prod_t \left(1 + \sum_i w_i r_{it} \right) - 1 &\approx E \left[\sum_i w_i r_{i.} \right] \\ &\quad - \frac{1}{2} \text{Var} \left[\sum_i w_i r_{i.} \right] \\ &\approx \sum_i w_i r_i - \frac{1}{2} \sum_{ij} w_i w_j \sigma_{ij}.\end{aligned}$$

The difference between the two is called the *excess growth rate*:

$$\frac{1}{2} \left(\sum_i w_i \sigma_{ii} - \sum_{ij} w_i w_j \sigma_{ij} \right).$$

Stochastic portfolio theory and stock market equilibrium
R. Fernholz and B. Shay
Journal of Finance (1982)

A continuous-time derivation of the *excess growth rate*.

Model uncertainty and forecasting, a practitioner point of view
B. Bellone and E. Michaux (2006)

The article compares several model selection procedures:

- Linear regression bayesian model averaging (BMA) is good, especially for the short term;
- Dynamic factor models (DFA), *i.e.*, regression on the factors from a factor analysis and their lags, is not bad, especially for the long term.

The article also examined

- Median BMA (the model obtained from the variables whose inclusion probability is beyond 1/2);
- The general-to-specific (GETS) algorithm (a step-wise variable selection, with multiple steps and tests).

The authors use a Scilab econometric toolbox developed at the ENSAE: “Grocer”.

Portfolio insurance: the extreme value approach to the CPPI method
P. Bertrand and J.L. Prigent (2001)

The CPPI (constant proportion portfolio insurance) method is a simplified asset allocation strategy that tries to guarantee a minimum terminal wealth. The *floor* is the present value of the insured terminal value; the *cushion* is the difference between the portfolio value and the floor (it should remain positive). CPPI suggests to invest a fixed proportion (the *multiple*, e.g., 10) of the cushion in the risky asset and keep the rest in the risk-free asset – if the cushion is already large, 10 times the cushion could exceed the portfolio value: in this case, everything would be invested in the risky asset.

The article explains how to choose the multiple, using quantiles.

Options-based portfolio insurance (OBPI) is another portfolio insurance (PI) method.

Financially-motivated model performance measures
C. Friedman and S. Sandow
Journal of credit risk (2006)

Classical performance measures (e.g., contingency table-based measures such as the type I and type II error rates; rank-based measures (that fail to properly account for extreme events); calibrated measures (?); conditional information entropy ratio (CIER) (?), etc.) do not easily generalize beyond two states and are not consistent with utility theory. The article suggests to compare the performance of two models with their Kullback–Leibler distance to the data:

$$\text{KL}(\text{model 1, data}) - \text{KL}(\text{model 2, data}).$$

Those Kullback–Leibler distances can be expressed in terms of a utility function, to be chosen – preferably of the form

$$U(\text{wealth}) = \frac{\text{wealth}^{1-\kappa} - 1}{1 - \kappa}.$$

This setup can be robustified and generalized to multi-state or continuous models.

A heteroskedasticity-consistent covariance matrix estimator and a direct test for heteroskedasticity
H. White, Econometrica (1980)

In presence of heteroskedasticity, the coefficients of the linear model $y \sim x$ are consistent, but their variance matrix, usually defined as

$$\frac{1}{n} \sum_i \hat{\sigma}^2 x_i' x_i$$

is not. Instead, one can replace the standard deviation $\hat{\sigma}$ by the residuals $\hat{\varepsilon}_i$:

$$\hat{V} = \frac{1}{n} \sum_i \hat{\varepsilon}_i^2 x_i' x_i.$$

V. DeMiguel et al. (2005–2006)

If you do not have much data, assign the same fraction of your wealth to each asset in your universe; if you have more data, use a minimum-variance portfolio; only if you have huge amounts of data (years of tick data, centuries of daily data) should you consider mean-variance optimization. In all cases, imposing constraints to your optimization problem is a good idea.

Towards a new early warning system of financial crises

M. Bussiere and M. Fratzscher
Journal of international money and finance
(2006)

Early warning systems (EWS) of financial (currency) crises for emerging market economies (EME) should not consider two states (crisis, non-crisis) but three (pre-crisis, crisis, post-crisis), to avoid the *post-crisis bias*.

The january effect

M. Haug and M. Hirschey
Financial Analysts Journal (2006)

The *January effect* (small capitalizations that experienced large losses the previous year have high returns in January) is still there.

How profitable is capital structure arbitrage?

F. Yu
Financial Analysts Journal (2006)

If you need an introduction to capital structure arbitrage (CSA) and the CreditGrades model...

The conclusion of the article is that CSA is profitable, unless you “forget” to build a diversified portfolio and focus on a single company – this is, unsurprisingly, too risky.

Stock price reaction to public and private information

C. Vega
Journal of Financial Economics (2006)

We already use the dispersion among the analyst estimates as an investment signal: this article claims that dispersion in the news (measured by the amplitude of the subsequent excess returns) is also an important signal, more important than the number of news items or the private-information-based trading (PIN).

Is information risk priced for NASDAQ-listed stocks?

K.P. Fuller et al. (2007)

The PIN (probability of informed trading – they recall the formula but do not provide any insight) work on the NYSE but not on the NASDAQ.

The copula-GARCH model of conditional dependancies: an international stock market application

E. Jondeau and M. Rockinger
Journal of international money and finance
(2006)

There are several models describing the evolution of correlation matrices (multivariate GARCH, CCC, etc.) but they do not fully account for fat tails. The copula-GARCH model introduced in the article allows for Student innovations and copulas to capture non-elliptical distributions and time-varying higher moments (coskewness, cokurtosis).

Are our FEERs justified?

G. Barisone et al.
Journal of International Money and Finance
(2006)

To gauge whether current exchange rates are at equilibrium or if some currencies are too expensive or cheap, one often uses purchase power parity (PPP) models, such as The Economist’s Big Mac Index. The fundamental equilibrium exchange rate (FEER) method uses import/export volumes/prices. Contrary to PPP, the resulting exchange rates are cointegrated with the actual exchange rates.

Axioma’s alpha factor method
Axioma (2006)

The alpha factor method is a modification of the definition of the risk of a portfolio with respect to a risk model that tries to account for risk underestimation. For instance, optimizers can tell you that 0% of the risk is due to the size factor, which is almost always wrong. This is due to the “null space of the exposures matrix” being very large. The alpha factor accounts for the risk hidden by the closeness to this null space.

$$\text{risk}^2 = w'(EVE' + ff' + \Delta)w$$

$$f = \sigma \frac{Pw}{\|Pw\|}$$

$$P = I - B(B'B)^{-1}B'$$

(Here, P is the orthogonal projection onto $\ker B'$ and \cdot^{-1} is a generalized inverse.)

Hybrid risk models (*i.e.*, risk models with added *statistical factors*) are another way of accounting for those missing phantom factors, but the alpha factor method is adapted to the portfolio – and since the portfolio changes during the optimization process, the alpha factor changes as well.

Their optimizer allows for several benchmarks and can therefore be used to combine several alpha components: first build a *pure portfolio* for each alpha component, with no constraints; then build a portfolio, with constraints, and control the tracking error to each of the pure portfolios.

***The earnings quality skew
and long-short investing***

J.J. Mezrich and J. Feng, Nomura (2006)

With the alpha used in long-short strategies, e.g., earnings quality, the long and short performance are usually not synchronized – this can be referred to as an *alpha skew*. One can tap into that phenomenon by optimizing a two-asset portfolio made of a long-vs-market pair and a market-vs-short pair (requiring that the weights be positive and that the maximum weight be 1, or whatever your leverage is). This can be seen as “shrinking” either the long or the short portfolio towards the market portfolio. Those dynamic weights exploit the full variance matrix between the excess long returns and the excess short returns – this includes, but is not limited to (as the article claims), their correlation.

The article fails to compare this approach with a full-blown optimization, over the whole universe: is it more than a poor man’s optimized portfolio?

Edgeworth binomial trees

M. Rubinstein

Journal of derivatives (1998)

Option pricing need not be confined to the log-gaussian realm: one can devise “binomial trees” that match prescribed mean, standard deviation, skewness and kurtosis and use them to price options.

The *Edgeworth expansion* of a univariate distribution is a tractable approximation whose first four moments match.

This sounds very similar to the Cornish-Fisher value at risk.

The strategy of professional forecasting

M. Ottaviani et al.

Journal of financial economics (2006)

Analysts can have two goals:

- be the best – they then formulate bold forecasts: if their forecast is not the best, how wrong they are is irrelevant, so they try to have as few competitors as possible;
- be good, most of the time – they then shrink their forecasts towards the consensus, in order to take as few risks as possible.

***Political relationships, global financing
and corporate transparency:
evidence from Indonesia***

C. Leuz et al.

Journal of financial economics (2006)

The authors measure the closeness of a company to the current president by looking at the returns on the days presidential health problems were announced.

Divergence of opinion and equity returns

J.A. Doukas et al.

**Journal of financial and quantitative analysis
(2006)**

Stock returns are positively associated with divergence of opinion – not negatively as previously thought.

***Stock returns, implied volatility innovations
and the asymmetric volatility phenomenon***

P. Dennis et al.

**Journal of financial and quantitative analysis
(2006)**

The *asymmetric volatility phenomenon* (AVP) is yet another stylized fact: negative return shocks are followed by a higher volatility than positive returns.

Actually, those shocks do not affect the idiosyncratic volatility, but only the systematic one.

***Multivariate market association
and its extremes***

D. Baur (2006)

Besides the dispersion, *i.e.*, the cross-sectional (target) standard deviation, one can also consider the upward or downward dispersion.

A simple framework for time diversification

F.J. Fabozzi et al.

Journal of investing (2006)

The *time diversification index* (TDI) is

$$\frac{\text{Short-term Sharpe Ratio}}{\text{Long-term Sharpe ratio}}$$

where the (generalized) Sharpe ratio is

$$\text{Sharpe ratio} = \frac{\text{Risk}}{\text{Expected returns}}$$

for some measure of risk (standard deviation, value at risk, etc.)

***Using neural networks to analyze
intermarket relationships***

L.B. Mendelsohn

Journal of trading (2006)

The author suggests to look at momentum not only backwards (previous returns) but also sideways (returns in other markets), for instance using neural networks.

***Let's play hide-and-seek: the location and size
of undisclosed limit order volume***

S. Bongiovanni et al.

Journal of trading (2006)

Predicting hidden order volume in high-frequency data (we do not only use the trades but also the quotes).

***A fresh look at
investment performance evaluation***

R.J. Surz

Journal of Portfolio Management (2006)

The author advocates the use of random portfolios.

Are optimizers error maximizers?

M. Kritzman

Journal of Portfolio Management (2006)

Actually, no – the profile (returns, risk, exposures, etc.) of the correct and incorrect portfolios are very similar.

Smoothly mixing regressions

J. Geweke and M. Keane (2005)

One can extend the mixture of gaussians model by allowing the probabilities to depend (via a probit link) on covariates.

***The information in option volume
for future stock prices***

J. Pan and A.M. Poteshman (2006)

An options-based order flow imbalance (OFI): the put-call volume ratio.

***Portfolio optimization
with robust estimates of risk***

V. DeMiguel and F.J. Nogales (2006)

Mean-variance portfolios, or even minimum variance portfolios, are very unstable. One can replace the 2-step process “estimate the risk model then compute the minimum variance portfolio” by a 1-step process (just put the formula for the variance matrix in the objective function) and then replace the squares that appear in the objective function by a robust loss function (either slowly increasing, such as the *Huber function*, leading to *M-estimators*; or bounded, such as the *biweight function*, leading to *S-estimators*).

***Beauty contests and
iterated expectations in asset markets***

F. Allen et al.

Review of Financial Studies (2006)

The law of iterated expectations (today’s expectation of tomorrow’s expectation of the price in two days equals today’s expectation of this price) holds for expectations given the public information, for expectations given the information available to a given investor, but does not hold for the average expectation over all investors – and those average expectations play a central role in establishing future prices.

***Estimation of approximate factor models: is it
important to have a large number of variables?***

C. Heaton and V. Solo (2006)

Principal Component Analysis (PCA) decomposes a sample variance matrix as $V = EE'$ (while factor mod-

els try to write it as $V = EE' + \Delta$, where Δ is diagonal); this decomposition converges to the population PCA when $T \rightarrow +\infty$ with N fixed. This article examines what happens when T and N both tend to infinity with the ratio N/T fixed.

Who herds?

D. Bernhardt et al.

Journal of Financial Economics (2006)

Analysts do not shrink their forecasts towards the consensus – on the contrary. The absolute value of the forecasts is irrelevant: focus on the forecasted value relative to the consensus.

A conditional approach to hedge funds

F. Pochon and J. Teiletche

Journal of Alternative Investments (2006)

Fit a *regime-switching* model (mixture of gaussians, estimated with the EM algorithm) to a chosen *core asset* (e.g., the S&P 500 index, if you are interested in equities) to identify two market regimes: quiet and hectic. You can then compute exposure, correlation, etc., conditional on the market regime, *i.e.*, you have two values for each measure, a quiet and a hectic one. You can also perform (simulation-based) statistical tests to check whether the regime makes a difference.

***How sub-optimal – if at all –
is goal-based asset allocation?***

J.L.P. Brunel

Journal of Wealth Management (2006)

A behavioral (or goal-based) portfolio is a combination of efficient portfolios, each corresponding to a different goal, *i.e.*, to a different risk aversion. But a combination of efficient portfolios need not be efficient – how inefficient is it? Not much, actually.

***Optimization and quantitative
investment management***

A. Khodadadi et al.

Journal of Wealth Management (2006)

We need a decent IT infrastructure, with an easy to access and maintain database – a *data warehouse* (DW) – and an optimizer.

***Optimal portfolio allocation
using funds of hedge funds***

J.-P. Gueyie et al.

Journal of Wealth Management (2006)

Hedge fund (HF) indices over-estimate their returns, mainly because of *survivor bias* – probably 3% per year. This problem is mitigated by *funds of funds* (FOF).

The article presents several risk measures, adapted to hedge funds, and runs portfolio optimizations with them:

– *Standard deviation* (one can also consider skewness and kurtosis, which are not risk measures, but can

complement the standard deviation to build other risk measures);

- *Expected loss* and Ω ;
- *Semi-variance*: $E[(X - EX)^2 | X < EX]$;
- *Target semi-variance*: $E[(X - X_0)^2 | X < X_0]$, for some user-chosen X_0 , e.g., $X_0 = 0$;
- *Maximum drawdown*;
- *Value-at-Risk* (VaR), i.e., a quantile, that can be computed empirically, empirically with exponentially-decaying ($\alpha = .99$) weights, assuming a gaussian distribution, using a *Cornish-Fisher expansion* (a kind of Taylor expansion of the quantile function of a distribution, around the gaussian quantile, that involved excess skewness S , excess kurtosis K and the corresponding gaussian quantile z)

$$\text{CFVaR} = \sigma \left(z + \frac{z^2 - 1}{2} S + \frac{z^3 - 3z}{24} K + \frac{2z^3 - 5z}{36} S^2 \right)$$

or using *extreme value theory* (EVT).

To select a portfolio on the efficient frontier for one of those measures you can use the *modified Sharpe ratio*

$$\text{MSR} = \frac{\text{Expected returns}}{\text{Chosen risk measure}}.$$

The conclusion of the article is that hedge funds (or funds of funds) are good, but non-gaussian.

A data-driven optimization heuristic for downside risk minimization **M. Gilli, Journal of Risk (2005)**

This article advocates *threshold accepting* (TA), a variant of simulated annealing (replace the probability by a threshold; select the cooling scheme from the empirical distribution of the differences of the objective function), together with downside risk measures such as value at risk (VaR), expected shortfall (ES) and Ω .

$$\begin{aligned} I_1 &= \int_{-\infty}^0 F(z) dz \\ I_2 &= \int_0^{\infty} (1 - F(z)) dz \\ I_3 &= \int_{\text{VaR}(\alpha)}^{\infty} (1 - F(z)) dz \\ \text{ES}(\alpha) &= \text{VaR}(\alpha) + \frac{1}{\alpha} I_3 \\ \text{EL} &= I_2 - I_1 \\ \Omega &= I_2 / I_1 \end{aligned}$$

Comparing downside risk measures for heavy-tailed distributions **J. Danielsson (2005)**

For random variables *with regularly varying tails*, i.e., their tail can be approximated by a Pareto distribution, i.e.,

$$\forall x > 0 \quad \lim_{t \rightarrow -\infty} \frac{F(tx)}{F(t)} = x^{-\alpha},$$

i.e., $F(-x) \underset{x \rightarrow +\infty}{\sim} Ax^{-\alpha}$, expected shortfall does not depend (much) on the tail coefficient A but only on the tail index α , which is bad news for financial applications, where the tail index α is the same across stocks but where the tail coefficient A varies. Other downside risk measures (VaR, semi-variance, first lower partial moment, zeroth lower partial moment) do not have this problem.

Modeling model uncertainty **A. Onatski and N. Williams (2002)**

To account for model uncertainty, say, a regression preceded by a variable selection procedure, you can:

- Forget about the bias introduced by variable selection and compute prediction intervals; if the model is more complicated than linear regression, use bayesian methods to get the distribution of the estimators;
- Consider the set of models (i.e., selected variables) containing the chosen model, with suitable weights;
- Use the set of all models.

This article applies those ideas to State Space Models (SSM) and uses them to make the best decision in the worst case (minimax).

Mining source code elements for comprehending object-oriented systems and evaluating their maintainability **Y. Kanellopoulos et al.**

Clustering source code metrics of Java classes (number of lines, number of methods, number of public methods, number of children, tree depth, number of coupled classes) can help us understand (and assess the maintainability of) large software projects.

The problem of disguised missing data **R.K. Pearson (SIGKDD Explorations, 2006)**

Beware of missing data; beware of missing data not labeled as such (outliers or even inliers); look at the data.

Graph-theoretic scagnostics **L. Wilkinson et al. (2005)**

Scatterplot matrices can be insightful, but when you have dozens or hundreds of variables, the scatterplot matrix is unreadable: on which cells of this matrix should we focus? To answer this question, one can devise several measures of “interestingness” or “peculiarity” of a scatterplot: presence of outliers, skinniness, curvature, skewness, clumpiness, etc.; then, one can look at the scatterplot of those peculiarity measures (the variables are the interestingness measures and the

observations are the cells of the initial, large scatterplot matrix, *i.e.*, the pairs of initial variables) and select, interactively (this is called *brushing*) the outliers and look at the corresponding scatterplots.

Those measures are sometimes called *scagnostics*.

Classical scagnostics are parametric and/or do not lend themselves to large data sets: this article provides non-parametric, algorithmic, graph-based scagnostics, suited to situations with 100,000 observations and 100 variables.

***After-tax asset allocation*
W. Reichenstein (FAJ, 2006)**

You learnt not to mix present value (PV) and future value, and to convert everything to PVs – you should do the same with taxes, and convert everything into after-tax value.

***Covariance misspecification in asset allocation*
S.P. Peterson and J.T. Grier (FAJ, 2006)**

Estimates covariance matrices can be “wrong” (biased and overly noisy) for two reasons:

- Not all the assets have the same history length: people usually truncate the time series to match the shortest, but this discards information and is suboptimal: for instance, we lose precision on the variance of the longer time series;
- Some return series (e.g., real estate, private equity) are smoothed: their variance will be biased towards zero.

The article recalls that covariance matrix estimators allowing for missing values do exist (Stamgaugh variance) and that unsmoothing methods do exist (Fisher–Geltner method – actually a special case of ARMA innovations) – details are lacking, though.

***Gradient maximization: an integrated return/risk portfolio construction procedure*
J.S. Brusk and V.K. Schock (2006)**

Portfolio construction is usually a two-step process: first predict the returns of all the stocks, then build a portfolio. This can be replaced by a one-step process. A straightforward (linear) implementation proves more robust to non-linearities.

***Holistic asset allocation for private individuals*
G.B. Fowler and V. de Vassal, Journal of wealth management (2006)**

Private investors often allocate their assets to goals (“retirement”, “charity”, “next generation”, etc.) and typically partition their total assets into separate buckets for those goals.

It is preferable not to separate things and to state the client requirement in a single (more complicated) optimization.

***Optimal rebalancing strategy for institutional portfolios*
W. Sun et al. (2006)**

Dynamic programming-based rebalancing performs better than scheduled rebalancing or fixed tolerance band rebalancing – it is adaptive.

The article compares the three strategies with several utility functions (quadratic, log wealth, power) and examines their robustness.

Dynamic programming (you should know what it is before reading this: the article is too technical) is not amenable to current computers beyond a dozen assets.

***Parameter estimation of ARMA models with GARCH/APARCH errors: an R and SPlus software implementation*
D. Würtz et al. (2006)**

If you want to understand how GARCH (or APARCH) is implemented in R, or if you want to modify the code to accommodate other models.

***Dynamic forecasting behavior by analysts: theory and evidence*
J. Clarke and A. Subramanian
Journal of financial economics (2006)**

Significant underperformers or outperformers are more likely to issue bolder forecasts.

***Stock returns, implied volatility innovations and the asymmetric volatility phenomenon*
P. Dennis, S. Mayhew and C. Stivers
Journal of financial and quantitative analysis (2006)**

The relation between stock returns and volatility innovations is mainly due to the market; can be refined by including the market previous returns; the volatility innovations can be proxied by the implied volatility innovations.

***A portfolio of stocks and volatility*
R.T. Daigler and L. Rossi
Journal of Investing (2006)**

Volatility (e.g., VIX futures, variance options, swaps) is negatively correlated with the S&P 500 and should therefore be included in equity portfolios.

But beware: as investors are getting more familiar with options, the usefulness of options-based strategies change – in your simulations, do not assume that the situation is stationary.

***Improving risk-adjusted returns of fixed-portfolios with VIX-derivatives*
G. Dong (2006)**

As above.

***A tactical implication of predictability:
fighting the FED model***

R. Salomons, *Journal of Investing* (2006)

The *FED model*, that selects between equity and bonds by comparing earnings yield and bond yield, is not valid: it forgets inflation (*money illusion*) and that the relation between bonds and equity is not constant over long stretches of time.

The author suggests to regress earnings yield against bond yield and a few more variables such as equity volatility and bond volatility.

useR! 2006 conference

Last week, I attended the 2006 useR! conference: here is a (long) summary of some of the talks that took place in Vienna – since there were up to six simultaneous talks, I could not attend all of them...

0. General remarks

There were 400 participants, 160 presentations.

Among the people present, approximately 50% were using Windows (perhaps less: it is very difficult to distinguish between Windows and Linux), 30% MacOS, 20% Linux (mostly Gnome, to my great surprise).

1. Tutorial: Bayesian statistics and marketing (Peter Rossi)

The goal of statistical inference is to make probability statements from various information sources: the data, but also *prior* sources, for instance, “this parameter should be positive” or “this parameter should have reasonable values”. The difference between marketing and econometrics is that in the latter, those statistical statements lead to actions – see J. Berger’s book, *Statistical decision theory and bayesian analysis*.

Bayesian methods produce the whole posterior distribution of the parameters, from which you can extract any information – not simply “the most likely value” of this parameter, as with maximum likelihood (ML) estimators. This is akin to the *sampling distribution*, *i.e.*, the distribution of the estimated (say, ML) parameters if we had run the experiment millions of times.

Bayes’s theorem simply says that the *posterior* probability (or probability density function) is (proportional to) the product of the prior and the likelihood.

Bayesian statistics can be applied to any kind of model, *e.g.*, binomial, regression, multiple regressions, probit, logit, hierarchical, etc.

The *beta distribution* is a good candidate for parameters in $[0, 1]$: it can be symmetric or skewed, with a large or narrow peak, or even U-shaped.

The *inverted χ^2* distribution is often used as a prior for variances, because it is amenable to computations: it is said to be *conjugate* – but in the computer era, there is no reason to limit ourselves to these.

In the prior distribution, one often has to choose parameters: these are called *hyper-parameters*.

Bayesian estimators are often said to be *shrinkage estimators*: they are “between” the prior and the maximum likelihood estimators (MLE).

The larger the sample size, the smaller the influence of the prior.

Sampling from multivariate distributions can be tricky: it is often easier to sample from univariate distributions, *i.e.*, to sample one dimension at a time. The idea of *Gibbs sampling* is to replace sampling from (x_1, x_2) by sampling from $x_1|x_2$ and then $x_2|x_1$. This bears a resemblance to the *EM algorithm* – it might even be exactly the same: for instance, both can be used to fill in missing data.

If we draw the intermediary steps of a Gibbs sampler sampling from a bivariate gaussian distribution, only one coordinate changes at a time and the path is a staircase one.

When using Gibbs sampling, be sure to check the following:

- the autocorrelation and the cross-correlation
- the time series of the sampled parameters: are they stationary?
- plot the bayesian estimators versus the ML ones; plot the bayesian estimators versus the bayesian estimators with a different prior
- run several chains (the sampled time time series are often called *Monte Carlo Markov Chains* (MCMC)) and check if they *mix* (*i.e.*, if they look interchangeable).

Having the full distribution of the parameters allows you to extract a lot of information: *e.g.*, you can investigate the distribution of $X_1 \cdot X_2$ or X_1/X_2 (with stan-

dard gaussian distributions, the latter does not even have moments).

In the bivariate gaussian example, since X_1 and X_2 are correlated, successive values of (X_1, X_2) will be correlated: the samples do not contain as much information as an independant sample of the same size.

With the probit model,

$$\begin{aligned} Z &= X\beta + \varepsilon \\ Y &= Z > 0 ? 1 : 0 \\ \varepsilon &\sim N(0, 1) \end{aligned}$$

(this can be seen as a *censored* (or truncated) model: Z is replaced by the intervals $(-\infty, 0]$ or $(0, +\infty)$ – there is less information in censored data than in complete data), bayesian methods provide more information: we also have the distribution of the *latent* (or hidden) variable Z – more generally, bayesian methods provide an estimation of the distribution of the parameters, latent variables and missing values.

Mixtures of gaussians can be tackled in the same way: the latent variable is the number of the cluster. But there, the situation is much worse: a permutation of the numbering of the components does not change anything – as a result, if there are n components, the likelihood has $n!$ modes... Actually, it is not a problem: the Markov chain will *switch the labels* from time to time, but this will have no consequence.

The *multinomial probit* model (the variable to predict is not binary but can take n values – say, margarine brands) is almost intractable with classical methods but is amenable to bayesian methods. Some care is needed, though: see the book.

The same goes for the *multivariate probit* model (the variable to predict is a subset of those n values – say, beer brands).

The *Metropolis algorithm* (an alternative to the Gibbs sample, that allows you to easily sample from a multivariate distribution, and which is preferable when the variables are too dependant) was not tackled – see the book.

Finally, the interesting part: *panel data* and *hierarchical model*. Since this is getting more intricate, I prefer to refer you to the book.

The presenter developped the **bayesm** package, that provides, among others, the following functions:

- **runireg** samples from the posterior distribution of the parameters of a regression $y \sim x$ with an inverted χ^2 prior on the variance σ^2 and a gaussian prior of $\beta|\sigma$
- **rmultireg** samples from the posterior distribution of the parameters of a family of regressions $Y \sim x$ with an *inverted Wishart* prior on the variance Σ and a gaussian prior on $\beta|\Sigma$
- **rbiNormGiggs** samples from a bivariate gaussian, using a Gibbs sampler
- **numEff** computes the effective sample size of a time

series, *i.e.*, the size of the series for independant variables that would contain the same information. It tells you how much thinning you should use.

- **runiregGibbs**: samples from the posterior distribution of the parameters of a regression $y \sim x$ with an inverted χ^2 prior on the variance σ^2 and a gaussian prior of β (and not $\beta|\sigma$)
- **rbprobitGibbs**: samples from the posterior distribution of the parameters of a binary probit regression $y \sim x$ with a gaussian prior on β (and $\sigma = 1$)
- **rmixGibbs**: samples from the posterior distribution of the parameters of a mixture of gaussians with a *Dirichlet prior* on the probabilities of the components, a gaussian prior on their means, an invert Wishart prior on their variance.
- **rmnpGibbs**: samples from the posterior distribution of the parameters of a multinomial probit regression (Beware of the results: they are not intended to be stationary – consider $\beta/\sqrt{\sigma_{1,1}}$ and $\Sigma/\sqrt{\sigma_{1,1}}$ instead)
- **createX**: ancillary function to create the design matrix given to **rmnpGiggs**.
- **rmnlIndepMetrop**: multinomial logit
- **rhierBinLogit**, etc.: there are also a lot of hierarchical models: this is a slippery slope, do not use them unless you *really* know what you are doing.

Conclusion

Mixed models are only partial bayesian methods: you have to provide a prior, but you do not look at the whole posterior distribution, which might be misleading if it not gaussian. Given the power of current computers, there is no need for such a restriction: we can afford a full bayesian method.

There are more general bayesian packages (*Bugs*, *JAGS*), with which you can simulate any kind of model, but that generality comes at a price: on special cases, the computations are not as fast as they could be – by several orders of magnitude...

2. Tutorial: Rmetrics (Diethelm Wurtz)

Rmetrics is a set of R packages for quantitative finance and econophysics, initially developped for educational purposes. This tutorial reviewed those packages one at a time.

The **fBasics** package helps study the stylized facts of financial time series.

The **fCalendar** package is devoted to time manipulations. The notion of *time zone* (TZ) is replaced by that of *financial center*, that encompasses daylight saving time (DST) rules and holidays (to perform operations such as “next business day”). This is still imperfect: different markets in the same financial center have different holidays (e.g., Chicago/Equities and Chicago/Bonds).

The **timeSeries** package defines the `timeSeries` class: those objects contain one or several time series, having the same set of timestamps.

The **fSeries** package provides the **garchFit** function, for fit GARCH models and their variants. GARCH

models are a bit of a problem with statistical software: for a long time, there has been no *benchmark* against which to assess an implementation, yielding very disparate results across systems (*Ox* is not that good, but the others, including SPlus and SAS, are much worse).

The **fExtreme** package is devoted to extreme values. It contains a set of functions to (visually) study distribution tails (`emdPlot`, `lilPlot`, `mePlot`, `msratioPlot`, `qqPlot`, `recordsPlots`, `sllnPlots`, etc.)

To compute the *Value at Risk* (VaR) or the *Expected Shortfall* (ES) one can try to fit a distribution to the tail of the data, chosen from the family of limit distribution of tails of distributions: the *Generalized Pareto Distribution* (GPD).

```
pgdriskmeasures(gpdFit(
  x,
  threshold = .95,
  method = c("pwm", "mle", "obre")
))
```

(Here, `obre` stands for “optimally biased robust estimator”).

Extreme Value Theory (EVT) also studies the distribution of the maximum of iid random variables: there is a limit theorem, similar to the central limit theorem (with `max` instead of `mean`) that identifies the limit distribution as one of the GEV (*Generalized Extreme Values*) distribution (of which the Gumbel, Frechet, Weibul are special cases).

The **fCopulae** package is devoted to *copulas*. The implementation is more reliable than that of SPlus (SPlus seems to use numeric differentiation, which is unstable in extreme cases; Rmetrics uses formal derivatives, computed in Maple).

Copulas address the following fallacies.

- Fallacy 1: Marginal distribution and their correlation matrix uniquely determine the joint distribution.
- Fallacy 2: $\text{Var}(X_1 + X_2)$ is maximal when $\text{Cor}(X_1, X_2)$ is maximal
- Fallacy 3: $\text{Cor}(X_1, X_2)$ small implies that X_1 and X_2 are almost independant.

The **fOptions** package is the best-known part of Rmetrics: all the (equity-based) options, priced by exact formulas (when available), binomial trees, Monte-Carlo simulations (with *antithetic variables*, *low discrepancy sequences*), PDEs.

The **fBonds** package is devoted to bonds (but I am not familiar with bonds).

The **fBrowser** is an Rcmdr-based GUI that provides the above functionalities. You can extend it and add your own menus.

Conclusion: The coverage is impressive, and Rmetrics should be considered if we plan to use options or if/when we start to investigate *Econophysics*.

You may also want to have a look at the Rmetrics

website (Diethelm also has a company, Finance Online Gmbh).

3. Recurring topics

The following topics were tackled in several talks.

GUI

Windows users are typically intimidated by the almost empty starting screen of R and wonder “where is the GUI?”.

Novice users, who do not want to tamper with the command line, are probably better off with an Rcmdr-like interface: indeed several projects build on John Fox’s Rcmdr (which provides basic statistics) to provide domain-specific functionalities with a menu-driven interface: `fBrowser` in Rmetrics for finance, `GEAR` for econometrics, etc.

Programmers also complain about the difficulties of debugging R code and the lack of a VisualStudio-like IDE (Integrated Development Environment). Note that SPlus is addressing this concern by providing an Eclipse-based workbench – there is an Eclipse plug-in for R, but many features are still missing.

Let us also mention ESS, Texmacs and JGR.

Interactive graphics

Some people claim that the lack of interactive graphics is one of the major drawbacks of R: they would like to be able to have several plotting windows, presenting different views of the same data set, to be able to select points in one plot and see the corresponding points highlighted in the others (this is called *brushing*).

iPlots (built with `rJava`) provides those facilities, together with a (portable) GUI, but is still under development – it seemed perfectly useable, though.

GGobi can already do all that, but it is a separate application (that can talk to R) and it does not provide user-defined plots.

The *rgl* package leverages *OpenGL* (one of the technologies used by the graphics card found in most computers and needed to play most video games – a large, untapped source of computational power) to produce 3-dimensional plots, that can be interactively rotated; but their elements cannot be selected, brushed, etc.

Of course, one can still use Tk widgets (and the `tkrplot` package) to produce plots that are automatically updated when the user moves a slider.

e-Learning and collaborative documentation: Wikis galore

Though the R documentation is often better than that of other software, it still has a few problems: the manual pages are terse reference manuals, often unsuitable to begining users; the contributed manuals, that cater to users with very specific backgrounds, are not updated as timely as R is.

To tackle this problem, some suggested to write collaborative documentation, in the spirit of Wikipedia:

after several months of discussions on the R-SIG-Wiki mailing list (about which wiki engine to use, how to have it understand R, which structure the site should have, etc.), Philippe Grosjean opened the R Wiki as the conference started, with already some contents (R tips, the R Tk tutorial, and the first chapter of my *Statistics with R*).

Wikis are also used in several e-Learning projects: the teacher sets up the structure of the site and the students fill it in, with the notes they have taken, the statistical analyses they have carried out, the problems they have had, how they have solved them, etc.

Some companies (Microsoft, IBM, GM, Dresdner, etc.) are using a *corporate wiki* for their intranet and part of their web site – in particular large companies, when they want to show that their employees are human, that their projects are steadily progressing. (If you want another buzzword for that, you can use the more general term *Web 2.0*.)

Frank Harrell suggests to use Wikis for *knowledge management* – his web site is a wiki, and has been so for years. He also encourages us to use Sweave for *document management*.

For more about Wikis, CMS (*Content Management Systems*), and web sites in general, check, for instance GNU/Linux Pratique HS 5 (in French).

Reproducible results

Several people advocated the need for reproducible results, mainly with *Sweave*, and indeed, most of the presentations were made with Sweave and *Beamer*.

Some people (Dirk Eddebuettel) even suggested to cryptographically *fingerprint* the datasets used (do not do that in the US, though: someone managed to patent it – you can fingerprint files, but not files containing data).

Enterprise Business Processes (EBP)

I did not attend all those presentations.

Some explained that R could be used as a component in a larger process, scheduled in an automated way: they usually resort to Rserve or rJava to access R as a web service or as a Java class.

Some of those systems exhibited pretty, impressive but utterly useless (Java) graphical front-ends.

Some explained how to exchange structured data between R and other systems (for simple data, such as a `data.frame`, simply use a CSV file or a database), us-

ing an XML schema (this is sometimes called a DTD) to store `data.frames`, lists, lists of lists, etc. They provide an R package (`StatDataML`) and a Java class (`JStatDataML`) to this end.

(There used to be an XML schema to store and exchange statistical models and data between statistical applications, called PMML, but it was not mentioned and I do not know if the project is still alive.)

Some explained how to extend XSLT to have it call R and perform statistical computations on the data being transformed.

Some explained how to embed R into a web server.

Of course, in this area, the most important thing is the number of acronyms and buzzwords you can fit in a single sentence: as an exercise, try to form a sentence using the words XML, XSLT, JAXB, PyXML, R/Apache, POI, JDBC, Jython, Struts, Hibernate, YAWL, Ruby on Rail.

Large scale computations

When your computational needs grow, you will want to run computations in parallel, on several computers, or several processors on the same machine: these could be completely different processes, similar processes on different data, or a single computation that can be split up into several pieces.

A few packages can facilitate this parallelization: `rpvm` (uses PVM), `rmpi` (uses MPI), `snow` (to transparently parallelize parallelizable code) or `nws`.

The problem of large datasets, that do not fit into memory, was not tackled – the advice did not change, use a database to store the data and/or buy more memory (and use an operating system that can use it).

Unification

There are often several packages on the same subject, each providing similar but different, complementary and incompatible capabilities. In several areas, such as robust statistics (with the `robustbase` package) or econometrics (with the `GEAR` package, that will provide basic econometric functions and a GUI), people are starting to unify all this.

Also note the forthcoming book, *Applied Econometrics with R*, by C. Kleiber and A. Zeileis.

Real-time data, stream processing

One of the challenges faced by R is the increasing amount of data to process and the timeliness of that processing: more and more, we will want real-time results or plots, that pop up as soon as the data arrive, that are updated as soon as the data is.

There is some progress in that direction (such as algorithms to compute a moving median, a moving quantile; or frameworks for enterprise processes that encompass R), but the path to a real stream-processing engine will be long.

(I only attended one of those talks, so I do not know

if the following was mentioned: it is possible to write triggers in R for PostgreSQL and thus launch computations when the data arrive.)

Including R in other software

As non-statisticians progressively want to harness the power of R, they will want to access it from the software they are familiar with, such as spreadsheets or databases.

It is already possible to access R from Gnumeric (a spreadsheet) and from PostgreSQL (a database management system (DBMS)).

(There were also presentations and tutorials about R and Windows, but I did not attend them: they usually assume that you are already a proficient Windows programmer.)

Machine learning

There was a whole session on machine learning, with emphasis on Support Vector Machines (SVM).

Bayesian networks and neural networks were not forgotten, though: an R neural networks toolbox is being developed, similar to the Matlab one.

Bayesian statistics

Bayesian methods rely on two ideas.

First, before doing an experiment or before looking at the data, we have some information: it can be, for instance, a “reasonable” range for the quantities to estimate. This information is called the *prior*.

Second, instead of computing the single “best” value for the parameters of interest, we want the full *sample distribution* of those parameters, *i.e.*, the distribution of the “best” parameters that we would observe if we could repeat the experiment tens of thousands of times: this is the *posterior* distribution.

Those methods used to require lengthy simulations, but the are becoming more and more amenable to commodity PCs.

People have long been using Bugs (WinBugs or the supposedly portable OpenBugs, or its open source replacement JAGS) to sample from the posterior distribution. Those software can accomodate any kind of model, but because of that generality, the computations can take a lot of time.

For very specific models, the computations can be greatly sped up: this is what the *bayesm* and *MCMCpack* packages do – *MCMCpack* also provides you with the building blocks needed to sample from other models.

Bayesian methods can also be used to compare models, as a replacement of *p*-values: check the *BayesFactor* and *PostProbMod* functions in the *MCMCpack* package.

When using bayesian methods, one should not forget to perform a few *diagnostic* tests or plots: this is what the *coda* package does.

Robust statistics

A robust statistical method is one that is not sensitive to outlying data: even if part of the data is outrageously wrong, it has little impact on the results.

This is often measured with the *breaking point* of an estimator (say, a regression): this is the proportion of observations you can tamper with without being able to make the estimator arbitrarily large.

The *influence* of an observation is the change its inclusion or deletion induces in the result.

One can sometimes spot outliers with the *Pearson residuals*:

$$\frac{\text{sample density}}{\text{density according to the model}} - 1$$

(a presenter showed this with circular data, where outliers are not really “far”...).

The *robustbase* package is an attempt to unify the elementary robust methods currently scattered across various packages: it will provide robust regression (*lmrob*, *glmrob*), replacements for the Mean Average Distance (MAD) (*Qn*, *Sn*), MCD (Minimum Covariance Determinant) covariance matrix, etc.

One can “robustify” the (linear, gaussian) *Kalman filter* by replacing the matrix estimations it uses (mainly expected values and covariance) by robust equivalents (median and MCD covariance).

One can robustify Principal Component Analysis (PCA): this is then called *projection pursuit*. PCA finds the direction in which the “dispersion”, as measured by the variance, is largest; robust PCA replaces the variance with a robust equivalent.

One can generalize this to other measures of dispersion, or measures of non-gaussianity (this is called *Independent Component Analysis* (ICA)).

One problem with robust covariance matrices is that their robustness decreases with size (since projection pursuit uses 1-dimensional subspaces, it might not be much of an issue, but for other applications, it is).

There is a mailing list devoted to robust methods in R: R-SIG-Robust.

Regularization paths

A *shrinkage* estimator is an estimator somewhere on the path between a prior estimation (very stable, reliable, but hardly informative) and an estimator (e.g., a MLE estimator: it contains all the information, but can be extremely noisy).

The “best” position on the path can be chosen by *10-fold cross-validation* (CV).

There are variants of this idea:

- *Principal component regression* is a regression in the first k principal components (the path is discrete, indexed by the number of components retained).
- *Forward variable selection* (here again, the path is discrete and corresponds to an order on the set of variables)
- *Ridge regression* is a regression with an L^2 penalty on the amplitude of the coefficients (if some of the predictors are correlated, the corresponding coefficients can be extremely large, with opposite signs: the penalty tries to avoid this)
- *Lasso regression*: idem with an L^1 penalty
- *Forward stagewise regression*: instead of completely adding the variables, as in forward variable selection, just add a small part of them, say $0.1 \cdot X_i$ (the same variable may be added several times, to increase its coefficient)

Least angle regression (LARS) is very similar to forward stagewise regression:

- find the variable X_i the most correlated with the variable to predict Y
- add it in the model, with a small coefficient, and increase the coefficient until another variable, X_j , becomes more correlated with the residuals: then, progressively change the coefficients of the two variables, X_i and X_j , until a third variable...

Lasso and forward stagewise regressions are actually special cases of LARS.

The regularization path of LARS is more stable, less chaotic than that of the lasso.

The number of degrees of freedom if a LARS regression is the number of variables that have been included – with, say, variable selection, it is much more!

There are further generalizations of LARS: *elasticnet* (a mixture of L^1 and L^2 penalties, that tend to select the variables in groups); *glm*path (e.g., for logistic regression); *pathseeker* (take the top k variables instead of the best); *Cosso* (we know, a priori, that the variables are grouped); *svmpath*.

R on Windows and MacOSX

Uwe Ligges tried to convince us that using R on Windows, installing packages from source or even writing you own R packages on Windows was not difficult. He almost made his point: he only needed one slide to list

the prerequisite software (not mentioning how to install them and forgetting about the incompatibilities with other already installed software) and two more slides to explain how to install a package (targeted at advanced Windows users: he tells to change environment variables without reminding us how) – a stark contrast with similar explanations for a Unix platform where, if you do not understand, you simply copy and paste the instructions.

He also noted that using Windows instead of Linux “only” reduced the speed by 10% – which is even more impressive if you consider that 64-bit R on Linux no longer runs slower than 32-bit R on Linux.

However, his talk was followed by a similar talk, by Simon Urbanek, that tried to do the same thing on MacOSX: the differences are amazing (the only instruction is “do not forget to install R”; R is well integrated with other MacOSX applications).

After those two talks, *it really seems insane to use R on Windows* (or anything else than R, for that matter – most of the problems are not specific to R).

By the way, most of the developers of R (“R-core”, not the people writing the add-on packages, but the people writing the core of the R system itself) are on MacOSX...

4. Other topics

ggplot

You might already know that there are four ways to use Object Oriented Programming (OOP) with R: S3, S4, R.oo and proto.

Similarly, there is now a third way of producing graphics: after the old graphics (with the `plot` function), the lattice graphics (with the `xyplot` and `grid.*` functions), there is now ggplot, that implements the ideas of the book *The Grammar of Graphics*.

forecast

This Windows-only package fits ARMA models to time series, but can infer the order by itself.

Time series modelling

Two talks presented methods to automate the fitting of time series (for instance, with an ARIMA model, you no longer have to select the order(s) of the model).

Multivariate GARCH models

Some multivariate generalizations of the GARCH model were presented, such as *Constant Conditional*

Correlation (CCC: same equation, with diagonal matrices); *Dynamic Conditional Correlation* (DCC: idem, but those matrices are allowed to change over time); *Smooth Transition Conditional Correlation*; *Extended Conditional Correlation* (ECC: the matrices are no longer diagonal, but in order to ensure that the variance matrix is positive definite, you have to add an infinite number of conditions – people usually replace these conditions by a single one, but this is too restrictive); *BEKK*.

All the code presented was developed with a 2-dimensional (or low-dimensional) case in mind.

Particle Filter

A *particle filter* is very similar to a Kalman filter, but it neither assumes that the underlying process is linear nor that the noise is gaussian.

The basic idea is that of an MCMC simulation. Instead of performing 10,000 (independent) simulations, one can try to mix them: at each step, the particles are simply resampled (it sounds trivial, but it is the only difference with an MCMC simulation).

They were applying that to currency data.

Markov Decision Process

It looked interesting, it is related to the use of *dynamic programming* to build portfolios and rebalance them over time, in a multi-period world, but they only had five minutes and I did not understand anything.

They use those ideas to trade currencies.

For more information, google for *Markov Decision Processes* (MDP), temporal distance learning, TD-learning, Q-learning, *reinforcement learning*.

Calibrating the evidence in experiments

You are probably familiar with my rant against *T*-values (stating *T*-values assumes that your readers are very familiar with the *T* distribution and that they know how the number of degrees of freedom affects those values and does not extend to other tests, you should rather use *p*-values, that simply assume that your readers understand the uniform distribution on $[0, 1]$; the significant level, usually 5%, has a completely different meaning depending on the size of the sample and neither you nor your readers know how to interpret it; you can state a difference of BIC instead of a *p*-value): that presentation (which I did not attend), gives more details about the meaning of the significance level depending on the sample size.

Non-metric clustering

The **riffle** package provides yet another clustering algorithm.

Challenges in cluster analysis

This talk highlighted several areas where cluster analysis is not yet a mature subject: *transaction data* (i.e., clustering subsets, e.g., clustering shopping baskets) and *time series*.

Indian commodity markets

To find a consensus price for a commodity, across a multitude of local markets, in order to set up a futures market, they use an *adaptively trimmed mean*.

Random portfolios

To check if a portfolio manager is a good portfolio manager, one can compare his performance with that of a “random” portfolio: simply generate permuted portfolios from the actual one.

The problem is that these permuted portfolios breach all the constraints the portfolio manager has to abide by. To recover them, one can feed these permuted portfolios to an optimizer, with no alpha and no variance matrix – just the constraints.

According to Patrick Burns himself, the resulting portfolios are not as uniformly distributed as they should be...

If you do not know his company, he sells an optimizer, based on genetic algorithms, that can be called from R (and soon Matlab), and he also does some consulting.

Sparklines

Sparklines are word-like plots, that can be used inside a sentence or in a table.

The dataset is that of the American Statistical Association (ASA) visualization contest.

Barcodeplot and Generalized pairplot

Histograms fail to spot ties in the data: a barcodeplot is similar to a rugplot, but the other dimension is used to indicate ties. It can be seen as a alternative to the boxplot.

This is not unlike the result of the **describe** function, in the **Hmisc** package.

The `pairs()` function in R only accomodates quantitative variables: one can modify it to account for qualitative variables as well, with boxplots or barcode plots when one variable is qualitative and mosaic plots when both are.

Linked micromaps of large financial datasets

When displaying information (here, about mortgages in the UK) on a map, one usually divides it into regions that are coloured according to the average (or total) value of the variables. This is called a *choropleth map*.

But this is misleading: the information conveyed by the plot can change depending on the colour scheme chosen (the boundaries between the colours can be chosen at round values (say, 1, 2, 5, 10, 20, 50, 100, etc.) or at the quantiles of the variable displayed), on the regions chosen (there is a wealth of different, incompatible, administrative (or not) decompositions into regions); larger regions (which tend to have a low density, in our example), are over-emphasized; there is no indication of estimation uncertainty (confidence intervals).

A linked micromap plot is actually a table, with the maps in the first column, and the variables in the others; each row corresponds to four regions, highlighted in the map, with a dotchart in the remaining columns.

See also: <http://www.amstat-online.org/sections/graphics/newsletter/Volumes/v132.pdf>

Impulse response theory (IRT)

(There were several talks about psychometrics.)

Letter-value boxplots

With large datasets, boxplots are not as informative as they should be: in particular, too many points are unduely labeled as “outliers” – such points are supposed to be examined one by one...

Letter-value plots generalize boxplots, by displaying the 1/2, 1/4, 1/8, 1/16, etc. fractiles instead of just the median and the quartile, the zone between two such fractiles is represented by a box, of decreasing width (and or changing colour).

Visualization of multivariate functions, sets and data: denpro

The `denpro` package helps you visualize high-dimensional datasets, as a 2-dimensional plot, stressing its multimodality, its dispersion or its tails.

This looks great, but the presentation was impossible

to understand. The original articles might be easier to read.

Can R draw graphs?

Grid graphics can now draw *X-splines*, connect non-rectangular elements with arrows, clip rectangular regions and (with the `grImport` package) import vector graphics (SVG, PDF, PS – you should transform tem in PostScript first).

Parametric link functions for binary response models

The logit and probit link functions are not always sufficient: tests exist to check if they reflect the data, and if they are rejected, we need to look beyond them.

This talk presented the *cauchit* link function (which is more tolerant to surprising observations), the *Gosset* family (based on tyhe Student T distribution), and the *Pregibon* family (or Tukey lambda family).

Those links are implemented in the `gld` package.

The SPlus package system

If R started as a system “not unlike S” (S in the ancestor of SPlus), the situation is now reversed: to survive, SPlus cannot afford to ignore R.

The next version of SPlus will have a package system very similar to (and compatible with) that of R.

They also try to keep the lead they have in the user interface, by providing an “SPLus workbench” based on Eclipse.

In case you do not know, Eclipse, developped by IBM, is a Java IDE (Integrated Development Environment), *i.e.*, a text editor for Java programmers, that can be extended to accomodate other languages, such as C or C++. There is already an R Eclipse plugin, but it still lacks many features.

Statistical principles to live by (Frank Harrell)

Do not overfit the data: use *shrinkage*, use *penalized likelihood* estimators.

Respect continuous variables, do not bin them before computation.

Use non-parametric methods (not everything is linear).

Account for *multiple tests*: when performing several tests, *i.e.*, when you have several *p*-values, correct those *p*-values.

Be honnest with *multi-step procedures*: you might feel safe when you perform a gaussianity test and decide on the path to follow next (e.g., parametric versus non-parametric tests) depending on the results of this test, but this is actually a multiple test, whose final *p*-value should be corrected – and do not be fooled by the power of non-parametric tests.

Use effective graphics, routinely.

Graphical EDA (Exploratory Data Analysis) using half-space depth

The notion of *depth* of a point in a cloud of points (minimum number of points of the cloud in a half-space passing through that point) can be used to define *bag-plots*, a 2-dimensional generalization of boxplots.

This was the funniest and fastest-paced talk.

Operational Risk management

This talk explained how to use FFT (*Fast Fourier Transform*) to estimate a loss distribution. The data gathering part of their process required a lot of social engineering.

Robustness assessment for composite indicators with R

I did not attend this talk: the author explains how to build a robust (stock) index for a country or a region – this can be seen as a *robust portfolio*.

Capturing non-observed heterogeneity

I did not attend this talk: they cluster discrete time series, using transition matrices.

Random Recursive partitioning

I did not attend this talk: to assess a clustering algorithm, you can apply it on the initial data and on resampled data, and check if the results are similar.

Missing data and Partial Least Squares (PLS)

(not attended)

Supervised self-organized maps

(not attended)

Term structure and credit-spread estimation with R

(not attended)

5. Conclusion

In the forthcoming years, R will face the following challenges:

- real time data processing
- embeddability in other software (spreadsheets, databases)
- large scale computations (distributed or not)

To that list, I would like to add:

- relational data (data that do not fit in a single rectangular table)
- large datasets

Tackling those changes may require drastic changes to R, that will trigger incompatibilities with existing code (the situation could be similar to the switch from Perl 4 to Perl 5, for those of you who lived it).

Game programming gems 6 M. Dickheiser editor (2006)

As the previous ones, this volume contained a few articles that might be relevant outside game development, such as: an explanation of the coding and use of *floating point numbers*; an application of *fuzzy inference*

systems (FIS) to manage scene complexity; the use of *support vector machines* (SVM) on a moving window to implement short-term memory in NPC (non-playing characters); a review of scripting languages (Lua and Python still dominate, but specialized languages are emerging); unit testing in C++ with *CppUnit*; many articles about BSP (binary space partitions) and ABT (adaptive binary trees); parallelism on multicore machines with *OpenMP*; fingerprinting; UDP hole punching (STUN); Python coroutines as *microthreads*; MMOG (but there is not enough liquidity and volatility for a currency manager to step in).

There was also a funny article about “synthesis of realistic idle motion for interactive characters” that managed to combine PCA (principal component analysis), Lie algebras, Markov chains and MST (minimum spanning tree) clustering.

I failed to understand the GPU (shader) articles, though.

Enhancing the tree awareness of a relational DBMS S. Mayer (2004)

One can store an XML document (or any rooted tree) in a relational database by storing the preorder and postorder traversal rank (*i.e.*, the order of the opening, respectively closing, tags): this is the *XPath accelerator* coding – you can quickly get the set of preceding, following, ancestor, descendant nodes (those four operators (there are 13 in the XPath specification) are called *axes*).

An XPath expression starts with a (set of) node(s), applies one of the operators above to get another set of nodes, etc.

One can speed up the evaluation of an XPath expression by removing duplicates in those sets of nodes; by replacing those sets of nodes by a “minimum set” on which the next operator gives the same result (*pruning*); by scanning the table one (vertical or horizontal) slice at a time (*partitioning*) or even *skipping* some of those slices.

This speed up process is called the *staircase join*, because the sets of nodes, in the pre-, post-order plane, look like a staircase.

Fat tails and asymmetry in financial volatility models P. Verhoeven and M. McAleer (2003)

Even though GARCH models can account for fat tails, they rely on the unrealistic assumption that once the volatility is known, the returns are gaussian. Instead, one can use the *asymmetric T-distribution* – and the resulting GARCH parameter are more robust to outliers.

Return-based style analysis with time-varying exposures L. Swinkels and P.J. van der Sluis (2001)

The *Kalman filter* is an advantageous replacement for “rolling regressions”.

***Incorporating trading strategies
in the Black–Litterman framework***

F.J. Fabozzi et al. (Journal of trading, 2006)

Yet another introduction to the Black–Litterman framework.

***Portfolio risk forecasting*
G. Connor (2007)**

(These notes do not refer to the book, but to a series of lectures drawn from it.)

(1) The portfolio management setting

There is a difference between stock risk and portfolio risk: a portfolio is a linear combination of stocks, but it changes over time.

The book does not focus on *knightian uncertainty* – this notion is not defined, but it may be what you want if you seek a behavioral perspective.

The efficient market hypothesis suggests that you separate the returns as expected returns (that will disappear if you can forecast them and if people know how you do it) plus a zero-mean, pure risk return (that is there to stay).

Traditional portfolio optimization is myopic: it maximizes an investor’s utility over a single period. Multi-period, intertemporal approaches exist, but are not tackled in this book.

There are several notions of risk: *variance* (or rather its square root, the *standard deviation*, sometimes referred to as *volatility*), *value at risk* (VaR), *expected shortfall* (sometimes called *conditional value at risk* or CVaR) or even the full distribution of returns. The book will mainly focus on variance, the other quantities will appear as an overlay once the variance has been figured out.

Optimizers typically assume that the investor’s utility function has *constant absolute risk aversion* (CARA):

$$u(x) = -\exp(-\lambda x).$$

This leads to an optimization problem of the form

$$\begin{aligned} \text{Maximize} \quad & w'r - \lambda w'Vw \\ \text{such that} \quad & w'1 = 1 \end{aligned}$$

where λ is the absolute risk aversion of the investor, w are the portfolio weights, r are the expected stock returns and V is the variance matrix of the stock returns

You can solve that problem in various ways: either fix the portfolio returns and find the portfolio that minimizes the risk; or fix the risk and find the portfolio that maximizes the returns. Both computations can be carried out with Lagrange multipliers (the details were not given: check Campbell, Lo and MacKinlay,

The econometrics of financial markets) and actually yield the full efficient frontier.

Using active returns instead of total returns in the optimization yield inconsistent results – I do not know why.

The author stresses that *valuation models* and *risk models* are unrelated (indeed, they answer different questions) and, invoking Grinold and Kahn, suggested that the models even be orthogonal. (If you want to optimize a portfolio, I agree (but including the alpha components in the risk model is probably harmless, because you would then provide an alpha to the optimizer) and some people even suggest to *rotate* the risk model so that it be orthogonal to the valuation model used; but if you want to see if your portfolio corresponds to the bets you think you made, to quantify those bets, to check that there are no other unwanted bets, it might be better to include the valuation model in the risk model).

Risk is not additive across a portfolio, but if you want that property, you can use *marginal contribution to risk* (MCTR) instead. You can define the MCTR of a stock or of a “tilt” (a portfolio indicating the direction in which you might want to move your portfolio).

The CAPM is a decomposition of stocks returns into a market component and residuals (it does not claim that the residuals are gaussian iid: there is still some structure in them).

$$\text{returns} = \alpha + \beta \cdot \text{market returns} + \text{residual returns}.$$

This leads to a decomposition of the variance matrix of the returns into a market-related (scalar) variance matrix and a residual variance matrix.

$$\begin{aligned} V &= \text{market variance} \cdot \beta\beta' + \text{residual variance} \\ &= \sigma^2\beta\beta' + \Delta \end{aligned}$$

To get a risk model, you can simply impose some structure on that residual variance matrix – e.g., ask that it be diagonal.

Under this assumption, the market portfolio is mean-variance efficient.

The CAPM can be seen as a linear regression with a single predictive variable: you can have several, instead. This is the *Arbitrage Pricing Theory* (APT – this sometimes also stands for Advanced Portfolio Theory). This leads to the notion of factor model we are used to.

One can also build *factor mimicking portfolios*.

The book does mention the interpretation of the APT in terms of arbitrage – but not clearly.

The CAPM is a 1-period model: you can define an *Intertemporal CAPM* (ICAPM, Merton) instead: the factor exposures (betas) are not time-dependant.

The book also mentions the (admittedly useless) *Consumption CAPM* (CCAPM, Breeden), but not clearly.

(2) The structure of Portfolio Risk Forecasting Models

In a portfolio optimization problem, you have to provide expected returns and a variance matrix: these are not known precisely. One can decompose the utility to be maximized into a sum, the actual utility and a term resulting of the error on the expected returns and the variance matrix. When maximizing the utility, you are actually maximizing both terms – and it might be easier, faster to maximize the second one – this is the *error maximization problem*.

This chapter presents several (mainly bayesian) methods to mitigate that problem.

To tackle the effects of the estimation error on the expected returns, you can shrink those estimates towards more conservative ones:

- Jorion suggest a *Bayes-Stein prior*, i.e., the mean of the forecast returns as a prior (all the stocks have the same prior return), with variance equal to the sample variance of those forecasts
- *Black and Litterman* suggest using the alphas (expected returns) implied by the CAPM, i.e., those for which the market is efficient.
- Grinold suggests something complicated that is actually a special case of the Black-Litterman prior

You can take the same ideas to mitigate the effects of the error in the estimation of the variance matrix, by shrinking it to a more conservative prior, such as:

- a diagonal matrix
- a constant correlation matrix
- the variance matrix of a 1-factor (CAPM) model
- the variance matrix of a multi-factor (APT) model

Actually, it might be better and simpler to shrink it completely and to stay with the prior.

To mitigate the effects of estimation errors in a portfolio optimization, one can also add *position limits* – this can actually be reformulated as a *shrinkage estimator*.

Resampling to estimate the distribution of the alphas and the variance matrix can also help mitigate the problem: without position limits, it does not improve anything, but with position limits, we get a biased estimator that “might” be helpful. (The lecturer failed to mention that this bias can tell you to buy stock with a known null or even negative return.)

This chapter also stressed the difference between arithmetic returns and log-returns.

(1bis) Each lecture was followed by a discussion:

- The risk aversion parameter is not knowable
- Some people want the risk model to be orthogonal to the valuation model; other the former to contain the latter.
- The CAPM does not provide a decent risk model
- The market is not efficient: it is cap-weighted. (?)

(2bis) After the second lecture, there was a small discussion on the relative merits of

- Cross-sectional risk models (start with the factor ex-

posures use regression to get the factor returns: the residual variance, assumed to be diagonal, need not be so)

- Times series risk models (start with the factor returns and use regression to find the exposures: the residual variance is closer to being diagonal, but the number of parameters to estimate is larger, yielding higher estimation errors)
- Hybrid risk models (more about this in a forthcoming lecture)

(3) Industry and country risk

In short: there are very strong country effects, even in western Europe, and they are more important in smaller countries.

When people did not have stock-level data, they were using contry index returns and country weights.

The model is typically written

$$\text{returns} \sim 1 + \text{industry} + \text{pure_country}$$

where the intercept is the market returns, and the pure country returns are orthogonal (uncorrelated) to the industry returns, and estimated as a *random coefficient model* (or *mixed model*): this means that the coefficients of the regression (the exposures of the stocks to the country or industry effects) are considered as random (gaussian) variables. Most mixed models practitioners will focus on the mean of those random variables: we shall focus on their variance.

Estimating this covariance matrix can be tricky – and his confusing explanations do not help.

To account for the differing volatility of the stocks (heteroskedasticity), one can use a weighted regression: either using “feasable weighted least squares” (this sounds like iteratively reweighted least squares: first set the stock variances to the same value, fit the model, estimate those variances, use the to get another fit, iterate) or using root-capitalization weighted regression (but this introduces a bias, especially in concentrated markets).

You can test for the significance of the country (or industry) returns by performing monthly T- and F-tests and looking whether they are significant “overall”. (He does not seem to know anything about *multiple tests* and the corresponding *p*-value adjustments – or about *p*-values in the first place.)

This generalizes to industry and country weights, instead of boolean exposures, either by asking analysts to come up with those exposures for each stock, or by regressing the stock returns against the country and industry returns obtained on a first run using boolean exposures – but expect the results to be noisy.

This lecture was followed by a few comments by James Sefton (UBS):

- Is the cross-sectionnal method the best? It allows one to have time-varying betas – but here, they are set to 0 and 1... Iterative time series/cross-sectionnal approaches may be worth considering.

- Is the country effect really strong? Doesn't it stem from the inclusion of a few (small and) very different countries? There is a difference between the two questions:

Q1: Is a country index affected by its industry composition?

Q2: Is a given stock more sensitive its country or its industry?

Academics are interested in Q1, practitioners in Q2.

The lingering importance of countries may be linked to the very slow disappearance of the *home bias*.

(4) Statistical factor models

(4a) Structure of statistical factor models

The model underlying statistical factor models can be written as

$$\text{returns} = \alpha + Bf + \varepsilon$$

or, since we are interested in B (exposures, betas), f (factor returns) and the variance matrix of the returns,

$$\text{Variance}(\text{Returns}) = BB' + \text{Variance}(\varepsilon).$$

(With my usual notations: $V = EE' + \Delta$.)

Here, we want to estimate both B and f (in the previous chapter, we had B (boolean exposures, or exposures given by analysts) and we wanted the factor returns f ; in macro factor models, we have the factor returns f and we want the stock exposures B): there is some indeterminacy – one can multiply B by any invertible matrix.

Statistical models do not impose any prior judgement about which factors are relevant.

Statistical models do not require complicated data: the returns suffice.

One can define several more or less complicated models by imposing restrictions on the variance of epsilon:

- In a *noiseless factor model*, it is set to zero
- In a *scalar factor model*, it is scalar (diagonal with always the same value on the diagonal)
- In a *strict factor model*, it is diagonal
- In an *approximate factor model*, I do not know (it was not defined rigorously). Examples include block-diagonal matrices (say, one block for each subindustry (*)), or matrices whose non-diagonal elements decrease as they get far away from the diagonal – more generally, matrices with a lot of zeroes or a lot of small elements

(*) This suggests another way of finding clusters of stocks, to be interpreted as industries or sectors:

- Compute the variance-covariance matrix of the stock returns;
- Remove the effects of a few factors (either statistical factors or factors you can interpret);
- try to write the matrix as a block-diagonal one (hint: try correspondance analysis to reorder the rows/columns).

(4b) Estimation of variance matrices

The first step is to estimate the sample variance matrix. If there are no missing values, if there all the stocks have the same history length, it is easy to do. Otherwise, one can use the EM algorithm to fill in the missing early values.

The EM (Expectation-Maximization) goes as follows: from some data (X, Y) , with Y missing, you want to estimate some parameter θ . You can just iterate through the following two steps:

- E-step: compute the distribution (not the expected value) of the missing observations given the estimated parameters
- M-step: estimate the parameters given the distribution of the missing observations

One may want to reduce the amount of data (with fewer stocks, the estimates should be less noisy): this can be done by grouping the stocks (say, by replacing them by subindustry portfolios) or (this is mainly a historical curiosity) by sampling the universe.

On the other hand, one may want to increase the number of dates: this can be done by extending the period in the past (but things have changed since the 19th century) or by using higher frequency data: weekly or daily instead of monthly.

With “high” frequency data, you have to adjust for *stale prices*: simply replace the sample variance of the returns at time t by

$$\begin{aligned} &\text{Cov}(r_t, r_t) + \text{Cov}(r_t, r_{t-1}) + \text{Cov}(r_{t-1}, r_t) \\ &\quad + \text{Cov}(r_t, r_{t-2}) + \text{Cov}(r_{t-2}, r_t) \\ &\quad + \dots \end{aligned}$$

(If there are no stale prices, the added terms have a zero expectation.) Otherwise, the variance estimator is biased.

The *Solnik diversification curve* (of a universe of stocks at a given date) plots the sample variance of a random, equi-weighted portfolio as a function of the number of stocks in the portfolio. (Actually, its computation is straightforward and does not require any simulation.) It can be generalized to capital-weighted portfolios.

(4c) Small- n methods (few stocks)

Principal Component Analysis (PCA) can be used for the noiseless factor model (zero stock-specific variance – all but the first few eigenvalues are zero) or the scalar factor model (all the stocks have the same specific variance – all but the first few eigenvalues are equal).

For a strict factor model, $V = EE' + \Delta$, just consider $\Delta^{-1/2}V\Delta^{-1/2} = \Delta^{-1/2}EE'\Delta^{-1/2} + I$, which is a scalar model. Since you do not know Δ , start with an initial estimation of E (noiseless model), estimate Δ , then E , then Δ , then E , etc. – this is the *Joreskog algorithm*.

You can test the fit of the model with Likelihood ratio tests or with R^2 .

(4d) Large- n methods (many stocks, approximate factor model)

Asymptotic Principal Components (APC) (?), i.e., eigenvectors of $\frac{1}{n}R'R$ (we were previously considering $\frac{1}{n}RR'$), directly provide the factor returns.

As before, the EM-algorithm can be used to fill in the missing values.

Estimating the number of factors to retain by looking for a sharp drop in the eigenvalues is not reliable. You may have more success with the variance ratios or penalized likelihood (AIC, BIC).

(4e) Hybrid factor models

In a hybrid factor model, one first uses interpretable factors and then refines the residual variance matrix using statistical factors.

The discussion by Tim Wilding (EMA) mentioned the following points:

- The importance of Maximum Likelihood (ML) estimators
- *Independent Component Analysis* (ICA)
- The distinction between large- n and small- n methods is historical and irrelevant
- Even though G. Connor does not like statistical models, some factors are not knowable (Tim mentioned *behavioral factors*, Ruppert mentioned restructuring in Japan)

Jason MacQueen recalled that there is no “right” answer – only more or less useful ones.

Though the words *Random Matrix Theory* (RMT) were never uttered during the lectures, the “Asymptotic Principal Components” (APC) are extremely similar: RMT studies the distribution of all the eigen values of a random matrix while APC studies the distribution of the largest eigenvalue of a random matrix – since the idea is to discard the smallest eigenvalues, it is equivalent.

(5) The Macroeconomy and Security Market Returns

Macro-economic risk models are risk models whose factors are macro-economic time series, such as oil price, interest rate, unemployment, GDP, etc.)

Macro-economic factors need to be “detrended” before use. You can use *AR models*, Hansen-Rodrick models (?) or a *Kalman filter* to remove the *predictability bias* from the time series and get the innovations time series. For historical studies, you can also use an “AR” model that also includes the forward values of the time series – this introduces a *look-ahead bias*, but allows you to remove the predictability bias.

The sensitivity to those macroeconomic variables is very different in a bull or bear market: you can compute two sensitivities, a bull one and a bear one.

You can build mimicking portfolios, whose returns replicate those of a macro-economic factor – but they are often illiquid and have a high turnover.

Discussion (Ed Fishwick, Merrill Lynch):

- Macroeconomic factors are important (we speak of

them all the time), but they are not reliably used in quantitative risk models – they contain information, but it is hard to extract.

- Macroeconomic factors yield time-varying betas: jumps in prices (e.g., after earnings announcements) can lead to jumps in exposures.
- If you check the proportion of variance explained by macro-economic factors or by other risk model factors, you realize that they explain very little.
- Conclusion: macroeconomic factors contain relevant information, that cannot easily (linearly) be extracted.

Q&A: The useful variables depend on the investment horizon (in the short term, you have all the variables you are used to, in the long term, mainly the yield remains). For macro-economic factors, that horizon would be three months rather than one.

(6) Corporate Characteristics and Security Market Returns

In a statistical risk model, you have to estimate both the factor returns and the stock exposures to those factors. In a macro-economic (or cross-sectional) risk model, you know the factor returns and you compute the stock exposures (using cross-sectional regressions). In a *characteristic (or time-series) risk model*, you know the stock exposures and you compute the factor returns (using *Fama-MacBeth regression*).

Here are a few factors for equities: industry, country, size, value, momentum, volatility, liquidity, yield, index membership, ROE or ROE, leverage, currency sensitivity.

Here are a few factors for fixed income: ... (I might have missed a few ones), McCauley duration (?), twist factor (?), butterfly factor (?), convexity, options.

The factor returns can be computed by a regression or by *portfolio sorting* (or *quintile spreads*): the returns of a portfolio long the top quintile and short the bottom. Contrary to the mimicking portfolios of macro-economic factors, those portfolios are actually investible.

One can lower the number of parameters to be estimated in a risk model by requiring that the specific risk be a linear combination of the factors – you just have to estimate the coefficients of this linear combination, instead of each individual specific risk.

Discussion (Ian Paczek):

- The way you choose to tackle outliers (e.g., *wind-sorization*) has an effect on the estimation – that will end up biased or wrong.
- Question: can we get a daily risk model by tweaking a monthly one with an estimate of the daily volatility? (see chapter 13)
- When a physicist wants to use a signal at some frequency, it samples it at a higher frequency (the *Nyquist frequency*, explained somewhere in most computer music books, for instance <http://www-crcs.ucsd.edu/~msp/techniques/latest/>

book.pdf). Why don't we do the same thing in finance?

- Dummy (boolean) variables may not be a good idea: some companies work accross several industries.

Q&A:

- In a time-series model, the estimation errors in the exposures should diversify away when the number of stocks grows; in a cross-sectional model, they will stay.
- Momentum, as a risk factor, can be problematic, because of its time series properties (its computation involves a moving average) and it is only relevant for short-term forecasts.
- Risk model factors do have a predictive power in the long term, but it gets eaten by the increased kurtosis.

(7) Measuring and hedging foreign exchange risk

(7a) Foreign exchange risk

Currencies are very different from other classes of assets: they are symmetric (e.g., the returns of USD/EUR are the opposite of those of EUR/USD – this does not sound like a compelling argument: you can be long or short a stock), they tend to have fatter tails, and they are more volatile.

The speaker stresses the drawbacks of ratio returns versus *log-returns* – but since we eventually want portfolio returns, he decides to stick to ratio returns.

If you like formulas, here are a few (with log-returns, they are exact, with ratio-returns, they are approximations, valid as long as the returns remain small – this is called the approximate linear model):

$X^{\text{EUR/USD}}$: exchange rate

$F^{\text{EUR/USD}}$: forward exchange rate

r^{EUR} : returns in EUR of an investment in EUR

r^{USD} : corresponding return in USD

$r_{\text{Hedged}}^{\text{USD}}$: returns of the corresponding hedged investment

$r^{\text{EUR/USD}}$: currency returns

r_f : risk-free return

$$(1) r^{\text{USD}} = r^{\text{EUR}} + r^{\text{EUR/USD}}$$

$$(2) X/F = -r^{\text{EUR/USD}} + (r_f^{\text{USD}} - r_f^{\text{EUR}})$$

$$(3) r_{\text{Hedged}}^{\text{USD}} = r^{\text{EUR}} + (r_f^{\text{USD}} - r_f^{\text{EUR}})$$

$$(3') r_{\text{Hedged}}^{\text{USD}} - r_f^{\text{USD}} = r^{\text{EUR}} - r_f^{\text{EUR}}$$

$$(4) r^{\text{USD}} = (r^{\text{EUR}} + (r_f^{\text{USD}} - r_f^{\text{EUR}})) + (r^{\text{USD/EUR}} - (r_f^{\text{USD}} - r_f^{\text{EUR}}))$$

(The second term in the second equation is called the *carry*.) The third equation can be read as: you can eliminate currency risk, but you have to pay the *interest cost of hedging*; the fourth equation says that the excess returns are the same.

(7b) Currency hedging

To estimate the risk of a (non-hedged, international) portfolio, one can decompose it into hedged equities and currencies and compute the corresponding variance matrix: the diagonal blocks are the equity variance and the currency variance matrices, and the off-diagonal block is the covariance between those two asset classes.

The simplest currency hedging strategy consists in buying exactly the amount of currency forwards to balance the value of your equities: this is the *unit hedge*.

If the covariance matrix between equities and currencies is non-zero, the unit hedge is not the minimum variance hedging strategy – the problem is that this matrix is difficult to estimate, especially if the returns distributions have fat tails.

The use of ratio-returns instead of log-returns leads to an under-hedging bias, that can easily be corrected.

Those hedges are valid for a 1-year horizon, but can be divided by 10 on a longer (8-year) horizon.

(7c) Macroeconomic influences on currency returns

In the short term (up to 1 year), macro-economic variables cannot predict exchange rates, even if you cheat and use the future values of those variables – but in the longer horizon (4 years), it works better.

Exchange rates have some undesirable properties, such as the consequences of central banks interventions and currency crises (including *endogenous crises*, triggered by *herding behaviours* and leading to *contagion*).

Discussion (David Buckle, Merrill Lynch):

- He recalls a few formulas, and adds formula (4) to the list
- Benchmark providers do not hedge the currency returns but a forecast of it – but they fail to disclose how they compute this forecast.
- The minimum variance hedge is $h^* = -\beta$
- The mean-variance hedge is

$$\lambda^{-1} \frac{E[\text{currency}]}{\text{Var}[\text{currency}]} - \beta.$$

This is *very* sensitive to currency expectation: a variance of 0.2 standard deviations yields a 100% change in the hedge factor – what was believed to be hedged is not.

- The “compounding effect”, *i.e.*, the consequence of the choice of ratio-returns instead of log-returns, can be written as

$$E[\text{currency log-returns}] = 0$$

$$E[\text{currency returns}] = 12 \cdot \text{Var}[\text{currency returns}]$$

- (There was also a remark about *change of numeraire*, with a couple of formulas, but it was not very clear.)
- *Currency overlay* is a good idea
- Some people advocate *latent hedge*: the correlation of the returns of european stocks with the USD/EUR exchange rate should be -1 : if this is the case, you do not have to hedge international portfolios –

but, surprisingly, you should hedge domestic portfolios... If you believe that there is no correlation, you should hedge international portfolios, but not domestic ones. The truth is somewhere in between.

(8) Integrated risk models (“drill-down risk models”)

There might be some integration (*i.e.*, the distinctions between countries might be disappearing) for valuation models, but not for risk models, even in Europe. Some people saw an integration trend until 2000, but it was mainly due to the bubble. Here are several ways to build a world model, accounting for this segmentation.

(8a) Build local models and assume they are independent, *i.e.*, the global covariance matrix is block diagonal – this assumption is unrealistic.

(8b) Build local models and also build a global model – both models may be fine, but they fail to match...

(8c) To ensure that *drill-down consistency*, build a *second order factor model* with:

- a world market factor
- country factors
- global industry factors
- local industry factors, asked to sum up to zero
- global style factors
- local style factors, asked to sum up to zero

(8d) An *orthogonal double Procrustes* model is build as follows:

- compute the local models
- consider the space of global (non-parsimonious) models that specialize to the local model
- project the data onto that space to get the global model

Remark: I would personally add in some penalty to have a more parsimonious global model.

Discussion (Ely Klepfish, UBS):

- Are there links between the orthogonal double Procrustes problem and group representations of $SO(n)$?
- Do these models significantly differ from segmented model? (This question is worth asking: there are only theoretical results about this...)

Questions from the audience:

1. Can we do that with statistical models?
2. How does this compare with the Barra approach?
3. Even though there is a lot of segmentation, it is not enough to stick to country models.

(9) Dynamic volatilities and correlations

Traditional risk models try to estimate the variance matrix of the past returns, naively assuming that it will remain valid in the near future. Instead, one can model the dynamics of this variance matrix and forecast its next value.

For a single asset, one can use a *GARCH model* (the *news impact curve*, *i.e.*, the plot of the change in standard deviation versus the previous returns can help vi-

sualize the amount of information it brings), or its variants (but they assume that the frequency is fixed) or a *stochastic volatility* model (that does not make that assumption but whose estimation is only amenable to simulations).

The *realized variance*, *i.e.*, the integrated volatility on a time interval, can be seen as a model-free filter and could prove more useful than GARCH or SV models; even without intra-day data, the (under-used) *high-low range* is a good realized variance estimator.

The presentation of multivariate volatility models was confusing: in a nutshell, you start with a *VAR model* for the variance matrices (for n assets, there are n^4 parameters to estimate) and you try to reduce the number of parameters.

Examples of such models:

- Bollerslev’s *Constant Correlation* (CCor) model;
- Engle’s *Dynamic Conditional Correlation* (DDC) model;
- *Dynamic factor volatility models* (a factor risk model, with GARCH factors).

Downside correlation, *i.e.*, the increase in correlation when the market drops or simply becomes more volatile, is a problem.

The *dispersion* (*i.e.*, the cross-sectional standard deviation of the returns) changes with time.

Questions from the audience:

- High frequency data introduce fat tails, autocorrelation, covariances, etc.: is it really worth using them?
- Daily data (especially index data) are mainly used to *rescale* the variance matrix produced by risk models.
- Realized variance depends on the time interval – it should be proportional to it, but it is not.

Discussion (Dan diBartolomeo, Northfield):

- There are two kinds of innovations in the time series modeled by GARCH or SV models: *announcements* (we know the date beforehand but not the contents) and *shocks* (actual surprises). GARCH models cannot model announcements: they assume that the volatility has a trend, while the volatility will decrease before an announcement and increase after.
- Daily high-low ranges can be used to adjust variance matrices
- Beware when using dynamic factor models: the full variance matrix may be “strange” – you might need to add some constraints to get a sensible result.
- There are also non-parametric measures of correlation, such as *Kendall’s tau*.
- For more on dispersion, see the Northfield seminar, last month.

(10) Return Densities

(11) Liquidity and Credit Risk For credit risk, check *Credit risk: pricing, measurement, and management*, D. Duffie and K.J. Singleton, 2003.

(12) Long-short portfolios

(13) Long-horizon risk forecasting (five years and beyond)

The risk is supposed to be proportional to the square root of the time interval. The *variance ratio* statistic,

$$\frac{\text{Variance on } T \text{ periods}}{T \cdot \text{Variance on 1 period}}$$

measures the deviance from this rule (it is negative in the short term and the long term, positive in-between).

Returns are more volatile than company fundamentals: this *excess volatility* leads to *mean reversion*.

In the long term, variance is not really dynamic: we can forget chapter 9 (but see the *multiple component Engle-Ng model* (?)).

In the long term, we can no longer use ratio-returns: but luckily *log-returns* have almost the portfolio property.

Systems-based risk forecasting suggests to predict, not only the returns, but also the fundamental values (earnings, sales, GDP, etc.) that drive them, for instance with a VAR model – see *Strategic Asset Allocation*, Campbell and Viceira.

In the long term, *macro-economic factors* become important, differing *currencies* are no longer a source of risk but a hedge, and *active returns* disappears.

Risk forecasting cannot be separated from portfolio planning: rebalancing makes the portfolio risk non-linear and path-dependant.

Asset-liability management (?) is problematic, but beyond the book.

Discussion (David Miles, Morgan Stanley):

- Bonds are a good example of mean reversion: in the UK, they have been issued since the 17th century.
- Shouldn't we take care of rare events (world wars, 1929, 9/11, etc.)? See *Rare Events and the Equity Premium*, R.J. Barro, 2005. From a practical point of view, modeling rare events would be counterproductive.

(14) Portfolio risk forecast evaluation

This is important: you should assess your risk model before actually using it.

Fuzzy logic toolbox handbook Matlab

The idea of *Fuzzy Inference Systems* (FIS) is to replace boolean values by continuously varying values – think “probabilities”.

This can be generalized to boolean operators (**and** becomes **min**, **or** becomes **max**, **not(x)** becomes **1-x**) and *deduction rules* (**then** becomes **min**). Note that there might be incoherences in the rules – it is not a problem.

You can tune the fuzzy inference system by changing

the membership functions (or even the boolean operators).

As with bayesian methods, the result is a probability distribution, not a single number.

So far, it looks like bayesian networks, with a very simple, fixed network structure, and no learning capabilities.

Actually, you do not have to provide the set of rules: you can simply take your data, cluster it, and ask the computer to write a rule for each cluster. This is called *Adaptive Neuro-Fuzzy Inference Systems* (ANFIS)

This looks very similar to nearest-neighbour methods – and, if you impose some parsimony, it can be seen as a machine-learning analogue of Generalized Additive Models (GAM, **mgcv** package in R).

Fuzzy C-means clustering is a generalization of the *k*-means clustering algorithm where cluster membership is fuzzy – i.e., is a probability. (In R, it is implemented in the **fanny** or **cmeans** functions.)

For a different application of FIS, to control the level of detail in video games, as the number of objects in a scene increases, check *A fuzzy-control approach to managing scene complexity*, in *Game programming gems 6* (2006).

Maximum drawdowns of hedge funds with serial correlation B.T. Hayes (Journal of alternative investments, 2006)

Value at Risk (VaR) understates potential losses for less liquid and autocorrelated assets (e.g., hedge funds): instead, replace the returns by the *maximum drawdown at risk* (MDaR).

Its estimation is hampered by the short history of hedge funds, thereby calling for an *extreme value theory of drawdowns*.

This article suggests a (Markov chain, discrete) model (options people would call that a “tree” model) that accounts for autocorrelation but not for skewness and fat tails: the probability of an up or down movement depends on the direction of the previous movement.

This leads to explicit formulas – auto-regressive models only seem amenable to simulations.

The importance of being value F. Bourguignon and M. de Jong (Journal of portfolio management, 2005) J. Karvanen (2005)

Value (here, the price-to-book-value ratio (P/B)) can be decomposed into long-term P/B and current deviation from this long-term P/B; only the deviation leads to outperformance.

Price momentum and investor sentiment by sector

Y. Ishikawa (Nomura, 2006)

Stock-wise momentum does not work in Japan, but sector-wise momentum does.

Order imbalance and stock returns
H. Tamura and Y. Shimizu (Nomura, 2006)

The predictive power of the Order Flow Imbalance (OFI) is enhanced if you restrict yourself to the stocks with an auto-correlated OFI.

Estimation of quantile mixtures via L-moments and trimmed L-moments
J. Karvanen (2005)

The method of moments (equating sample moments to theoretical moments to estimate the parameters of your model) may look appealing (for instance, it allows you to dispense with gaussianity assumptions), but moments have a high variance (especially with small samples), are very sensitive to outliers – and need not even be defined for fat-tailed distributions. *L-moments* are defined using the *order statistics*: $X_{k:n}$ is the k th element of a sample of n observations from your distribution and

$$\begin{aligned}L_1 &= E[X_{1:1}] \\L_2 &= \frac{1}{2}E[X_{2:2} - X_{1:2}] \\L_3 &= \frac{1}{3}E[X_{3:3} - 2X_{2:3} + X_{1:3}] \\L_4 &= \frac{1}{4}E[X_{4:4} - 3X_{3:4} + 3X_{2:4} - X_{1:4}].\end{aligned}$$

Similarly, one can define *trimmed L-moments* (or *TL-moments*) by replacing $X_{k:n}$ by $X_{k:n+2t}$ for some value of t : they can be defined even for fat-tailed distributions with no mean. L-moments and LT-moments can be computed from the quantile function of the distribution.

The article advocates the use of *gaussian-polynomial* or *Cauchy-polynomial quantile mixture* distributions, *i.e.*, distributions whose quantile function is a sum of a gaussian or Cauchy quantile function and a polynomial: their parameters can easily be computed from the L- or LT-moments.

The article ends with a case study: skew Student, gaussian-polynomial and Cauchy polynomial quantile mixture distributions fit financial data (stock returns) equally well.

Biologically inspired algorithms for financial modelling
A. Brabazon and M. O’Neil (2005)

Multi-layer perceptrons (MLP) can be seen as parametric non-linear regressions, the number of layers indicating how deep the function calls can be nested. The functions you are combining can be linear (this is just linear regression), sigmoidal (S-shaped) or radial (bell-shaped).

Self-Organizing Maps (SOM, aka Kohonen maps) are a completely unrelated algorithm, sharing the same biological analogy (hence it is a *Neural Network* (NN)),

that can be used to find clusters in a data set – intuitively, it tries to cluster data while retaining information about the closeness of the observations by throwing a 2-dimensional net on the cloud of points.

Evolutionary algorithms (EA) take a population of potential solutions and mutate and merge them. *Genetic Algorithms* (GA) encode those potential solutions as binary strings; *Genetic Programming* (GP) encodes them as trees (a mathematical formula, a computer program, can be represented as a tree); *Grammatical Evolution* (GE) is a way of implementing a GP by encoding the tree as a binary string (the grammar is fixed and can include domain knowledge, but you can also evolve it: these are “GE by GE” or GE²). (If you are not familiar with BNF grammars, you can have a look at the Parse::RecDescent Perl module – there are similar modules for Python.)

One can combine Evolutionary Algorithms and Neural Nets, *e.g.*, to find which weights of the neural net are non-zero (MLP-GA) – this yields a more parsimonious model, less likely to overfit the data.

Differential Evolution (DE) is an evolutionary algorithm that explores the values of continuous parameters, where a new candidate x_{new} is obtained from three individuals x_i, x_j, x_k , as

$$x_{\text{new}} = x_i + \lambda(x_k - x_j).$$

Particle Swarm Optimization (PSO) is similar to DE and maintains a population of potential solutions, each being subject to three influences: inertia, attraction to the best solution found so far by the particle, attraction to the best solution found so far by the swarm.

Ant Colony Optimization (ACO) is a path-finding algorithm (but many combinatorial problems can be expressed in terms of the Traveling Salesman Problem (TSP), which is a path finding problem, so the algorithm is more general than it seems) that lets ants explore the various paths and mark the most promising path fragments by pheromones.

Ants can also be used as a classification tool (*Ant-Inspired Classification Algorithms*): put the objects to classify in 2-dimensional grid and have the ants move around and pick an object if there is no “similar” (for some distance) object nearby (say, in the last N cells visited) and drop it if there is (with some probability). This is very similar to SOM. Sadly, they conclude that ant classification does not outperform Linear Discriminant Analysis (LDA).

An *Artificial Immune System* (AIS) takes a model at random and rejects it if it does not work sufficiently well, until it reaches the desired number of models. This can be seen as a “Monte Carlo model selection” or as an EA with neither mutations nor mating, *i.e.*, with no evolution (some variants, such as the “clonal expansion and selection algorithms” do allow for mutations, though), followed by crude model averaging. AIS are often used in asymmetric situations, *e.g.*, to detect bad companies: healthy companies are homogeneous, but

companies can be sick in many ways – they are sometimes called *Negative Selection Algorithms* (NSA).

To cluster a large number of observations (think: points in a 2-dimensional space) you could divide the space into a grid and cluster the non-empty cells (in high dimensions, the grid would be sparse); *Artificial Immune Networks* (AiNet) proceed along a similar idea: take each observation as a center of a cluster, discard similar observations, link each remaining observation to its closest neighbours.

The second part of the book details ten case studies (equities, currencies, intraday trading, corporate failure prediction, bond classification) and gives potential inputs, fitness functions and post-processing ideas.

Here are a few performance measures, to be used as fitness functions:

- Mean Square Error (MSE, aka RMS or Root Mean Square);
- R^2 , AIC, BIC;
- Information Ratio (IR) or Sharpe ratio: returns / risk;
- Rank correlation (aka Information Coefficient or IC);
- Stirling ratio and its variants
return / drawdown
return – drawdown
return / drawdown \times win ratio
return / (1 + max(2%, drawdown)).

To examine a strategy, you can have a look at:

- the number of trades;
- the proportion of profitable trades;
- the average profit per trade;
- the average profit per profitable trade;
- the average loss per losing trade;
- the profit factor (ratio of the previous two averages);
- the p -value of a test for the positivity of the profits;
- descriptive statistics of the returns per trade;
- Sharpe ratio, Stirling ratio;
- maximum drawdown.

The model found by the algorithm should pass the *intuition test*: it should be understandable and meaningful. For neural networks, this might be difficult – but you can compute the *contribution* of an input variable (the sum of the absolute values of the weights between that input and the hidden layer, divided by the sum of the absolute values of all the weights to the hidden layer). Neural network with only a handful of non-zero weights (e.g., MLP-GA) are easier to interpret.

The book does not mention *bayesian networks*, that are very similar to neural nets, but much easier to interpret.

The *post-processing* of the models can include:

- *gating*, *i.e.*, inferring the “market regime” and using one of several models accordingly;
- *soft gating*, a market-regime-dependant mixture of models;
- stacking (averaging) of several models.

Here are some of the technical variables one may want to include:

- Moving Averages (MA);
- MACD (MA Convergence Divergence) oscillators (an oscillator is a mean-reverting signal, that suggests an action should be taken when it crosses its mean – here, when it crosses zero), *i.e.*, differences of MA with different window sizes;
- Momentum;
- *Trading range breakout*: take an action if the price move beyond its n -day maximum or minimum; *Bollinger bands* are a variant of this idea, with standard deviations instead of extrema;
- $\%K = (\text{close} - \text{low}) / (\text{high} - \text{low})$, where high and low are taken on an n -day window;
- $\%D$ is a moving average of $\%K$;
- *Relative Strength Indicator* (RSI): $R / (R + S)$ where R is the average of the positive returns and S the average of the losses (people usually write it as $100 - 100 / (1 + R/S)$);
- Volume (which is a measure of volatility and can be used as a volatility parameter in GARCH-like models);
- Ease of Movement (OEM) – their definition has a unit problem.

You can also add in market sentiment indicators:

- indices;
- number of advancing/declining securities;
- number of stocks reaching a new high/low;
- short-interest ratio (?);
- volume of options traded;
- put options/call options;
- VIX (a volatility index).

Clusterv tutorial **G. Valentini (2005)**

To assess the reliability of a clustering, this R package perturbs the initial data set by projecting it onto a smaller-dimensional subspace, while trying to preserve the distances – this is designed to work in very high dimension, typically a few thousands.

Efficient computation of the skyline cube **Y. Yuan (VLDB 2005)**

The *skyline cube* is the set of skylines for all the possible set of dimensions – since the number of subspaces for which we want the skyline is huge, this calls for algorithms that can iteratively build the skylines.

Sometimes, you are not interested in the whole cube, but only in the cells above a certain threshold: the corresponding sparse cube is called an *iceberg*.

Catching the best views of skyline: a semantic approach based on decisive subspaces **J. Pei et al. (VLDB 2005)**

Databases contain more and more complex data (typically, graphs) and one may want algorithms tailored to one's specific needs (hence the need to be able to program close to the data, in the DBMS).

This article focuses on the *skyline problem*, i.e., the query of objects that minimize two (or more) attributes (say, distance from the beach and price, if the database contains information about hotels) – this can be seen as a combinatorial *efficient frontier* problem, the problem of finding the set of *Pareto-optimal* objects, the set of *maximal objects* (this is a partial order relation).

The articles finds all the subspaces (sets of dimensions) for which a given object is on the skyline.

***Bridging the gap between OLAP and SQL* J.-P. Dittrich et al. (VLDB 2005)**

An OLAP system is an interface to a database that performs aggregation in as many dimensions as desired (in R, it would simply mean writing things like `tapply(x, list(a,b), sum)`): if the data is represented as a hypercube, the OLAP layer computes and displays all its margins. Things can get more complicated by the fact that the factors used to aggregate can be nested (e.g., sector, industry group, industry, subindustry; year, month, day) or may overlap (e.g., year, month, week, day; or, for each year, “compute the moving average over the past three years”) – some of this is in the SQL-99 standard, but they awkwardly try to force the cube margins into a 2-dimensional table and end up using NULLs with two different semantics.

Furthermore, the OLAP engine should represent extracts of the cube margins in a 2-dimensional format (a *pivot table* in Excel-speak) and the user should be able to interactively select dimensions to add (*drill down*) or remove (*roll up*) – ideally without having to ask the DBMS to recompute everything.

In spite of this rather clear presentation, the authors do not seem to understand what a cube is, they seem to be unable to think in more than two dimensions – a syndrome of excessive spreadsheet usage. As many, they do not seem to know that the relational model does provide user-defined types (called “relational domains”) and can thus accomodate “cubic” data – current SQL RDBMS do need to be reworked, though.

***Heuristique pour l'optimisation difficile, les algorithmes de colonies de fourmis* J. Dréo et al. (2003, Eyrolles)**

Ant colony algorithms are used to solve combinatorial problems that can be expressed as a path-finding problem in a graph – this is more general than it seems: many problems can be reformulated as a Traveling Salesman Problem (TSP). The idea is to ask the ants to find a path and to “reinforce” the components of the best paths found so far, by leaving *pheromones* on them. New ants will choose their path depending on those pheromones. The algorithm can be refined by taking into account the attractivity of the path com-

ponents, pheromone evaporation, by allowing the ants to disregard pheromones to increase diversification.

***An introduction to econophysics, Correlations and complexity in finance* R.N. Mantegna and H.E. Stanley (2000)**

From the central limit theorem, the Gaussian distribution can be seen as an “attractor” in the space of probability distribution functions; but its basin of attraction does not cover the whole space and it is not the only attractor: the other attractors are called *stable distributions* – this is the *generalized central limit theorem*.

Such stable distributions, e.g., the Cauchy distribution, often have no *characteristic scale*: the basin of attraction of the stable distributions contain the distributions with *power-law* tails.

You can refine the cartography of the space of probability distributions by considering the *infinitely divisible random processes*, i.e., distributions of random variables that can be written as sums of n iid random variables, for all n : Poisson, Gamma or stable distributions are infinitely divisible, while uniform distributions are not.

All those properties can be investigated through the Fourier transform.

The authors present and compare several definitions of returns and suggest to stick to *log-returns*.

You may want to study your data with respect to different *time scales*: physical time; physical time minus nights, week-ends and holidays; number of transactions; volume.

The autocorrelation function R (physicists would call that a *two-point function*, as opposed to *higher order statistics* or *n-point functions*) and the *power spectrum* S contain the same information and can be used to measure the memory of a time series. The process has *short memory* if $\int_0^\infty R$ is finite, e.g., if $S(f) \sim 1/f^2$ – one can then define an (ad hoc) *characteristic time scale*. It has *long memory* if that integral is infinite, e.g., if $S(f) \sim 1/f$ – this can be approximated by a process with many time scales. Note that this integral can be indefinite.

To that regard, financial time series exhibit an unusual behaviour: though the returns have a short memory, the volatility (roughly speaking, the squared returns) have a long memory – higher-order statistics are relevant.

One can try to account for the fat tails of returns by modeling them as stable distributions, T distributions, mixtures of gaussians, truncated stable distributions.

For small values, stock returns are well modeled by a stable (non-gaussian) distribution; for larger values, the tails are too thin for the stable distribution but too fat for a gaussian one.

GARCH processes (with gaussian innovations) are fat-tailed (you can even compute the kurtosis, if you want), they fit stock returns much better than gaussian or stable distributions and they have non-trivial higher order statistics.

The book devotes a chapter to the similarities between stock prices and turbulence phenomena in fluid mechanics – only to conclude there are none.

The distribution of the correlation of stock returns changes over time and gets closer to zero. They mention *random matrix theory*, with neither details nor results.

You may want to check the cross-correlations (after a lag): there is some information, larger capitalizations tend to move ahead of smaller ones.

A correlation matrix can be interpreted in terms of distances which, in turn, can be represented as a Minimum Spanning Tree (MST – if you want to look cultivated, you can speak of *ultrametric distance*) or a dendrogram; you can do this on your whole universe or on the stocks in your portfolio. They fail to see that dendrograms are badly affected by fat tails and are far from stable.

The book ends with an introduction to options: first on an idealized market, then on a real one, that complicates the picture (discontinuous stock returns, unknown and changing volatility, discrete time, transaction costs, round lots, non-gaussian distributions): replicating portfolio and perfect hedging strategy do not exist.

Among the interesting plots:

- Probability distribution function with a vertical log-scale, to assess the fatness of the tails;
- Autocorrelation function with a log-scale on both axes;
- Spectral density with a log-scale on both axes;
- Probability distribution function of the stock returns over time (3-dimensional graph);
- Probability of returning to the origin after n steps, with a log-scale on both axes;
- Histogram of the correlation matrix of the stock returns, over time.

Quantitative stock selection in Japan and the United States: some past and current issues **J.B. Guerard (2006)**

The author computes Information Coefficients (ICs) for a dozen yearly, quarterly, monthly factors.

They perform a robust (biweight) “latent root regression”: robust to account for the outliers, “latent root” to account for multicollinearity (“latent root” seems to be a weird synonym of “eigenvalue” – I do not know how “latent root regression” relates to PCR (Principal Component Regression), PLS (Partial Least Squares) or ridge regression).

Bayesian clustering of many ARCH models **L. Bauwens and J.V.K. Rombouts**

Instead of fitting a GARCH model to each time series in you sample, you can try to fit your data as a mixture of GARCH models. As usual with mixtures, you can fit them with bayesian methods (MCMC: Monte Carlo Markov Chains).

This can be seen as a clustering method or as a poor man’s mixed GARCH model.

Multiple alpha sources and active management **E.H. Sorensen et al. (2004)**

This article builds on very unpedagogical foundations: Grinold and Kahn’s book.

They try to devise “optimal” (in the sense that they maximize the rank correlation with the forward returns – this is a form of robust regression, albeit not a very academic one) weights to combine two factors using their ICs – forgetting that the ICs are relevant for non-gaussian data while they assume theirs are gaussian.

In a later article, the same authors claim that this article claims (or even “proves”) that the optimal weights are

$$\mathbf{w} = (\text{Var IC})^{-1} \cdot \text{IC}.$$

Temporal data and the relational model **C.J. Date et al. (2003)**

The relational model can handle temporal data: just define an “interval” type and a few operators to handle them – optimizing the queries is a non-trivial and non-tackled *implementation* problem.

“Time point” types are granular: they come with “next” and “previous” operators, e.g., “date with daily granularity”, “date with monthly granularity”, “date with business day granularity”, etc.

PACK and UNPACK operators, that merge overlapping/abutting intervals and that split intervals into unions of 1-point intervals, are handy to write queries or constraints – e.g., primary key constraints.

Other operators can be readily generalized: unpack everything, apply the operator, pack the results. A few intricacies arise, because in higher dimensions, *i.e.*, if

you have several interval columns, the packed form is not unique.

A semi-temporal (or *current*) table is a table with a SINCE column.

A *historical* table is a table with a DURING column.

The book suggests to avoid a NOW special value (its semantic would be changing...) and to avoid using the end-of-time timestamp for open-ended intervals (indeed, that would mean putting incorrect values in the database): instead, use two sets of tables, one for historical data (with a DURING column) another for current data (with a SINCE column) – but updating the tables (since it may involve moving data from one set of table to another) or writing the constraints becomes inordinately complex.

Bitemporality is briefly mentioned: “The database is not the database. The log is the database. The database is merely an optimized access path to the most recent version of the log.”

The book uses the vocabulary of the relational model (“relation” instead of “contents of a table”, “relvar” instead of “table”, “attribute” instead of “column”, “tuple” instead of “row”) and the examples use the *Tutorial D* language (recalled in the introduction).

There is an *annotated* bibliography.

Needles, Haystacks and hidden factors **G. Miller (2006)**

In a risk model, statistical factors can be used to complement fundamental factors and help mitigate portfolio risk under-estimation.

(The article distinguishes between three kinds of factors: *fundamental factors*, whose exposures are estimated by hand and whose returns are computed from the exposures; *macroeconomic factors*, whose returns are known and whose exposures are computed from the returns; and *statistical factors*.)

Independant variable selection: application of independant component analysis to forecasting a stock index **A. Cichocki et al. (2005)**

The article generalizes PCR (Principal Component Regression) by replacing PCA (Principal Component Analysis) by ICA (Independant Component Analysis) – ICA is used for source separation in acoustics and to build some statistical risk models (perhaps APT).

The authors also add a bit of neural networks, because it is trendy – but they apparently fail to understand what ICA is...

Introduction to modern portfolio optimization **B. Scherer and D. Martin (2005)**

Chapter 1 introduces linear and quadratic optimization – but assumes you already know about scenario optimization or the Black–Litterman model.

Quadratic optimization, aka *mean-variance optimization* or *Markowitz optimization* or *modern portfolio theory* goes as follows: you have n (jointly) gaussian random variables $X = (X_1, \dots, X_n)$, you know their mean $\alpha = E[X]$, their variance matrix $V = \text{Var } X$ (that matrix is also called a *risk model*) and you want to find a linear combination $w_1X_1 + \dots + w_nX_n = \mathbf{w}'X$ (*i.e.*, a *portfolio*) with $w_1 + \dots + w_n = \mathbf{w}'\mathbf{1} = 1$ under the condition that $\text{Var } \mathbf{w}'X$ be below some threshold (the risk constraint the client asks you not to breach), *i.e.*,

$$\begin{aligned} &\text{Maximize } \mathbf{w}'\alpha \\ &\text{such that } \mathbf{w}'\mathbf{1} = 1 \\ &\quad \mathbf{w}'V\mathbf{w} \leq \text{threshold} \end{aligned}$$

There are variants where the risk constraint is turned into a *soft constraint*, depending on the *risk aversion* parameter λ .

$$\begin{aligned} &\text{Maximize } \mathbf{w}'\alpha - \frac{1}{2}\lambda\mathbf{w}'V\mathbf{w} \\ &\text{such that } \mathbf{w}'\mathbf{1} = 1 \end{aligned}$$

Caveats:

- If two assets are correlated, the optimizer will not manage to distinguish them and the weights will vary a lot (but the sum of their weights will be better defined): this is the same problem as multicollinearity in regression.
- The estimation of α and V can have an impact on the optimal portfolio (nowhere in the book do they use a risk model: always the sample variance matrix, or a “robust variance matrix”).

If you have enough data, you can dispense with the gaussian assumption and use a *scenario-based optimization*. For instance, let S be a matrix whose rows are realization of the random variable X ; to test for *arbitrage* situations, one could solve

$$\begin{aligned} &\text{Minimize } \mathbf{w}'\mathbf{1} \\ &\text{such that } S\mathbf{w} \geq 0 \end{aligned}$$

The first line is the money you invest (ideally, none) and the second is the requirement that the payoff be positive in *all* the realizations.

This first chapter also presents (or, rather, assumes that you already know) the Black–Litterman model and remarks that adding constraints to a quadratic optimization problem so that the solution looks better is equivalent to imposing a *view* – but a very strict one.

Chapter 2 presents the syntax of SIMPLE, the “language” used to describe the optimization problems (actually, it is plain S+, with a lot of placeholders, as in template-intensive numerical C++). It is a general optimizer: linear, quadratic, MIP (Mixed Integer Programming), convex, non-convex; the examples given range from Maximum Likelihood Estimators (MLE) to multistage stochastic programming to problems with CDS. The chapter also presents semi-quadratic, CRRA and other utility functions – but without a proper background in utility theory, this is not readily understandable.

Chapter 3 enumerates the extensions one can make to mean-variance optimization: constraints on the MCTR (Marginal Contribution to Risk), tracking a benchmark, tracking several benchmarks, using several risk models, using several risk measures, imposing lower bounds on weights, imposing bounds on the number of assets, including transaction costs, etc.

The more constraints you add, the weirder the efficient frontier and the more irregular the portfolio composition: a slight change in the acceptable risk threshold can yield drastic changes in the optimal portfolio composition – constraints actually chisel more edges on the simplex on the boundary of which the optimal portfolios lie...

Chapter 4 focuses on *resampled portfolios*, *i.e.*, portfolios optimal for resampled values of $\hat{\alpha}$ and \hat{V} ; similarly, a *resampled Sharpe portfolio* is the Sharpe portfolio for resampled values of $\hat{\alpha}$ and \hat{V} .

That notion provides a good argument against the long-only constraint: if you take many resampled Sharpe portfolios and average them, you get the true Sharpe portfolio; but with a long-only constraint, you do not – constrained optimal portfolios are biased...

Not bad enough? If one of your assets has zero expected returns (say, a lottery ticket), the long-only constraint will, on average, suggest that you buy it.

This chapter also suggests the use of the *Mahalanobis distance* (they almost clearly recall what it is)

$$d_{\text{Mahalanobis}}(\mathbf{w}_1, \mathbf{w}_2) = (\mathbf{w}_1 - \mathbf{w}_2)' V^{-1} (\mathbf{w}_1 - \mathbf{w}_2)$$

to compare portfolios. Some people also advocate the use of the *tracking error distance*,

$$d_{\text{TE}}(\mathbf{w}_1, \mathbf{w}_2) = (\mathbf{w}_1 - \mathbf{w}_2)' V (\mathbf{w}_1 - \mathbf{w}_2).$$

You can use them to design a statistical test to compare portfolios – but that test turns out not to have any power.

The chapter confusingly ends with a compendium of problems with resampled portfolios and/or the long-only constraint (mainly, they tend to invest in every stock) and advocates the use of robust methods.

Actually, resampling can prevent the adverse effects of the long-only constraint: construct resampled portfolios without the constraint and discard the stocks whose weight is not positive often enough – *i.e.*, is not significantly positive.

Resampling, aka *bootstrap*, can also give you an idea of the distribution of Sharpe or Sortino ratios – and *double bootstrap* (they try to explain what it is) can help lower the bias.

Chapter 5 addresses non-gaussianity, starting with *scenario optimization* and expected utility; they mention *copulas* but do not use them; finally they suggest replacing variance by MAD (Mean Absolute Deviation), semi-variance or CVaR (Conditional Value at Risk, aka Expected Shortfall or ES). The chapter closes on an application of scenario optimization and CVaR to CDOs.

Chapter 6, devoted to robust statistics, is the gist of the book. The most straightforward robust methods are the *trimmed* ones (trimmed mean, trimmed regression (LTS), estimation of the volatility of a time series where you discard the observations beyond 2.5σ , etc.). Where least squares methods minimize the sum of squared residuals, $\sum_i r_i^2$, an *M-estimator* minimizes $\sum_i \rho(r_i)$, for some function ρ . This is equivalent to a weighted regression.

The robust Mahalanobis distance between r_t (the returns of the stocks on a given day) and its historic (robust) mean can help spot hectic times.

When computing a historical variance, all the series need not have the same length: it is possible to compute a maximum-likelihood estimator of the variance matrix and the means that do not discard the information available (*Stambaugh method*); this method, in turn, can be robustified (they just give a recipe, with no theoretical foundation).

The book also presents “*robust portfolio optimization*”, *i.e.*, portfolio optimization with a robust variance matrix: if the robust efficient frontier and the classical one coincide, use the classical one; if they differ, investigate.

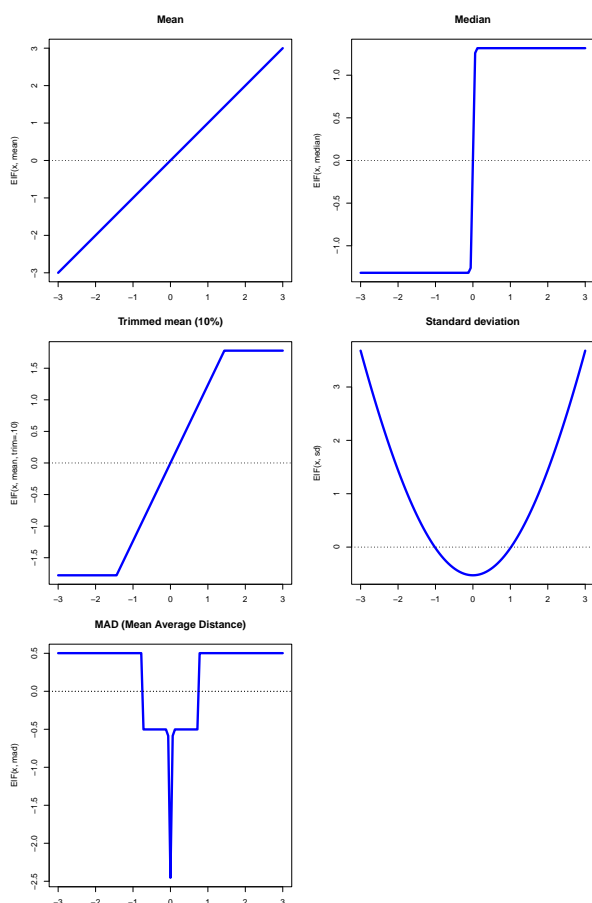

In these “robust portfolio optimizations”, we are concerned by the fat tails of the distribution of returns – and to solve the problem, we end up cutting those tails. To estimate the returns, *i.e.*, the center of the distribution, this is legitimate, but to compute the variance matrix, *i.e.*, the dispersion, this is dubious...

This chapter ends with an original section on *influence functions*. The *empirical influence function* or *finite-sample influence function* of a family of estimators $\hat{\theta}_n$ (e.g., $\hat{\theta}_n$ could be the mean of n numbers) is

$$\text{EIF}(x, \hat{\theta}, \mathbf{x}) = (n+1) \left(\hat{\theta}_{n+1}(x, \mathbf{x}) - \hat{\theta}_n(\mathbf{x}) \right),$$

i.e., it is the change in the estimator $\hat{\theta}_n(\mathbf{x})$ brought by a new observation x – the $n+1$ coefficient is a normalizing coefficient, ensuring that, under mild conditions, the large-sample limit exists.

```
## Error in huber(a)$s: $ operator not defined
for this S4 class
```

In a portfolio optimization setup, one can compute the influence of an asset (*i.e.*, the pair risk-return) on the risk of the optimal portfolio, its expected return, its Sharpe ratio, its weights – since there are two dimensions, the plot is actually a contour plot.

Chapter 7 is an unreadable introduction to bayesian statistics and Monte Carlo Markov Chain (MCMC) simulations. They insist on the importance of *Composition sampling* but fail to clearly explain that notion. The book ends on the Black-Litterman model, including a few interesting remarks on its generalization (use of a non-gaussian prior) and applications (to get an idea of the distribution of the Sharpe ratio) and the *Bayes-Stein estimator*, which they fail to clearly explain.

If you remember something from this book, it could be:

- Use robust estimators, *i.e.*, discard the most extreme observations – especially if your computations assume the data are gaussian;
- The influence function;
- The (robust) distance between today's return and the historical average to find "hectic times";
- The plot of the composition of a portfolio as a function of the risk (you might already be used to a similar plot with respect to time).

Quantitative strategy: global model portfolio
A. Tsai, Bear Stearns (2004)

They model stock returns as ARIMA processes, with

the parameters estimated for each stock, with the AIC, on a 30-month moving window; they claim that on a large, diversified universe (MSCI World), with a monthly rebalancing, with a 15% stop-loss, with a crude optimization (only consider the top 7% stock and minimize the risk, regardless of the returns) it works – with an 85% turnover.

If most of the stocks are AR(1), this is an exponential momentum factor whose length is stock-dependant. Their model captures short-term momentum but fails to spot longer-term reversal.

Separating the winners from the losers
A. Hartman et al., ABN-Amro (2003)

The article builds an adaptive model to predict future stock returns, as follows:

- Take 60 factors, compute their returns (how?), compute their robust correlation matrix, cluster them;
- In each group, select a factor with a high IC (Information Coefficient, *i.e.*, rank correlation with the forward returns) and a high mean(IC)/sd(IC);
- Model the monthly ICs of each factor as AR(1) processes, independently;
- These AR(1) forecasts of the ICs are too noisy: shrink them towards their historical mean (use the explained variance of the AR(1) model and the estimated variance on the estimator of the historical mean);
- Combine the factors using the following weights:

$$\mathbf{w} = (\text{Var IC})^{-1} \cdot \text{IC}.$$

Neural networks in business: techniques and applications for the operations researcher
K.A. Smith and J.N.D. Gupta (2000)

A review articles on the history of neural networks, the families of neural networks (multi-layer feed-forward with back-propagation learning rule, Hopfield networks (for quadratic programming), Kohonen maps) and their applications.

Surrogate time series
T. Schreiber and A. Schmitz (1999)

A more detailed (but less readable) article about surrogate time series, stressing what you can and cannot test with them – and how powerful or powerless those tests are:

- For the ARMA surrogate data, they allow for the series to be transformed in order to be gaussian;
- For the Fourier Transform-based surrogate, they use an iterative process to compensate for some of the artifacts of the naive approach.

The non-linearity tests they suggest rely on a non-linearity measure, such as:

- The third-order statistic, $E[(X_n - X_{n-\tau})^3]$, that measures the asymmetry of a time series under time reversal;

- the RMS (Root Mean Square) error of a locally constant (k nearest neighbour) predictor;
- Coarse-grained redundancies (?);
- Symbolic methods (?);
- False nearest neighbour (?);
- Unstable Periodic Orbits (UPO) (?);

The appendix of the article discusses an implementation of those ideas: TISEAN – you should also have a look at the tseriesChaos package, in R.

***Detecting nonlinearity in data
with long coherence times***
J. Theiler et al (1992)

Bootstrap is not as straightforward for time series as it is for other types of data. In this context, resampled time series are often called *surrogate data*. Here are a few ideas:

- Bootstrap as with other kinds of data – but this assumes that the observations are independent and destroys any causality information;
- Cut the time series in chunks and reshuffle them – this is not as bad, but it creates structural breaks in the series;
- Fit an ARMA model to your data, reshuffle or resample the residuals and reconstruct the ARMA series;
- Idem, but sample the new residuals from a gaussian (or whatever) distribution;
- Compute the Fourier transform of your series, keep the amplitude, replace the phase by random data and take the inverse Fourier transform.

The result, however, may be quite different from the initial time series, e.g., for the following reasons:

- The signal is periodic and there is not an integral number of periods in the window used for the Fourier transform;
- Changing the phase at the main frequency of the signal and/or at its harmonics can have strange effects;
- The time series is not stationary;
- The time series is non-linear (surrogate data are often used to test for non-linearity, but one should be aware of these and other artifacts).

***The S^2 tree: an index structure for
subsequence matching of spatial objects***
H. Wang and C.-S. Perng

To index sequences of points (“trails” as used, e.g., for subsequence matching in time series databases), one can combine ideas from sequence indexing (suffix trees) and spatial data indexing (R^* -trees), as follows: build an R^* -tree with the points in your trail or the MBR (Minimum Bounding Rectangles) covering them and add the links you would have in a suffix tree.

***Efficient time series subsequence matching
using duality in constructing windows***
Y.-S. Moon et al. (2000)

This article refines the previous: instead of sliding a

window on the data sequences, one can cut them into chunks; one then has to slide a window on the query sequence, instead of cutting it into chunks.

***Fast subsequence matching
in time-series databases***
C. Faloutsos et al.

To look for subsequences in a time series database, preprocess it as follows:

- move a sliding window (of the same length as the query series, or smaller) in the data series;
- For each position of the sliding window, compute a DTF (Discrete Fourier Transform) or any other distance-preserving transform;
- Retain the first k coordinates: you get a *trail* in a k -dimensional space;
- Since the trail contains too many points to store them all, cover the trail with rectangles (MBR, Minimum Bounding Rectangles);
- Store those rectangles in an R^* -tree: it is a data structure to store or index geometric objects that allows you to efficiently look for objects that intersect a given query object (it is used by some spatial databases).

***Forecasting transaction rates:
the autoregressive conditional duration model***
R.F. Engle and J.R. Russell (1994)

Autoregressive Conditional Duration (ACD) models are models of irregular time series, very similar to GARCH, with the variance replaced by the duration (*i.e.*, the time between two values) – so similar that one may use GARCH software to fit those. It can also be seen as a State Space Model (but a non-gaussian one: durations are waiting times). The model can be generalized to accommodate for discrete increments.

A portfolio diversification index
A.M. Rudin and J.S. Morgan
Journal of Portfolio Management, 2006

To check if the risks in your portfolio are well diversified, you can:

- Look at the variance matrix of the returns of the assets in your portfolio (but you need a good pair of eyes for this: the matrix is huge);
- Cluster the stocks in your portfolio and count the number of clusters (but this is somewhat arbitrary).

This article suggests to count the number of “independent factors” in your portfolio, as follows:

- Perform a Principal Component Analysis (PCA) on the variance matrix of the stock returns, to get those “independent factors”;
- Compute the weights w_k of each factor k in your portfolio;
- Count the number of factors, as follows:

$$\text{PDI} = 2 \sum_k k w_k - 1,$$

(if there is a single factor, *i.e.*, if $w = (1, 0, \dots)$, then $\text{PDI} = 1$; (if there are n factors and $w = (1/n, \dots, 1/n, 0, \dots)$, then $\text{PDI} = n$).

To check if your portfolio is diversified as it should, you can compare its PDI with that of random portfolios of the same size, on the same universe.

Stepwise portfolio construction using the *marginal PDI* does not significantly change the returns but lowers the volatility – when compared to random portfolio construction.

***Risk management for hedge funds:
introduction and overview***

A. W. Lo

VaR (Value at Risk) is not a good risk measure:

- It is not sub-additive, *i.e.*, the VaR of a more diversified portfolio need not be lower;
- It does not provide a decomposition of the risk into different risk sources;
- VaR is a static measure: it does not account for events (e.g., crashes), time-varying risks or dynamic trading strategies; it is computed unconditionally;
- VaR is difficult to estimate: if you choose Extreme Value Theory, you use very few data points; if you assume the distributions are gaussian, you are plainly wrong.

If you have to choose a hedge fund, do not be impressed by their positive returns: it does not mean that hedge fund returns tend to be positive, but simply that hedge funds with negative returns disappear (survivorship bias).

To show the problems of risk measurement, the article presents an unscrupulous but impressive trading strategy: short deep out-of-the-money put options.

To introduce events (crashes, “phase locking”), consider two risk models, one for normal days, another for event days. You can then use conditional measures of risk,

$$\frac{\text{Risk}[\text{portfolio} | \text{normal day}]}{\text{Risk}[\text{portfolio} | \text{event}]}$$

To account for non-linearities, do not compute sensitivities (β), but sensitivities (β_+ , β_-) to positive and negative values of the factor you are interested in (e.g., S&P 500) and test for their equality.

You can use Ljung & Box’s Q statistic (or rather its p -value) to measure the illiquidity of a fund.

***Time series analysis and prediction using
recurrent gated experts***
C. Gilde (1996)

Neural networks can be extended to accommodate time series, by reusing the previous value of a node, e.g., with a recurrent architecture.

This document adds that feedback capability to gated experts.

***Stock market pattern recognition
with neural networks***
D. Vengerov (1997)

The gated experts look at different time scales.

***Gated experts for classification
of financial time series***
D. Vengerov (1997)

To forecast future stock prices, use a Markov mixture of neural networks:

- The markovian structure recognizes the regime;
- The neural networks fit the data.

***Stock market prediction using
artificial neural networks***
B. Egeli, M. Ozturan, B. Badur

One can forecast future stock returns (or an emerging market index returns) with a

- MLP (MultiLayer Perceptron) – the neural net everyone knows;
- or a GFF (Generalized Feed Forward net) – in which the signal can jump one or several layers.

The input variables are: the previous value of the index (yes, a single value), the USD exchange rate, the day of the week. They forget to mention the number of neurons in the hidden layer – probably as many as input variables – and just focus on the number of hidden layers.

It works best with a single hidden layer and GFF networks.

21 nonlinear ways to beat the market
G.T. Albanis and R.A. Batchelor

Presentation of several Machine Learning (ML) algorithms,

- LDA (Linear Discriminant Analysis);
- PNN (Probabilistic Neural Network);
- RRI (Ripper Rule Induction algorithm);
- LVQ (Learning Vector Quantization);
- OC1 (Oblique Classifier)

and suggests to combine them with some voting scheme.

***Dynamic detection of change points
in long time series***
**N. Chopin,
Annals of the Institute of Statistical
Mathematics (2006)**

This article tries to account for the fact that GARCH models poorly fit long time series, suggesting that the model does not remain the same over time, by looking for abrupt model changes.

This can be done with MCMC simulations (remember that MCMC simulations may be used whenever you

have an algorithmic description of the process producing the data, with a reasonable number of parameters), but the algorithm will be slow (quadratic) and the convergence poor.

Instead, one can use a “particle filter”. The differences with MCMC are twofold:

- instead of generating several times series one after the other, one generates them at the same time;
- For each instant, we compute the likelihood of each time series, and their probability of survival to the next step is proportional to this probability (this should remind you of genetic algorithms).

The discrete nature of the abrupt model changes hinder the algorithm: the rest of the article explains how to circumvent this problem – the article could have been titled “Speeding up MCMC simulations in the presence of discrete variables”.

***Random portfolios
for evaluating trading strategies***
P. Burns (2006)

Traditional means of testing an investment strategy are very basic: rank correlations (called “information coefficients”) or return spreads (difference between the returns of the first and the last quintile of our signal or “alpha”).

But they forget half the story: how the strategy will actually be implemented. Instead of those crude measures, one can compare

- your strategy, *i.e.*, the transactions suggested by your alpha when fed to an optimizer;
- the strategy obtained by feeding a random signal (with the same statistical properties as your signal – do not forget the autocorrelation) to an optimizer (with the same constraints and the same risk model);
- a random investment strategy (with the same constraints: turnover, maximum and minimum weights, etc.).

Repeat this for hundreds of random signals (I would even suggest 10,000) to get an idea of how you signal fares. Feel free to change the initial portfolio (you might want to draw it “at random”, but this would have to be defined).

You may want to draw the following plots, either in back-tests or to monitor a strategy in real time:

1. cumulated returns of your portfolio over time, together with the fractiles of the cumulated returns of the random portfolios;
2. the p -value of the Stouffer test (?) over time;
3. final wealth of your strategy versus that of a random strategy, for the same initial portfolio.

You can also use those ideas to assess the influence of constraints, to compare risk models – or to compare optimizers.

***Copulas and coherence:
portfolio analysis in a non-normal world***

**K. Dowd
The Journal of Portfolio management (2005)**

They remark that correlation might not be a very good measure of the dependance between stock returns and suggest the use of copulas instead. As an illustration, they consider a two-stock portfolio: in their example, correlation-based methods vastly underestimate the risk. The problem, is that this is a simulated example, very far away from a gaussian setup: are dependances between real returns that extreme?

Another untackled question is the estimation of the copulas with a large number of stocks. In a correlation-based framework, this estimation is unreliable and we have to make further assumptions on the structure of the variance-covariance matrix, *e.g.*, that it only depends on a handful of factors: this is a risk model. One would therefore have to build our own copula-based risk model. This is an ambitious undertaking.

***Optimal trading strategies
and supply/demand dynamics***
A. Obizhaeva and J. Wang (2005)

Classical models to study trading strategies,

- We want to buy X shares of company RHAT
- We do it at times $0, \tau, 2\tau, \dots, N\tau$
- the price evolves as $P_{n+1} = P_n + \lambda x_n + u_n$ where $u_n \sim N(0, \sigma^2 \tau)$
- We want to minimize the transaction costs $E[\sum P_n x_n]$ or the risk-adjusted transaction costs $E[\sum P_n x_n] + \alpha \text{Var}[\sum P_n x_n]$,

whose solution is $x_i = X/(N+1)$, are overly simplified. For instance, in the continuous limit, they can no longer distinguish between the strategies: the transaction costs are strategy-independant.

The article provides a richer model, based on the Limit Order Book (LOB).

Portfolios from Sorts
R. Almgren and N. Chriss (2005)

This article develops a theoretical framework to define and compute an “optimal” portfolio from ordinal information (“this stock will outperform this one”, etc.), *e.g.*, from an ordering of the stocks. In a nutshell, they look for the portfolio that performs best in the worst situation that respects the ranking.

Surprisingly, this boils down to imposing a predefined distribution on the returns – but not a gaussian one.

This can easily be generalized to any partial order (*e.g.*, a total order in each sector but no information about one sector outperforming another) or any set of linear equations (*i.e.*, portfolios outperforming other portfolios).

This article is a simplification (a special case) of *Optimal Portfolios from Ordering Information* (2004), by

the same authors.

Barra factor returns and macro indicators

M. Furukawa and H. Tamura, Nomura (2005)

Application of the previous article to the Barra JPE3 factors:

- momentum (contrarian);
- value (especially when the yen is weak);
- interest-rate sensitivity (industrial production and topix decline, strong yen);
- leverage (rising long-term interest rate and topix);
- size (contrarian, rising topix).

The impact of the macroeconomic environment on global factor effectiveness

H. Tamura and K. Iro, Nomura (2002)

One expects factors to efficiently forecast future returns at some times and poorly at others, depending on the “macroeconomic environment”.

One can define the macroeconomic environment as follows:

- select a few macroeconomic variables (interest rates, stock market indices, exchange rates);
- apply a low-pass filter (there is an example on my web page; they seem to forget the boundary problems);
- check when the resulting signal is up or down.

One can define the returns of a factor as follows: use the (normalized) factor values as the active alpha in a mean-variance optimization; impose that the resulting portfolio be neutral wrt the other factors – actually, their description is rather vague: they could be using a Black-Litterman model.

One can then study the effects of the macroeconomic environment on the factor returns: this effect is important in the US and for the valuation factors (P/E, P/B, P/DPS, P/Sales). The most important macroeconomic factors are the long-term interest rate and the stock-market indices.

The results can be represented graphically in the returns×risk plane, with a point (mean risk and return) and two arrows (mean risk and return in the up and down phases) for each factor.

Out-of-core tensor approximation of multidimensional matrices of visual data

H. Wang et al. (Siggraph 2005)

A generalization of PCA that acts on matrices (or higher-dimensional arrays) instead of vectors, based on multilinear (aka tensor) algebra. This is used in computer graphics, to compress Bidirectional Texture Functions (BTF, *i.e.*, a texture is not given as a single image, but as a series of images that depend on the viewing and illumination directions). Applications in finance could revolve around volatility surfaces.

Genetic algorithms with collective sharing for robust optimization in financial applications

O.V. Pictet et al. (1996)

One can use genetic algorithms to design trading algorithms, as above: combine arithmetic operations, **sign**, **<**, **ifelse** and exponential moving average to produce a result in $\{-1, 0, +1\}$. They are careful to “normalize” the data and modify the division in order to avoid divisions by zero.

To stay away from non-representative peaks in the log-likelihood landscape, one can reduce the fitness in a region depending on the number of individuals in this region. This notion of “region” can be defined with gaussian kernels (but one has to choose the width of those kernels) or by applying the *k*-means clustering algorithm.

Genetic programming with syntactic restrictions applied to financial volatility forecasting

G. Zumbach et al. (2001)

Genetic programming can be used to perform model selection among a (huge) set of non-linear regression models, as follows:

- represent each model as a tree (the syntax tree of the corresponding formula);
- define a few mutation operators (node substitution, subtree mutation, root splicing, node insertion, node deletion);
- define a cross-over mechanism (given two trees, select a node in each and interchange the corresponding subtrees).

The article suggests:

- Do not use genetic programming to estimate the constants in the model, use more classical (and faster) algorithms;
- Use *typed* trees to preserve the symmetry in the function to be estimated;
- Fine-tune the mutation probabilities (they apply the genetic algorithm on simulated data with various values for the mutation and cross-over probabilities and select the best – with yet another genetic algorithm);
- Penalize the score of a given model by its “complexity” (which they define).

They then apply those ideas to FX data to forecast volatility (using simple arithmetic functions, absolute value, square and exponential moving averages).

The misbehaviour of markets

A Fractal View of Risk, Ruin and Reward

B. Mandelbrot (2004)

Besides providing a bird’s eye view of the history of finance, the author advocates three ideas.

1. Financial data exhibit fat tails, that follow a *power law*; this can be measured by the corresponding exponent, α .

2. Financial data exhibit long memory, or long-range dependance; this can be measured by the *Hurst exponent*, H . The interactions between those two effects can be measured by the *R/S statistic*.

3. Financial data look as though they were produced from a “shuffled” fractal process, with time distortions – but the book fails to give any detail as to the shape of those “time distortions”.

The geometry of crashes: a measure of the dynamics of stock market crises

T. Araújo and F. Louçã
arxiv:physics/0506137

During a crash, all the assets become correlated: this can be seen on the correlation matrix (estimated on a 3-week window) e.g., by comparing its first eigenvalues with those of “random” data. The article suggests a measure of that difference,

$$S = \sum_{i=1}^6 \frac{\lambda_i - \mu_i}{\mu_i}$$

where the λ_i are the actual eigenvalues and the μ_i those of “random” data.

There are a few problems, though:

- The article forgets to define “random”;
- Between the correlation matrix computation and the eigenvalues computation, the authors perform a (useless, if linear) MultiDimensional Scaling (MDS);
- It can only be used in retrospect, to conclude “this was not just an impression, there really was a crash”.

C++ design patterns and derivatives pricing
M. Joshi, CUP (2004)

This book has a very good but undeserved reputation (but again, its competitors might be even worse). It explains how to price derivatives, using Monte Carlo methods, in C++, with as many *design patterns* as possible.

Without *any* picture.

The author also explains how to circumvent some of the intricacies of C++ (as Meyer’s *Effective C++*, but more untidy) or some of its implementations (the *only* comment in the code is “...should be in namespace `std` but aren’t in `VCPP6`”) – at times, it even looks like an advocacy for interpreted languages (where you can write a Monte Carlo sampler in one line instead of one page) or fonctionnal languages (where a function can accept another function as argument).

A new method to estimate the noise in financial correlation matrices

T. Guhr and B. Hälber
arXiv:cond-math/0206577

Yet another correlation cleaning procedure: if the returns are the sum of sector-specific returns and

stock-specific returns, the correlation matrix is block-diagonal. The *power mapping* of the sample correlation matrix,

$$c_{ij} \leftarrow \text{sign}(c_{ij}) \cdot c_{ij}^q,$$

for a well-chosen (well, hand-chosen) value of q (this is merely a shrinkage of the correlation coefficients towards +1 or –1) provides a matrix that looks like the sample correlation matrix on a much larger time scale (two distinct peaks) and can thus be used instead.

Note that the authors used simulated data: I have tried it with real data (500 stocks, 300 days) – to no avail.

Financial applications of Random Matrix Theory: old laces and new pieces

M. Potters et al., arXiv:physics/0507111

Other correlation cleaning ideas:

- Shrink all the eigenvalues of the correlation matrix towards zero;
- Idem, but shrink more the small eigenvalues than the large ones.

Cluster analysis for portfolio optimization

V. Tola et al., arXiv:physics/0507006

The article presents three ways of filtering a correlation matrix to be used to build a portfolio:

- convert the correlation matrix into a distance matrix, perform an average linkage hierarchical clustering, measure the distance along the resulting tree, convert the (ultrametric) distance back to a correlation matrix;
- Idem with simple linkage;
- Random Matrix Theory (RMT, *i.e.*, PCA-based filtering).

The average linkage performs better.

Parametric portfolio policies: Exploiting characteristics in the cross-section of equity returns

M.W. Brandt et al. (2004)

Quantitative investors do not forecast the returns of each and every stock: instead, they devise a formula that will predict those returns from the characteristics (financial ratios, etc.) of the stocks; then they find the optimal portfolio for those returns. It is a two-step process.

Instead of predicting the stock returns, we can directly devise a formula to find the portfolio weights and tune this formula to optimize some “utility function”.

If you are used to classical portfolio construction, this looks a bit weird: the utility function you are used to requires the expected stock returns and the variance-covariance matrix of those returns. The article suggests a utility function (called the Constant Relative Risk Aversion (CRRA) function) that only depends on

the portfolio returns – a function of a single variable.

$$\text{Utility} = \frac{(1 + \text{return})^{1-\gamma}}{1 - \gamma}$$

You would expect the utility to depend on the portfolio expected return but also on its risk; you would expect the utility of a risky portfolio to be lower than that of a less risky one with the same expected return – but the formula only depends on the return – why?

The trick is that it indeed depends on the returns, not the expected return: we do not maximize

$$\text{utility}(E[\text{return}], \dots)$$

but

$$E[\text{utility}(\text{return}, \dots)].$$

The advantages over the classical paradigm are that:

- This is a *dynamic* utility function;
- The approach is not limited to the first two moments of the returns: it can also account for asymmetries or fat tails in return distributions.

A step-by-step guide to the Black–Litterman model T.M. Idzorek (2002)

Classical Mean-Variance optimization poses a few problems:

- The optimal portfolios tend to only contain a couple of stocks – they are not diversified;
- The optimal portfolios are corners (vertices) in a simplex: if we slightly change the inputs, we might jump to another corner – the portfolio is over-sensitive to the inputs;
- For the optimizer, the most important information often lies in the tiny differences between forecasts for similar assets, and it will amplify those differences, even if they are not significant, even if they are mere estimation errors.

The *implied returns* (or *implied alphas*) of the market portfolio are the expected returns for which the market portfolio is optimal: they are the expected returns α such that the market portfolio weights \mathbf{w} maximizes the utility $\alpha' \mathbf{w} - \frac{1}{2} \lambda \mathbf{w}' V \mathbf{w}$, where V is the variance-covariance matrix of the stock returns and λ the risk aversion, *i.e.*, the α such that $\mathbf{w} = (\lambda V)^{-1} \alpha$, *i.e.*, $\alpha = \lambda V \mathbf{w}$.

The *risk aversion* coefficient λ can be estimated as

$$\lambda \approx \frac{\text{risk premium (i.e., expected excess return)}}{\text{market excess return variance}}.$$

(Do not ask me why.)

The Black–Litterman model will combine those implied returns with a few *views* on the returns of a few stocks or portfolios. We need not provide expected returns for all the stocks (that would be error-prone) and we can simply provide the returns of portfolios instead

of individual stocks (it is easier) – forecasting the returns of a few portfolios instead of those of hundreds of stocks is sometimes called *mixed optimization*.

The Black–Litterman model relies on *bayesian statistics*: we have a prior belief (the returns will be gaussianly distributed, with mean the implied alphas and variance matrix V), we have some new information (or views: that the portfolios we can predict will have the returns ν we forecast, with a certain (diagonal) variance matrix Ω), and we combine all that.

Here is the classical set-up for bayesian statistics:

- We are interested in some parameter λ defining the distribution of a random variable, say $X \sim \text{Exp}(\lambda)$;
- We have some prior knowledge about λ : it is sampled from a known distribution, the *prior distribution*, say $\lambda \sim \text{LogN}(0, 10^6)$;
- We have some new information, usually a sample from the random variable X , say X_1, \dots, X_n ;
- We compute the distribution of the parameter λ given the new information X , *i.e.*, $\lambda|X$ – this is the *posterior distribution*.

This can be seen as an extension of Maximum Likelihood Estimation (MLE), whose prior contains no information at all, and whose result is the *mode* of the posterior distribution instead of the whole distribution itself.

If you want formulas for the probability distribution functions, this is the *Bayes formula*:

$$\begin{aligned} \text{Prior: } & f(\lambda) \\ \text{Posterior: } & f(\lambda|X) = \frac{f(X|\lambda)f(\lambda)}{\int f(X|\mu)f(\mu) d\mu} \end{aligned}$$

If you do not like probability distribution functions and prefer discrete probabilities, replace f by P :

$$P(\lambda|X) = \frac{P(X|\lambda)P(\lambda)}{\sum_{\mu} P(X|\mu)P(\mu)}.$$

But the Black–Litterman model does not follow those lines – it merely reuses the same ideas, “prior”, “new information” and “posterior”:

- Prior: the forward returns r should look as though they were sampled from a gaussian distribution, with mean the implied alpha α , with variance matrix τV , a scaled-down version of the variance matrix V of the stock returns provided by the risk model. Setting $\tau = 0$ would mean that we believe that the returns will exactly coincide with the implied alphas; some people suggest $\tau = 0.3$, others $\tau = 1$, others $\tau = 0.01$.
- New information: the returns Pr of the portfolios we can predict should look like they were sampled from a gaussian distribution with mean our view ν and variance Ω – a user-supplied matrix, usually diagonal to simplify things.

– Posterior: we try to somehow combine the prior and the new information. Algorithmically, one could proceed as follows:

- sample the portfolio returns Pr from their distribution $N(\nu, \Omega)$;
- sample the stock returns conditionally to the portfolio returns, *i.e.*, from $N(\alpha, \tau V) | Pr$;
- iterate and take the average.

Alternatively, you can *compute* the distribution of $N(\alpha, \tau V) | Pr$ (with the Bayes formula) (?)

$$-2 \log \text{Lik} = (x - \alpha)'(\tau V)^{-1}(x - \alpha) + (Px - \nu)' \Omega^{-1}(Px - \nu) + \text{constant}$$

and compute the Maximum Likelihood estimator. Equivalently, one can solve the following “GLS system”

$$\begin{aligned} r &= \alpha && \text{with variance } \tau V \\ Pr &= \nu && \text{with variance } \Omega. \end{aligned}$$

This yields

$$r = [(\tau V)^{-1} + P' \Omega^{-1} P]^{-1} [(\tau V)^{-1} \alpha + P' \Omega^{-1} \nu].$$

In this framework, the user has still too many parameters to specify: the views ν (this is the only one we want to provide the algorithm with), Ω (it says how confident we are in our view, but it is rather tricky to set) and τ . The article provides a simple and intuitive means of setting up those parameters. Well, actually, only Ω/τ appears in the formulas, so you can set $\tau = 1$ and only specify Ω .

Their recipe is as follows. For each view k (they consider only one view at a time):

- Compute the returns $r_{k,100\%}$ with $\Omega = 0$ (100% certainty);
- Compute the corresponding unconstrained weights $w_{k,100\%} = (\lambda V)^{-1} r_{k,100\%}$;
- Adjust the weights according to the confidence level C_k for the k th view ($C_k = 0$ for 0% confidence, 1 for 100%),

$$w_k = w_{\text{market}} + C_k(w_{k,100\%} - w_{\text{market}});$$

- Imagine that w_k comes from the Black–Litterman formula, for some value of ω_k : find the corresponding value of ω_k , in the Least Squares sense.

Then, put all the ω_k in the diagonal matrix Ω and apply the Black–Litterman formula.

Analysis of longitudinal data **P.J. Diggle et al. (2002)**

Chapter 1 contrasts *cross-sectionnal data* (a single observation for each subject) and *longitudinal data* (several observations for each subject, usually across time): different methods are needed to account for the lack of independence of the observations for a given subject and to avoid the *ecological fallacy*.

Here are three ways of dealing with longitudinal data:

- Marginal analysis: you look for the mean and the variance (at each point in time) over all the subjects;
- Random effect models: you have a model for each subject, $E[Y_{ij} | \beta_i] = x'_{ij}$, and the model parameters β_i are themselves iid random variables;
- Transition models: you have a model for $E[Y_{ij} | Y_{i,j-1}, Y_{i,j-2}, \dots]$.

I have not read the second chapter, *Design considerations*, that deals with power and sample size.

Chapter 3 suggests a few plots to explore longitudinal data:

- The variable to predict vs time, you can highlight some subjects (selected at random or not: *e.g.*, the lowest final value – or any other fractile); you may want to add a lowess curve;
- The variable to predict vs one of the predictive variables, again with a non-parametric curve estimation;
- The variable to predict vs its lags, as a pairs plot; the Auto-Correlation Function (ACF) – for irregularly-spaced and/or non-stationnary data, replace the ACF by a *variogram* – for binary data, replace the variogram by a *lorelogram* (LOR stands for Log-Odds Ratio).

Chapters 4 and 5, *Generalized Least Squares (GLS) and parametric models for the variance-covariance matrix*, present three correlation structures: the uniform correlation model, $\text{Cor}(X_i, X_j) = \rho$ if $i \neq j$ (equivalent to a subject-specific intercept), the exponential one (the equivalent of an AR(1) model for irregularly spaced data: $\rho(u) = e^{-\phi u}$) and the gaussian one ($\rho(u) = e^{-\phi u^2}$); an alternative approach is to perform a regression for each subject and then look at the distribution of the estimated coefficients – or, more rigorously, a random effects model.

GLS are simply weighted least squares, with weight matrix equal to the inverse of the variance matrix. One could use Maximum Likelihood (MLE) to estimate this variance matrix, but the results are biased: Restricted Maximum Likelihood (REML) gives better results (in short: with MLE, you estimate the regression coefficients β and the variance matrix V , but the estimators $\hat{\beta}$ and \hat{V} are not independent; with REML, you transform the problem into estimating β and another matrix H , so that $\hat{\beta}$ and \hat{H} be independent and that \hat{H} do not depend on β). For best results, estimate the variance matrix with as saturated a model as possible (*e.g.*, if no predictive variable is time-dependant, add a separate parameter for the mean response at each time with each treatment). The estimates of β , the confidence intervals and the tests remain valid even if the variance matrix is mis-specified.

When estimating the error, you can decompose it as a sum of three terms: the random (subject-specific) effects, the serial correlation, and the measurement (residual) error.

Chapter 6 explains how *Anova* (Analysis of Variance) provides a simple but unsatisfactory means of studying longitudinal data:

- With *cross-sectionnal anova*, *i.e.*, one anova for each time, you do not know how to combine the results (if they all agree and say there is something slightly significant, how do we combine them? how do we account for the correlation of the data in strengthening the significance of the result?) nor how to spot time-dependant effects (e.g., the slope);
- The idea of *derived variables* is to replace the observations for one subject by a single or a few numbers (say, the mean, the average rate of change, the parameters of a meaningful non-linear model) and perform an anova with this derived variable – but with several derived variables, you run into the same problems as before.
- *Repeated measures anova*, *i.e.*, a mixed model of the form $y \sim \text{treatment} + \text{treatment} : \text{time} + (\text{treatment}|\text{subject})$, completely forgets the time ordering of the data.

Chapter 7 presents the main models used to fit longitudinal data:

- *Marginal models*, *i.e.*, GLS: you specify the structure of the variance and of the correlations of the random variables;
- *Random effects models*;
- *Transition models*: you can model discrete data as a Markov chain whose transition probabilities follow logistic models.

Visual Explorations in Finance with Self-Organizing Maps **G. Deboeck and T. Kohonen Eds., 1998**

A *Self-Organizing Map* (SOM) or *Kohonen map* is a hybrid between the *k*-means algorithm and multidimensional scaling (it provides a clustering *and* a graphical representation of the proximity of the clusters), implemented via a “neural network” (a “non-linear, multi-layered, parallel regression technique” – if you already know about neural nets, bad luck, it has nothing to do with it: it stems from the same biological analogy, but it is a completely different species of neurons).

Intuitively, it takes a net and tries to cover the data with it.

The algorithm goes as follows: each node of the net corresponds to a cluster center; assign them to initial values (e.g., random values); for each observation, find the closest cluster center, drag it *and its neighbours* towards the observation (this is the difference with the *k*-means algorithm); iterate until convergence.

You will remark that SOM can handle missing values (however, for the observations with too many missing values, it might be wiser to remove them to compute the map and see afterwards where they belong).

You can also use SOM for forecasting purposes, in a *semi-supervised* way: use only the predictive variables to select the winning neuron, use all the variables to update the weights.

To speed up the building of the map and avoid insta-

bility problems with “large” (beyond 3×3) maps, you can start with a small map and later refine it – this is a *hierarchical SOM*.

A few ideas to display the map:

- Use a hexagonal grid with a neuron on every other tile; the other cells indicate if the nearby neurons are close (white) or not (black); this highlights frontiers between different regions of the map and/or areas of different densities;
- The *U-matrix* is similar, with a neuron on each tile and varying colours between the tiles;
- Colour the tiles according to the similarity of their neurons with their neighbours (aka *iso-contours*);
- Colour the tiles according to the number of observations they contain;
- The *Sammon projection* of the net, to see shriveled regions of the map;
- *Atlas* (or *component map*): colour the map according to one of the input variables (you get one picture for each variable, hence the name “atlas”); this can help interpret the regions of the map;
- Of course, it might be useful to display summary statistics for each cluster;
- Colour the map according to the *quantization error* (the distance between the observations and their neurons);
- Colour the map according to the *sensitivity* to changes in a component;
- The *synaptic weight map* indicates, for each neuron, which variable provides the greatest effect;
- Colour the tiles according to the curvature;
- You can imagine other ways of colouring the map: for instance, fit a circular (1-dimensional) SOM to the neurons and assign them rainbow colours;
- Parallel plot of the observations, with a different colour for each cluster.

Do not forget to estimate the quality of the map:

- its quantization error;
- its stability (try again with resampled data, without the outliers, with different parameters, etc.)

SOM are not only nice plots to look at:

- You can display the evolution of a subject (company) on the map (as the maps are not stable, you should reuse the same map);
- Given a new observation, you can highlight the closest neuron – or neurons;
- You can use a SOM for asset allocation: either invest in a single cluster, or invest equally in all the clusters, or assign weights to the clusters according to some other variables.

Some advice:

- Choose a rectangular hexagonal map: square maps are less stable; funny shapes (torus, Klein bottle) are only relevant if you *know* the data has this structure;
- Choose the number of neurons: either slightly less than the number of observations, if you want a compact map, or up to ten times the number of obser-

- ventions, if you want a more detailed map;
- Carefully choose the variables; you might want to discard some of them or even perform a Principal Component Analysis (PCA) and retain the first dimensions;
 - Carefully transform the variables, e.g.:
 - apply a logarithm or sigmoidal transform;
 - normalize them: $x \mapsto \frac{x - \mu}{\sigma}$;
 - range-normalize them: $x \mapsto \frac{x - \text{Min}}{\text{range}}$;
 - histogram-normalize them (this is a bad idea: it erases the clusters);
 - Transform unordered qualitative variables into binary variables;
 - Initialize the algorithm with PCA (only start with random data when you want to show that the map can self-organize – it works, but it is not optimal).

The book does not tackle variants of SOM:

- DEC (Dynamically Expanding Method);
- LSM (Learning Subspace Method);
- ASSOM (Adaptive Subspace SOM);
- FASSOM (Feedback-controlled ASSOM);
- Supervised SOM;
- LVQ-SOM (Linear Vector Quantization SOM).

The book provides examples in the following domains: Mutual funds, Firm failures, Russian banks, Emerging countries, Stocks, Real estate, Consumer preferences, Texts. You need not buy it: most of it is available on <http://www.dokus.com/PDF-files/>.

In R, have a look at `som` in package `som`, `SOM` in package `class` and `shardsplot` in package `klaR`.

Estimating the number of data clusters via the gap statistic

T. Hastie, R. Tibshirani and G. Walther (2000)

One can estimate the quality of a clustering with the *within cluster dispersion*, defined as the average distance between two points in the same cluster (weighted so that all the clusters have the same prevalence),

$$W = \log \sum_{r \in \text{Clusters}} \frac{1}{2|r|} \sum_{a,b \in r} d(a,b).$$

One can compare this number with that obtained from random data (uniformly distributed in a box aligned with the principal components).

The following algorithm suggests the number of clusters:

- Perform the clustering assuming $k = 1, 2, 3, \dots$ clusters and compute the within cluster dispersion W_k ;
- Do the same thing with random data and compute the average dispersion \bar{W}_k and its standard deviation s_k ;
- Define the gap as $\text{Gap}_k = \bar{W}_k - W_k$;
- Retain the smallest k such that

$$\text{Gap}_k \geq \text{Gap}_{k+1} - s_{k+1}.$$

Depending on the situation, the Gap statistic performs similarly or better than the Silhouette method.

Non parametric maximum likelihood estimation of features in spatial point processes using Voronoi tessalations

D. Allard

To denoise a spatial point process, one can model it as a mixture of two uniform variables, one on the whole space (the noise), one on a subset A of it. The partial log-likelihood (“partial” means that we have cheated: we need one more parameter, the probability of being in A , but we replace it by its maximum likelihood estimator) is

$$-n \log n + M \log \frac{M}{a} + (n - M) \log \frac{n - M}{1 - a}$$

where

- n is the total number of points;
- M is the number of points in A ;
- a is the volume of A .

The subset A is sought as a union of tiles from the *Voronoi tessellation* – actually, the union of the m smallest tiles, where the integer m is to be determined.

Nearest neighbor clutter removal for estimating features in spatial point processes

S. Byers and A.E. Raftery

To remove noise from a cloud of points:

- For each point, compute the distance to its k th nearest neighbour (the histogram of those distances should be bimodal);
- Model those points as a mixture of two Poisson processes, with different densities; estimate the model parameters with the EM algorithm (the model does not assume any shape);
- Label the points as “noise” or “not noise”.

The performance is close to that of the `mclust` algorithm, which is more computationnally intensive, and it works surprisingly well in high dimensions.

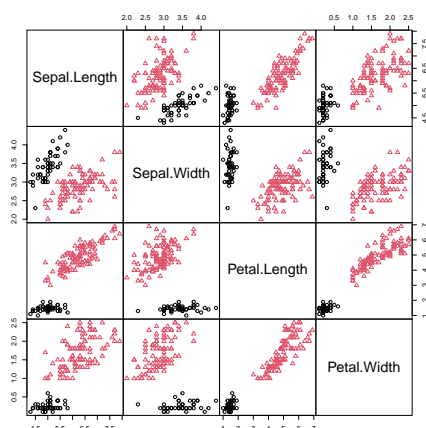

The idea can also be used to remove outliers.

In R, this is implemented as the `NNclean` function, in the `prabclus` package.

MCLUST: Software for model-based clustering, density estimation and discriminant analysis
C. Fraley and A.E. Raftery (2003)

Documentation of the `mclust` R package, that implements the EM model-based clustering algorithm – and its extensions to discriminant analysis and density estimation.

```
library(mclust)
r <- clustBIC(x)
plot(r) # BIC
s <- summary(r,x)
pairs(x, col=s$classification)
```

```
coordProj(x,
  z=s$z,          # Probabilities
  mu=s$mu,        # Cluster centers
  sigma=s$sigma,  # Cluster shapes
  what="classification")
```

Model-based clustering discriminant analysis and density estimation
C. Fraley and A.E. Raftery

Journal of the American Mathematical Association (2002)

The EM clustering algorithm can also be used in *density estimation* and *discriminant analysis* (the article has a lot of figures).

For high-dimensional data, new problems occur: the number of parameters (in the variance-covariance matrices) to estimate soars and calls for dimension reduction techniques (Principal Component Analysis (which may obscure the situation), Principal Curves, wavelets, Multidimensional Scaling (MDS)) or for extensions of the algorithms that directly deal with distance matrices.

Chameleon: a hierarchical clustering algorithm using dynamic modeling
G. Karypis et al.

Chameleon is a *graph-theoretic* clustering algorithm that takes into account the fact that clusters can have different densities and distinguishes clusters touching by a single point or a whole facet:

- replace the data by its k -nearest neighbour (sparse) graph, whose edges are weighted by the similarity of the vertices;
- find initial subclusters with the *edge-cut* algorithm;
- Merge the clusters whose Relative Interconnectivity (RI) and Relative Closeness (RC) are above a (user-specified) threshold, or according to the product $RI \cdot RC^\alpha$ (for a user-specified α).

The relative interconnectivity or closeness is defined from the absolute and internal interconnectivity (AI, II) and closeness (AC, IC), as follows.

$$AI(A, B) = \sum_{\substack{a \in A \\ b \in B \\ (a,b) \in \text{Graph}}} w(a, b)$$

$$II(A) = \min_{\substack{C \text{ is a} \\ \text{cut of } A}} \sum_{\substack{a,b \in A \\ (a,b) \in \text{Graph}}} w(a, b)$$

$$RI(A, B) = \frac{AI(A, B)}{\frac{1}{2}(II(A) + II(B))}$$

$$AC(A, B) = \text{Mean}_{\substack{a \in A \\ b \in B \\ (a,b) \in \text{Graph}}} w(a, b)$$

$$IC(A) = \text{Mean}_{\substack{a,b \in A \\ (a,b) \in \text{Graph}}} w(a, b)$$

$$RC(A, B) = \frac{|A \cup B| \cdot AC(A, B)}{|A| \cdot IC(A) + |B| \cdot IC(B)}$$

How many clusters?
Which clustering method?
Answers via model-based cluster analysis
C. Fraley and A.E. Raftery

The k -means clustering algorithm assumes that the clusters are symmetric and have the same size – hierarchical clustering algorithms similarly misbehave when confronted with clusters of varying shape, orientation

or size. The EM (Expectation-Maximization) algorithm finds the clusters by modeling the data as a mixture of gaussians, with potentially different variance-covariance matrices. The BIC (Bayesian Information Criterion) can help you choose the number of clusters and the variance-covariance matrix.

You can extend the algorithm to deal with noise:

- estimate the noise, by denoising the data (nearest neighbour method, Voronoi tessellations method);
- estimate the clusters, by a hierarchical classification of the denoised data;
- use the EM algorithm to fit the data as a mixture of gaussians (clusters) and a Poisson process (for the noise), initializing it with the previous two steps.

***CURE: an efficient clustering algorithm
for large databases***
S. Guha et al.

The *Birch* algorithm clusters large databases as follows: first replace dense regions by points (and discard less dense regions), then cluster those points.

The *CURE* (Clustering Using REpresentatives) algorithm is a variant of the *k*-means algorithm that does not use a single centroid for each cluster but *several* representatives: this allows for non-spherical clusters. You can adapt it to large databases by running the algorithm on a (random) sample of the data.

The article also briefly mentions other clustering algorithms for large databases: Clarans, R*-tree, DbScan.

***Determining the number of clusters/segments
in hierarchical clustering/segmentation
algorithms***
S. Salvador and P. Chan

There are four main categories of *clustering algorithms*:

- partitionning (aka *iterative relocation*, e.g., *k*-means)
- hierarchical (bottom-up or top-down);
- density-based (e.g., EM (Expectation Maximization));
- grid-based (e.g., SOM (Self-Organizing Map, aka Kohonen maps)).

Segmentation algorithms are related to clustering algorithms: they try to approximate a time series as a piece-wise linear function (PLR, Piece-wise Linear Representation); the main categories of clustering algorithms are:

- sliding window (grow a segment until the error exceeds a threshold, then start a new one);
- top-down (recursively split the entire series until the chunks can be approximated by segments);
- bottom-up (start with length-2 segments, merge the closest pair, iterate).

The number of clusters (resp. segments) can be guessed by:

- cross-validation;

- penalized likelihood:
 - MML (Minimul Message Length);
 - MDL (Minimum Description Length);
 - BIC (Bayes Information Criterion), AIC (Akaike Information Criterion);
 - SIC (Subspace Information Criterion);
- permutation tests (for segmentation: shuffle the time series);
- resampling;
- finding the maximum of a curve representing the quality of the cluster:
 - gap statistic;
 - prediction strength;
- finding the *knee* of the error curve.

The *L-method* finds the knee of an error curve by fitting it as a 2-segment broken line (to get more stable results, take a subset of the data so that there be as many points on each side th the knee; if the curve (or the time series) is too noisy, first smooth it by a moving maximum over a length 2 window).

Note that this does not work of there are only 1 or 2 clusters.

***Algorithms of maximum likelihood data
clustering with applications***
L. Giada and M. Marsili
arXiv:cond-mat/0204202

To cluster a cloud of points, the authors consider the following model: take n points at random, take k cluster centers at random, assign each point to a cluster at random, drag each point towards its cluster center. The likelihood is

$$\sum_{s : n_s > 1} \log \frac{n_s}{c_s} + (n_s - 1) \log \frac{n_s^2 - n_s}{n_s^2 - c_s}$$

where

- s is the cluster number;
- n_s is the number of points in cluster s ;
- $c_s = \sum_{i,j \in s} \frac{\langle x_i, x_j \rangle}{\|x_i\| \|x_j\|}$.

Contrary to most methods, you do not have to specify the number of clusters. You can try to find the configuration with the best likelihood by the usual means (steepest descent, simulated annealing), which is quite time-consuming. The article suggests a faster (less precise) hierarchical algorithm: start with N 1-element clusters, merge two clusters so as to maximize the likelihood, iterate until there is a single N -element cluster, retain the clustering with the best likelihood.

The hierarchical clusterings they get in their two examples are very different: with financial data, single stocks are repeatedly added to already formed clusters, while with biological data, larger clusters are merged.

***Data clustering and noise undressing
of correlation matrices***
M. Marsili, arXiv:cond-mat/0003241

A correlation matrix estimated on a sample (and not on the whole population or from the probability distribution of the random variables) is “dressed in noise”, *i.e.*, not equal to the theoretical one. To see if there is something behind this noise, one can compare the spectrum (*i.e.*, the eigenvalues, sorted from the largest to the smallest) of the correlation matrix with that of the correlation matrix of a sample of uncorrelated gaussian random variables (this is called Random Matrix Theory (RMT) – if your distributions are not gaussian, just resample each vector independently) or that coming from a given model. The proposed model is hidden behind an overly specialized physics’s vocabulary: take n points at random, take k cluster centers at random, assign each point to a cluster at random, drag each point towards its cluster center.

*Noise dressing
of financial correlation matrices*
L. Laloux et al.
arXiv:cond-mat/9810255

*Marginal Contribution to Risk
for GICS industries in Aegis 3.4*
Barra (2004)

To compute and balance the risk of a portfolio of stocks, we use the variance-covariance matrix of the stock returns. As this matrix is huge, we do not estimate each of its coefficients: instead, we assume that the covariances are due to several “factors”; we estimate the variance-covariance matrix of those factors, we estimate the exposure of each stock to those factors (this means: we perform a regression of the returns of stock i against the “factor returns”, the exposures are the coefficients estimated by this regression), we estimate the residual variance of each stock returns and we put everything in a nice formula,

$$V = e'v e + \Delta,$$

where V is the variance matrix of the stock returns, e is the exposures matrix, v is the variance matrix of the factor returns, Δ is the (diagonal) matrix of the residual (aka stock-specific, systematic) variance.

If \mathbf{w} are the weights of a portfolio (as a fraction of the market value of the portfolio), then the risk (aka volatility, standard deviation) of this portfolio is

$$\text{Risk}(\mathbf{w}) = \sqrt{\mathbf{w}' V \mathbf{w}}.$$

The Marginal Contribution To Risk (MCTR) of a stock i is

$$\text{MCTR}_i = \frac{\partial \text{Risk}}{\partial w_i} = \frac{(V \mathbf{w})_i}{\text{Risk}(\mathbf{w})}.$$

Similarly, the contribution of a sector (seen as a portfolio \mathbf{s} to the risk of a portfolio \mathbf{w} is the directionnal

derivative

$$\begin{aligned} \text{MCTR}(\mathbf{w}, \mathbf{s}) &= \lim_{\varepsilon \rightarrow 0} \frac{\text{Risk}(\mathbf{w} + \varepsilon \mathbf{s}) - \text{Risk}(\mathbf{w})}{\varepsilon} \\ &= \frac{\mathbf{s}' V \mathbf{w}}{\text{Risk}(\mathbf{w})}. \end{aligned}$$

(You can do the computations yourself: this stems from the Taylor expansion of $\text{Risk}(\mathbf{w} + \varepsilon \mathbf{s})$.)

But how do we turn a sector into a portfolio? We could take each stock in this sector, with a weight equal to one; we could also weigh them by the market capitalization. Alternatively, if we do not have a single sector but a *partition* of the universe into several sectors, we can try to build a portfolio with unit exposure to the sector we are interested in and zero exposure to the others. This can be done as follows. Let f be the matrix of exposures to your sectors (one row per stock, one column per sector, 1 if the stock is in the sector, 0 otherwise) and δ_j the desired exposure for the sector portfolio (1 in position j and 0 elsewhere). We want a row vector \mathbf{s}_j such that $\mathbf{s}_j f = \delta_j$: it is not unique, but the pseudo inverse of f gives one: $\mathbf{s}_j = (f' f)^{-1} f' \delta_j$.

Actually, these are *not* the formulas mentionned in the article: for a reason I do not understand, they first compute the contribution of their factors to the portfolio risk and then “translate” (yes, they use that word – weird for something that is actually a matrix multiplication) them to the (pseudo-inverse) sector portfolio.

They do not seem to realize that they have forgotten the stock-specific risk in the process. It might be correct if your sector decomposition is coarser than their factor decomposition, but otherwise, it is plainly wrong.

Incidentally, they also forget to suggest what to do with missing values – stocks whose sector is unknown – I suggest to set their exposures to zero.

Finally, they forget to stress the absence of a formula to compute the risk from the contributions to risk – which should not be called “contributions”, after all:

$$\sum_{j \in \text{sectors}} (\mathbf{w}' f)_j \text{MCTR}(\mathbf{w}, \mathbf{s}_j) \neq \text{Risk}(\mathbf{w}).$$

Japanese Equity Model
Barra (1999)

Risk can be decomposed into:

- *specific risk*, associated with individual securities (unless you are a stock-picker, you try to avoid it);
- *common risk factor*, associated with industries and other factors (these correspond to the bets we make);
- *systematic risk*, associated with the market (you cannot avoid it – well, with cash, futures or with no long-only constraint, you can).

The *Capital Asset Pricing Model* (CAPM) is a no-intercept linear regression of the (excess) returns of a stock against the (excess) returns of the market; the

coefficient is called the *beta* of the stock or its *exposure* to the market.

Multi-Factor Models (MFM) are linear regressions of the (excess) returns of a stock against various “factors” (industry, market excess return, oil price, temperature, etc. – you have to choose your own factors).

Arbitrage Pricing Theory (APT) is the use of MFM to estimate the variance-covariance matrix of the stock returns – more generally, a *risk model* is a means of estimating a variance matrix.

There are several types of active investment strategies: *market timing* (sell before the market goes down, buy before it goes up); sector emphasis, stock selection.

Risk models can be used to create a portfolio, to analyze one (check that the risk is where the manager claims it is), or to attribute its performance to the various factors.

This document does not stress the difference between the Barra way of estimating a risk model and others: you always have

$$\text{returns of stock } i = \sum_{k \in \text{Factors}} \beta_{i,k} r_k,$$

but

- Barra estimates the exposures $\beta_{i,k}$ of stock i to factor k and computes the factor returns r_k ;
- Northfield estimates the factor returns and computes the exposures;
- APT estimates the factor returns from the first eigen vectors of the variance-covariance matrix and computes the exposures (this is called a *statistical risk model*: you then have to interpret the various factors – it is also linked to Principal Component Analysis (PCA) and Random Matrix Theory (RMT));
- USB uses a hybrid approach: they start with the factor returns, use them to estimate the exposures, use the exposures to estimate the factor returns, and so on, until convergence.

The document ends with a rather comprehensive glossary.

MNP: R package for fitting the multinomial probit model

K. Imai and D.A. van Dyk, Journal of Statistical Software (2005)

The multinomial probit model models a qualitative variable Y , with values 1, 2,..., n as follows:

W_1, W_2, \dots, W_n are (unobserved, latent) gaussian variables, of unknown mean and variance,
 $Y = \text{Argmax } W_i$

This package fits the model with an MCMC. Before interpreting the results, the article asks us to use the *coda* package to look at the Gelman–Rubin convergence statistic (numerically and graphically), to look at the time series of the sampled parameters, to look at the distribution of those parameters.

The appendix also explains how to set-up a “local library directory”.

BugXLA: Bayes for the Common Man **P. Woodward, Journal of Statistical Software (2005)**

This is an Excel interface to WinBugs – but they seem to completely forget the convergence problem...

Calling the lp_solve linear program software from R, SPlus and Excel **S.E. Buttrey, Journal of Statistical Software (2005)**

There is another, faster, more reliable R package for linear and mixed integer programming (MIP), *lpSolve*; it relies on the free (LGPL) *lp_solve* library.

The article insists on the Excel interface and the fact that it yields the right result, contrary to Excel.

...
 ??. ? et al. (????)

This article explains how to perform a “regression with time-varying parameters”. The main difference with my current implementation is:

- They assume the parameters are AR(1) processes, I assume they are random walks.

There are other, minor differences:

- They take sensible initial values for the estimation of the coefficients, I take 0;
- They give the p -value of a Likelihood Ratio (LR) test to check if the parameters are indeed varying (but to compute it, they have to know the “number of degrees of freedom” of the model with time-dependant parameters – I am not sure how they estimate it);
- Their Kalman filter seems to be univariate;
- They forget to check that their data look gaussian, that the residuals look gaussian and iid.

Random matrix approach to cross-correlations in financial data

V. Plerou et al., Phys.Rev.E 65 066126 (2002)

Another article on the same subject:

- The bulk of eigenvalues is consistent with RMT (they look at the distribution of eigenvalues, at the distance between two adjacent eigenvalues (nearest neighbour spacing), at the next nearest neighbour spacing – and another quantity I do not understand);
- There are no significant negative correlations;
- The largest eigenvalue represents the market;
- The next eigenvalue represents the logarithm of the capitalization;
- The next eigenvalues represent sectors (they provide a formula to estimate the number of significant stocks in a normalized eigenvector: the inverse of the sum of the fourth power of the coordinates);
- The smallest, non-significant eigenvectors correspond to correlated pairs;

- Eigenvectors with large eigenvalue are stable over time (for this, they compute the *overlap matrix*, whose (i, j) element is the scalar product of the i th eigenvector at time t with the j th eigenvector at time $t + T$; discarding the smallest eigenvalues, *i.e.*, using a (statistical) risk model to optimize a portfolio yields more reliable risk and returns forecasts.

Shortcomings in advise versus the art and science of investing in hedge funds
G. Susinno, 2005

Risk models are ways of reliably estimating variance-covariance matrices. *Statistical risk models* proceed as follows: compute the variance-covariance matrix, diagonalize it and zero out the lowest eigen values. *Random matrix theory* tells us how many eigen vectors to retain: compute the variance matrix obtained after shuffling each time series, repeat several times to get an idea of the distribution of the eigen values.

To visualize this correlation matrix, turn it into a distance matrix and draw the *Minimum Spanning Tree* (MST) – when distance analysis and clustering fail to bring any insight on the data, MST often prove enlightening and can highlight the structure of the data. (The author tries hard to impress the reader by using the words “ultrametric distance” – an *ultrametric distance* is just a distance measured on a tree.)

The author falls into (at least) two traps. First, even though he stresses the non-gaussianity of the data, the lack of *power* (he does not seem to know that word) of gaussianity tests, he uses the eigen value distributions for gaussian random matrices, instead of the permutation-based tests. Second, the permutation-based tests assume that in the initial time series, consecutive observations were independent – a suspicious assumption.

Risk premia on european sectors
K. Reimer and H. Berster, Commerzbank,
april 2005

One can also use the Residual Income Model (RIM) to compute the

risk premium = k – risk-free interest rate.

EROS (Expected Returns on Stocks)
K. Reimer and H. Berster, Commerzbank,
april 2005

They have 3 ideas:

- Use the *Residual Income Model* (RIM) to compute the “market expectation of returns” k , remark that it has a very high rank correlation with future returns (IC, Information Coefficient) and use it to optimize a benchmark;
- Compute a *value* measure, as a forcefully normalized expected *divident yield* over the next 5 years, corrected to account for the end of the fiscal year;

- Similarly compute a *growth* measure, as the annual *earnings growth*; Use those two measures to interpret the portfolio.

This “forceful normalization” has a drawback: it allows you to compare individual stocks or sectors to the whole market, but does not give you any information for the market as a whole – its growth and its value are, by definition, zero.

The succinctly recall how the Residual Income Model (RIM) works:

- If the risk-free interest rate is high, investors will only invest in companies with a higher prospective return: the price of the companies will depend on the current risk-free interest rate – more precisely, it will depend on the current “interested rate” or desired return, k , for investments providing a similar risk profile.
- The price of a given company will also depend on its Return on Equity (RoE).

The RIM sums this up:

$$\text{Fair Value} = BV_0 + \sum_{t=0}^{\infty} BV_{t-1} \frac{RoE_t - k}{(1 + k)^t}$$

where

BV_n = Book Value in n years
 RoE_n = Return on Equity in n years

The difference $RoE - k$ is called *abnormal earnings* or *residual income*.

Of course, one has to provide a mode for the evolution of the book value BV_n and the returns on equity RoE_n – the article does not give any detail and simply mentions a “three-stage model using IBES consensus forecasts”.

We know neither the fair value nor the desired return k , but if we replace the fair value by the current market price, we get a market estimation of the desired return k .

Longitudinal and Panel Data: Analysis and Applications for the Social Sciences,
E.W. Frees, Cambridge University Press, 2002

Chapter 1 presents and motivates the subject, longitudinal data: it is a mixture of regression and time series analysis:

- Instead of studying a single time series, we study several at the same time; *i.e.*, we have several realizations of a stochastic process.

- We investigate a relation $y = \alpha + \beta_1 x_1 + \beta_2 x_2 +$ noise that evolves with time: α , β_1 , β_2 may change with time. This could suggest a 2-step procedure: for each t , estimate the coefficients $\alpha(t)$, $\beta_1(t)$, $\beta_2(t)$; then study the resulting time series. Longitudinal data analysis is a similar but reliable, 1-step procedure. The noise is often called *subject-specific dynamic pattern*.

Chapter 2 lists the plots used to investigate longitudinal data:

- density estimation (histogram, etc.) of each variable and evolution with time (violin plot, lattice plot);
- $y \sim x_i$ for the whole period and its evolution over time (in a lattice plot or as paths on a single plot);
- Time series of each variable for each subject (or group of subjects);
- Added variable plots, discarding the effects of time $y_i(t) - \bar{y}_i \sim x_i(t) - \bar{x}_i$, of the other variables $\text{lm}(y+x_2+x_3)\$res \sim \text{lm}(x_1 \sim x_2+x_3)\res , or of both

the possible temporal covariance matrices (independent, AR(1), AR(T)) and lists a few tests: e.g., you no longer test the *influence* of an observation (as with the Cook distance, in classical regression) but that of a whole subject on the regression results.

Chapter 3 motivates *random effects* and *mixed effects models*: the observations are grouped (various subjects (stocks) are studied over time, thus we have several observations per subject) but the subjects do not represent the whole population: we want to take into account the variations between subjects and to be able to extend the results to the whole population – to this end, we provide a model for the *subject-dependant parameters*. Those parameters (aka *nuisance parameters* or *random effects*), are themselves random variables, e.g.,

$$\begin{aligned} y_{i,t} &= \alpha_i + \beta x_{i,t} + \varepsilon_{i,t} \\ \alpha_i &\sim N(\mu, \sigma) \\ \varepsilon &\sim N(0, 1) \end{aligned}$$

Random effects can be computed as a Generalized Least Squares (GLS: like Ordinary Least Squares (OLS), but the noises can be correlated and/or heteroskedastic) problem (but you have to know the variances of the parameters: estimate them as you can). Restricted Maximum Likelihood (REML) provides better, less biased results than ML – but for tests, only use ML.

Chapter 4 stresses the difference between *estimators* (of the fixed effects) and *predictors* (of the random effects); predictors are actually *bayesian* Maximum Likelihood estimators, because we have a *prior* distribution for them – or, at least, a model for that distribution.

Chapter 5 generalizes the previous models to (multi-level) hierarchical models; they are still estimated as a single GLS problem, with a more parsimonious covariance structure. One should beware of the tests of hierarchical models: the usual ones are no longer valid, especially tests about the covariance.

Predictive variables in a regression can either be *stochastic* (i.e., random variables) or deterministic (e.g., fixed by the experimenter). Chapter 6, very technical, details the properties those stochastic predictive variables should have for a mixed model estimation to be valid. Problems appear, for instance, when you include the lagged variables to predict as a predictor or when the predictors are autoregressive.

Chapter 7 lists a few dangers of panel data models:

- If the model is too complicated, different elements of the model can lead to similar effects, making the model *unidentifiable*;
- You should account for (or beware of) omitted variables (subject-dependant, sector-dependant, time-dependant);
- You should account for missing data (discarding missing observations or imputing them can lead to suboptimal results).

Chapter 8 tackles dynamic models: if you want to use your model to forecast future values, spotting changes in the model is pivotal. Dynamic changes can be included in the model in several ways:

- add the time as a predictive variable (this works fine if its effects are linear);
- use the discrete derivatives of the variables;
- Allow for serial correlations (AR(1), etc.) in the noise;
- Allow for time-varying parameters;
- Include the lagged variable to predict as a predictor;
- *adapt* the Kalman filter.

The authors details the Kalman filter example (with the CAPM), unfortunately hiding the ideas behind complicated formulas. The important thing to note is that you should *not* proceed in two steps, first computing cross-sectionnal regression, then applying a Kalman filter on the coefficients, but instead *adapt* the Kalman filter to the model.

Chapter 9 focuses on logistic regression (i.e., predicting binary variables): here, for technical reasons, we need to replace the Maximum Likelihood Estimation (MLE) by *conditional MLE*. This chapter also succinctly presents the Generalized Method of Moments (GMM), aka Generalized Estimating Equations (GEE) – if you do not want to estimate the random effects but just their first two moments.

Chapter 10 presents the General Linear Model (GLM) and delves into the details of the GMM/GEE method (forgetting to state the ideas and instead giving equation after equation). I still have not understood what it is. As an example, they apply the Conditionnal MLE to the Poisson regression.

Chapter 11 tackles the case of a qualitative variable to predict, which can be treated as a multinomial regression problem or as a Markov chain one. In the middle of this chapter, they also mention the generalized Extreme Value Distribution (EVD) – but I do not know why. The slides do not mention survival models, but they appear in the book.

Mixed-Effects Models in S and S-Plus
J.C. Pinheiro and D.M. Bates
Springer Verlag, 2000

This is the official documentation of the R `nlme` package, that deals with mixed data, such as:

- Grouped data: several observations of one (or several) variable(s) for each subject, the subjects being partitioned into groups (and the groups can themselves form groups of groups);
- Longitudinal data: one (or several) variable(s) observed several times for each subject, at different points in time;
- Panel data: idem, but the observation times are the same for each subject, so that you can put the data in tables, one subject per row, one date per column;
- Repeated measures: several observations for each subject;
- Blocked design: several experiments (“experiment factor”) on several subjects (“block factor”);
- Split-plot design: idem;
- Multilevel data: each subject is in a group, each group is in a group of groups, etc.

These models could be written as:

```
y ~ x | subject/group
y ~ time | subject
y ~ 1 | subject
y ~ experiment | subject
y ~ 1 | subject/group
```

Chapter 1 is an overview of mixed models. When facing a new data set, you often assume that the observations are independent. But this is not always the case: in particular when you have several observations for each “subject” (a stock, in finance, a patient, in medicine), the observations for a given subject will be correlated. The same problem occurs if the subjects form several groups: the observations in a given group will be correlated.

One solution is to consider that the parameters to be estimated depend on the subjects, e.g. (this is a *fixed effects model*),

$$y_{it} = \alpha_i + \beta x_{it} + \text{noise}_{it}$$

Estimate: $\beta, \alpha_1, \alpha_2, \dots, \text{Var}[\text{noise}]$.

Alternatively, we can consider that the α_i are not parameters but random variables, following iid gaussian distributions (this is a *mixed effects model*):

$$y_{it} = \alpha_i + \beta x_{it} + \text{noise}_{it}$$

Estimate: $\beta, E[\alpha], \text{Var}[\alpha], \text{Var}[\text{noise}]$.

This is often preferable because there are fewer parameters and we can meaningfully extrapolate to subjects that were not included in the study.

This is a partly bayesian point of view: we have a prior on α (but not on β , and we take a Maximum Likelihood Estimator, which is very unbayesian).

Chapter 2 presents the underlying theory. In the following expression,

$$y_i = [X_i | Z_i] \begin{bmatrix} \beta \\ b_i \end{bmatrix} + \varepsilon_i$$

$$b_i \sim N(0, \Psi)$$

$$\varepsilon_i \sim N(0, V)$$

y_i, X_i, Z_i are known and we want to estimate β, Ψ and V . The coefficient β is said to be a *fixed effect* while b_i is a *random effect* – the word “effect” means “estimated parameter”.

This can be done by Maximum Likelihood (ML),

Likelihood(variance structure, parameters | data),

which produces biased estimates, or with Restricted Maximum Likelihood (REML): the restricted likelihood is the likelihood with the parameters integrated out; we use it to estimate the variance structure, and then, we plug this back into the likelihood to estimate the parameters.

From a computational point of view, one can first use the *EM* (Expectation–Maximization) method, that considers the random effects as unobserved (missing) variables (it goes very fast to the neighbourhood of the optimum, but then converges very slowly) and then the good old *Newton–Raphson* method (it converges fast when it starts close to the optimum).

The parameters are asymptotically gaussian, so one can use AIC, BIC and Likelihood Ratio (LR) tests (but you had better only use them to compare two models if the fixed effects are the same).

Chapter 3 presents the R functions to explore grouped data, fit mixed models and assess those models. For instance,

`lme(y~x, random= ~ 1 | subject/group)`

fits a model in which the slope is a fixed effect, the intercept is a random effect that depends on the two variables `subject` and `group`. If we wanted both the

slope and the intercept to be random, we would have typed (remember that when you write a model, the intercept is always implicitly included: we need not mention it)

```
lme(y~x, random= ~ x | subject/group)
```

or

```
lme(y~x, random=list(subject=~x, group=~x))
```

If you want your data to be easily plotted, with functions from the `lattice` library, you can store them in a `groupedData` object, that contains the data (as a data frame), a display formula (e.g., `y~time|subject`), “outer factors” (i.e., groups of subjects, e.g., `outer=~sex` or `outer=~Variety*Year`) and “inner factors” (i.e., other qualitative predictive variables, e.g., `inner=~Treatment`).

You might also want to investigate the functions `gsummary`, `intervals`, `augPred`, `plot.lme`, `summary.lme`, `VarCorr`, `lmList`, `simulate.lme`, `balancedGrouped`.

Chapter 4 suggests a model building strategy:

1. Fit a usual regression without taking the `subject` variable into account; look at the residuals in each `subject` (with a boxplot): if they are significantly different, this might warrant a mixed effects model with the `subject` variable. but we still do not know which effects should be fixed and which should be random.
2. Fit a regression for each subject, with the `lmList` function; look which coefficients vary a lot between subjects, with the `plot(intervals(...))` function: they will be your random effects; you may also want to look at the pairplots of the estimated coefficients, to get an idea of the covariance structure Ψ of the random effects.
3. Fit the model and examine it: boxplot of the residuals for each subject (to see outlying subjects), residuals vs fitted value (to check if there is a difference between groups: if so, add this new grouping variable), quantile-quantile plots of the residuals; also remember to check for heteroskedasticity and correlation problems.
4. Do not only look at the residuals: similarly, look at the random effects: quantile-quantile plot, pairplot (to see if you should add a coarser grouping variable, as above; and also to check if your assumptions about the covariance matrix were not unreasonable).

Chapter 5 explains how the covariance of the random effects (the Ψ matrix) can be specified. There is first the correlation structure among the random effects (investigated with the pair plots mentioned earlier). If you do not specify anything, the computer assumes that the covariance matrix has no remarkable property. If they are independent:

```
random=list(subject=pdDiag(~x1+x2+x3))
```

Other examples:

```
pdIdent(~ x1+x2+x3)
pdDiag(~ Variety-1)
pdCompSymm(~ Variety-1)
pdBlocked(list(~1, ~x1+x2+x3-1))
pdBlocked(list(pdIdent(~1), pdIdent(~ Variety-1)))
```

You should also tackle heteroskedasticity (the V matrix); e.g., if the variance of the noise depends on the `group` variable, you can say

```
weights=varIdent(form= ~ 1 | group)
```

But the general situation is more complicated: to simplify it, we decompose the noise variance matrix V into a variance component (a diagonal matrix, that will account for heteroskedasticity in the noise term) and a correlation component (a positive definite matrix with 1s on the diagonal, that will account for the lack of independence of the noise term), and we specify them separately.

Here are a few examples, to be given to the `lme` function as a `weights` argument.

The variance increases linearly with age:

```
varFixed(form= ~age)
```

The variance is constant in each group:

```
verbvarIdent(form = 1|group)
```

The variance increases linearly with the fitted values:

```
varPower(fixed=.5)
```

The variance increases linearly with the fitted values for one group only:

```
varPower(form= ~fitted(.) | Sex,
          fixed=list(Male=.5, Female=0))
```

There are other functions: `varExp`, `varConstPower`, `varComb`.

And now, the correlation structures, to be fed to the `lme` function as a `correlation` argument.

Compound symmetry: two observations for the same subject have a 0.3 correlation.

```
corCompSymm(value=0.3, form=~1 |Subject)
```

A general correlation matrix:

```
corSymm(form = ~ 1 |Subject)
```

An AR(1) correlation structure (by default, the order is that in which the observations appear – see also the `ACF` function):

```
corAR1(0.8, form = ~ 1 | Subject )
```

A continuous AR(1) correlation structure (the coefficient will be positive):

```
corCAR1(0.8, form = ~ time | Subject )
```

An ARMA correlation structure:

```
corARMA( c(.8, .4), p=1, q=1,
          form= ~ 1 | Subject )
```

There are also spatial correlation structures (see also the `plot(variogram(...))` function:

```
corExp( 1, form = ~ x + y )
corGauss(...)
corLin(...)
corRatio(...)
corSphere(...)
```

This chapter also presents the `gls` function (Generalized Least Squares), to fit (non-mixed) heteroskedastic linear models – because *the correlation structure and*

the heteroskedasticity can have the same effects and therefore specifying both can lead to unidentifiability. People often wonder how to tackle heteroskedasticity in R: this is one solution.

Part 2 (I have not carefully read it) tackles non-linear models: you should use them when you know the mechanism producing the data (this is often the case in chemistry) or when the data has natural properties, such as an asymptote. Otherwise, stick to linear models – with splines or local regression, if needed.

One limitation of the `nlme` package is the fact that, if we have several grouping variables, they have to be nested – but you can imagine mixed models in which they are not.

Another limitation is that it does not include Generalized Linear Models (GLM) such as logistic or Poisson regression: for those, you might want to have a look at `glmML` in the `glmML` package for GLM with a random intercept; `GLMM` in the `lme4` package for mixed GLM via REML; `glmPQL` in the `MASS` package (idem); `gee` in the `gee` package.

The under-hyped `lme4` package contains other interesting functions, such as the `lmer` function (a revised version of the `lme` function), that allows for nested and crossed random factors. The syntax for the mixed effects is the “natural” one:

$y \sim (x1 \mid g1) + (x2 \mid g2)$

Incorporating estimation errors into portfolio selection: robust portfolio construction
S. Ceria, R.A. Stubbs, 2005

Modern Portfolio Theory (MPT) works as follows: estimate the returns and the volatility of each stock, then try to find the combination of stocks (“portfolio”) with the highest return among those whose volatility is within the limits imposed by your clients.

$$\begin{aligned} &\text{Maximize } \alpha^T w \\ &\text{Subject to } w^T Q w \leq v \end{aligned}$$

where α are the predicted returns, Q is the covariance matrix of the predicted returns, v is the maximum volatility allowed, w is the portfolio composition (to be found).

This is a *quadratic optimization problem*: the set of feasible solutions is convex, with sharp edges (sharp because of the linear constraints we do not mention) and the best solution will be on one of its vertices. When we slightly change the inputs, the solution may switch from one vertex to another.

Several solutions to overcome the imprecision of returns forecasts have been proposed:

- shrink them towards the average expected return (James–Stein);
- shrink them towards that of the minimum variance portfolio (Jorion);

- Adopt a bayesian approach (Black–Litterman);
- Increase the risk-aversion parameter (Horst);
- Resample (Michaud) – if you have time and no non-convex constraints, such as a limit on the portfolio size or a minimum investment per asset.

The idea of robust optimization is:

$$\begin{aligned} &\text{Maximize } \text{Min}\{\alpha^T w, \alpha \in B(\bar{\alpha}, r)\} \\ &\text{Subject to } w^T Q w \leq v \end{aligned}$$

where $\bar{\alpha}$ are the return forecasts,

$$B(\bar{\alpha}, r) = \{\alpha : (\alpha - \bar{\alpha})^T \Sigma^{-1} (\alpha - \bar{\alpha}) \leq r^2\}$$

is an ellipsoid, centered on $\bar{\alpha}$, containing the actual forward returns and α are the worst-case returns in this ellipsoid. The magic is that one can actually compute that minimum:

$$\text{Min } \alpha^T w = \bar{\alpha}^T w - r \|\Sigma^{-1} w\|.$$

We thus have a new convex optimization problem – but it is no longer quadratic: we need either a general convex optimization algorithm or a “symetric second order cone optimizer”.

This was the general idea, but it still has to be refined. Two problems are:

- We are too conservative, we have assumed that the errors were always in the worst direction;
- This approach only works for long-only portfolios.

We can introduce a “bayesian prior” (they claim they do not like bayesian methods, but it is what they are doing) as a new constraint, stating that the upward and downward errors should cancel each other (but you can refine this, to account for the larger number of overestimated returns and for the volatility).

Axioma, the future of risk analysis, rebalancing and trading analytics
D. Cashion (2005)

Mean-Variance Optimization (MVO) consists in taking a set of assets, with their predicted returns and estimated volatility and building the portfolios with a given volatility, the maximum expected return, satisfying a set of constraints (e.g., long-only, at most 2% in each stock, etc.). The problem is that the computer assumes that the predicted returns are accurate while they are not: if we change them a bit, the resulting portfolios can drastically change. The reason is that the possible weights of the various assets in the portfolio form a convex set, with sharp vertices, and the result portfolio is on one of those vertices: when we change the inputs, either we stay on the same vertex, or we switch to another one.

Instead, Axioma incorporate uncertainty in the inputs, they replace exact values by intervals (ellipses, actually) of possible values; this amounts to bevel the vertices of our convex set.

They also add discrete heuristic algorithms for rules such as “maximum number of holdings” or “minimum holding”. if-then-else rules, etc.

***The generalized dynamic factor model:
representation theory***
M. Forni and M. Lippi

Here are a few ideas to study panel data:

- Consider the time series one at a time – but this will not account for the correlation between the time series;
- Use a VAR model – but this will only work if you have few subjects: we have thousands of them;
- In the *dynamic factor analytic model*, aka *index model*, there are (latent) orthogonal variables $f_1(t), \dots, f_n(t)$ and, for each subject, the variable studied is a linear combination of those factors plus an *idiosyncratic component* (aka *subject-specific dynamic pattern*), orthogonal to the factors and pairwise orthogonal among them,

$$x_i(t) = \beta_1^i f_1(t) + \dots + \beta_n^i f_n(t) + \varepsilon_i(t)$$

- You can also add in the lagged factors;
- Finally, you can remove the requirement that the idiosyncratic factors be pairwise orthogonal to account for, e.g., shock propagation.

This last model is the *generalized dynamic factor model*.

But how do yo estimate the coefficients of the model? Well, you do not. However, a preceding article, by the same author, explained how to infer the number n of factors and this articles states that the common component $x_i(t) - \varepsilon_i(t)$ is the projection of the signal on the first n “*dynamic principal components*” – but I have not understood what it meant.

TODO: Explain “dynamic Principal Component”.

***Linear regression with errors in both variables:
a proper bayesian approach***
T.P. Minka, 1999

Linear regression focuses oin the relation between (say) two variables, e.g., $y = \alpha + \beta x + \text{noise}$: we assume that there is a simple, deterministic relation between x and y and that y is observed with errors. But what if x is also measured with errors? You can:

- Forget about those errors if you just want to predict y from the imprecisely measured x ;

- Try more symetric methods, such as Principal Component Analysis (PCA): it gives you some insight as tp the relation between x and y , put focuses on the joint distribution $p(x, y)$, not the conditional distribution $p(y|x)$ – do not use it for predictions;
- Account for those errors with an EIS (Error In Variables) regression: we have a relation $y_0 = \alpha + \beta x_0$ but we can only measure $y = y_0 + \text{noise}$ and $x = x_0 + \text{noise}$ and we want to find α and β – we do not want to make forecasts, just to study the mechanisms behind the data.

The article presents three EIS estimators:

- TLS (Total Least Squares): write the likelihood (which depends on α, β and x_0), replace x_0 with its most probable value and find α and β by the values that maximize the likelihood;
- Maximum Likelihood (ML): integrate x_0 out of the likelihood and maximize this marginal likelihood;
- Posterior Mean: the posterior distribution tends to be bimodal: the ML estimator is not stable; we replace it by the expectation of the posterior distribution of (α, β) .

***Liquidity and autocorrelations in individual
stock returns, D. Avramov et al., 2005***

When an investor wants to buy or sell a large amount of a given stock, the price will rise or drop for a short moment and then revert to normal. Seemingly profitable contrarian trading strategies can stem from this phenomenon. To check wether they are profitable, the article combines

- Past returns;
- Illiquidity (defined as

$$\frac{|\text{returns}|}{\text{traded value}}$$

or as the average ask/bid spread);

- Turnover

to define their strategy, equally weighted or “relative strength”-weighted (more weight on the stocks whose recent returns were high) and estimates the transaction costs (in three ways, but the only detailed one is the ask/bid spread). In the end, the strategy is not profitable, the Efficient Market Hypothesis is not violated.

In other words: “non-informed trading is accompanied with high trading volume, informed trading is accompanied with low trading volume” – “changes accompanied with high volume revert”, “changes accompanied with low volume need not revert”.

**Panel data models for stock returns:
the importance of industries
R. Bauer et al, LIFE, 2003**

In finance, to study a factor, *i.e.*, a variable suspected of providing some insight into future returns, one usually uses the non-parametric (“non-parametric means that it does not rely on statistical assumptions that one could forget to check – it is fool-proof”) *portfolio method*: build five portfolios, each containing the stocks in one quintile of the variable and monitor their returns. This can be generalized to two factors – but not more: beyond that, many fractiles would be empty...

Instead, in order to include more variables, people have tried regression (often forgetting that there are assumptions to be checked, at least graphically, before performing the analysis, and forgetting to assess the quality of the results, *e.g.*, with diagnostic plots). But financial data is inherently bidimensional, *i.e.*, the variables we play with do not form vectors but rather 2-dimensional arrays, one stock per row, one date per column. One can forget this 2-dimensional structure and compute the usual (“Ordinaly Least Squares” or OLS) regression. But by doing so we discard some of the information available.

Instead, we can slice the data and consider one date (column) at a time, compute the regression coefficients for each date (people say “cross-sectionnally”) and take the mean of those regression coefficients: this is the *Fama-McBeth regression*; it takes into account the unbalancedness of the data.

But this suggests that the quality (variance) of the estimation of the regression coefficients is the same for each date – this need not be the case. We can estimate this variance and take it into account by computing a weighted average of the coefficients (the weight of a given coefficient at a given date is the inverse of its estimated standard deviation): this is called *weighted regression* or *weighted least squares*.

But we still have a problem: we assume that these regression coefficients are constant over time – this is surely wrong. To take this effect into account, we must leave the realm of DIY statistics and enter that of *mixed models*. We can then consider regressions of the form

$$\text{return} = \alpha + \beta \cdot \text{factor} + \text{noise}$$

where the regression coefficients α and β may themselves depend on other data, say:

$$\alpha \sim \text{stock} + \text{industry} \times \text{time}$$

$$\beta \sim \text{industry}$$

$$\text{noise variance} \sim \text{time}.$$

This is the example detailed in the article (with two differences: they have a dozen factors instead of one and they assume that the variance is constant), but you may change it as you want.

The numerical estimation of the parameters of those mixed models used to be very intricate (that is why

some people still use “Fama-McBeth regression” or “weighted least squares”) but, luckily, R can now do that for us.

The article also remarks that statistical tests with a 5% confidence level are useless in this context, because the huge volume of data leads to very small p -values. Instead, they use the Schwartz Information Criterion (SIC). We already mentioned this problem when we studied Bayesian Model Averaging (BMA) – we had used the Bayesian Information Criterion (BIC), aka Schwartz Bayesian Criterion (SBC).

**VWAP reversion
S. Usui, Nomura, 2004**

They propose the following (intraday) investment strategy:

- If $\text{index} \gg \text{15-minute VWAP} \gg \text{60-minute VWAP}$, then long the index;
- If $\text{index} \ll \text{15-minute VWAP} \ll \text{60-minute VWAP}$, then short the index.

where VWAP is the volume-weighted average price – it is a replacement of the moving average, better-suited for intra-day data. This is just a refinement of the strategy:

- If $\text{price} \gg \text{Moving Average}$, then buy;
- If $\text{price} \ll \text{Moving Average}$, then sell.

that relies on the belief that the price is mean-reverting – the refinement selects periods when the price has a significant upward (respectively downward) trend, visible both on the 15-minute VWAP and the 60-minute VWAP.

They motivate this strategy by a linear relation between (price – 15-minute VWAP) and (15-minute VWAP – 60-minute VWAP). Here, of course, regression is a bad idea: first the data are not normal (they are fat-tailed), second, regression is asymmetric (you try to predict one variable from the other) while the strategy is symmetric (if you want a plot, draw the first principal component, if you want a test, a simple correlation test would do).

They try to tune their strategy by modifying the thresholds above which those inequalities trigger the trades, but:

- They do not tune the time parameters (15 minutes and 60 minutes);
- Their tuning is not adaptive.

Trading Securities Using Trailing Stops
P.W. Glynn and D.L. Iglehart,
Management Science, 41:6 (1995)

To avoid losses, one can sell whenever the price (of a stock you have bought) goes to far away (say, \$5) below the previous maximum. The article investigates, from a theoretic point of view, the time you hold the asset, the return, the “best” limit to choose – under the unrealistic assumption that the price follows a random walk with a constant linear trend, oblivious of the fact that those stop-loss rules are designed to get rid of stocks that do not follow our model or to spot a change in the model.

High frequency data filtering
T.N. Falkenberry, TickData Inc. (2002)

High-frequency data may be unclean, even more so than traditional data because the sheer volume of data prevents their efficient automatic (or manual) detection.

The “errors” can be: isolated bad ticks, bad ticks in succession or real outliers (to be retained, otherwise we would build a model on data with an unrealistically low volatility).

The errors may be obvious at some scale but not at larger scale.

To automatically detect some of those errors, you may remark that:

- The tick frequency depends on the capitalization and on the volume;
- The tick frequency depends on the time of the day and the capitalization (constant accross the day for small-caps, constant accross the day except for an opening peak for mid-caps, U-shaped for big-caps).

The filter they provide takes into account: those different tick frequency profiles, changing volatility, overnight gaps.

They do not give any detail, but the filter could look like:

- Compute a MA and a moving standard deviation; start anew every morning to accommodate overnight gaps; if the standard deviation is too low, set it to 2 ticks;
- If a point is more than 3 standard deviations from the moving average, tag it as a bad tick; you may want to change the threshold;
- If the last tick was a bad tick and you would like the current tick to be a bad tick as well, don’t, and reinitialize the moving average and the moving volatility; you may want to modify this rule to accommodate repeated bad ticks (they would be equal);

- Replace bad ticks with ticks with the same volume and the preceding price.

Predicting Returns with Financial Ratios
J. Lewellen, 2003

To test if a factor x has a predictive power on the returns r , one usually uses Ordinary Least Squares (OLS, aka “classical regression”), even if the method’s hypotheses are not satisfied. But the model is often:

$$r_n = \alpha + \beta x_n + \varepsilon_n$$

$$x_{n+1} = \phi + \rho x_n + \eta_n$$

$$\text{Cor}(\varepsilon, \eta) = \gamma.$$

With just the first two equations and independent noises, OLS regression and tests give correct answers, but with the last equation, the results are biased towards predictability.

The article, oblivious of other methods, such as Maximum Likelihood Estimators (MLE), tries to *force* OLS into that framework and derive reliable tests.

Natural SelectionTM: Matching strategies to assets
Evolutionary Finance Ltd, June 2003

They present an investment strategy design software, based on “patented” genetic algorithms (it seems to be a UK company: software patents are illegal in Europe...), that proceeds as follows.

- Take a set of possible investment strategies, each yielding a “buy/sell” signal (they give an extensive list of such signals);
- Combine those strategies to find the “best mixed strategy” at a given time, for a given universe, for a given horizon;
- Given the history of those “best” strategies, try to predict the next best strategy.

There are a few problems:

- They do not explain how to *combine* strategies – this is the heart of the algorithm.
- Using *the* previous best investment strategy to predict the next best one means that you discard all the information about strategies almost as good as the best – the actual best strategy is sample-dependant, you surely do not want to discard all the information contained in the near-best strategies.
- They do not explain how they use genetic algorithms in the second step, to predict the next best strategy; one could use straightforward bayesian methods or a Markov chain: is there more than that?

Backtesting a strategy often suffers from a serious bias: it selects a strategy adapted to the backtest period, not to the present or to the future. The author advocates methods able to detect *regime shifts* – such as their evolutionary models.

***Detecting a currency's dominance or
dependance using foreign exchange network
trees***

M. McDonald et al. arXiv:cond-mat/0412411

This article applies “*distance analysis*” fo financial data. There are a few differences fromn the classical, idealistic situation you might be used to.

- Oftentimes, distance analysis simply does not work. In order to actually see something, you can compute and plot the *Minimum Spanning Tree* (MST) of the data. This is actually a crude, 1-dimensional form of “local distance analysis” – if you want more about this, have a look at the *isomap* algorithm.
- There are more missing data than usual. The distances are computed from a correlation matrix (there are several ways of doing so, e.g., $d = \sqrt{1 - \text{cor}}$ or $d = \sqrt{1 - |\text{cor}|}$). When you compute a correlation matrix, you have to remove all the observations (here, the dates) for which at least one value is missing – it you just remove the pairs for which one value is missing, you might not get a positive definite matrix.
- As the data are exchange rates, both USD/EUR and EUR/USD are present: with the chosen distance, the two points will be very far apart.
- The fact that the product of the exchange rates of any three currencies, say USD/EUR, EUR/JPY, JPY/USD, is 1 imposes some structure on the tree. To see if this structure dominates or if the resulting tree contains more information, they suggest to resample one (only one) of the currencies and to compare the two trees.
- They also check, visually, that the relations between the various exchange rate returns are linear.
- They check if lagged correlations contain some information: for hourly exchange rate data, there is none. If there were, we would depict the corresponding relations by a *directed* graph.
- They also investigate the sability of the tree over time (by looking at the edges that remain).

I did not read the book but just three extra “chapters” available on the Web (<http://www.bio.ic.ac.uk/research/mjcraw/statcomp/chapters.html>). The first one is about *gamma regression*, i.e., linear regression with (non normal) gamma-distributed noise: you use it when the relation looks linear but the noise is asymeric – however, the motivation and example they give could be dealt with a simple transformation ($1/y \sim 1/x$) – quite confusing.

The second chapter, about Generalized Additive Models (GAM) was superficial but fine.

The third chapter was the most confusing: they state that PCA and Factor Analysis are different but give the same interpretation (why, then, are the results different? Which method should we choose in which situation?); they mix up *supervised learning* (in *discriminant analysis* we know the classes beforehand we do not try to find if there are classes, how many there are or how to interpret them, as the author sometimes (but not always) seems to think) and *unsipervised learning*.

Neither buy nor even read that book!

Global Financial Data Products
M. Bulsing and A. Scowcroft
UBS Investment Research, April 2002

A badly written article (the abstract is too long, contains too many technical terms; there is no distinction between the data that come from the data sources and the data that has been computed from the data sources; etc. – the preceding article used marginal notes to improve readability: this was a good idea) that tries to explain what can go wrong when you handle financial data:

- multiple data sources, with multiple conventions;
- data cascades (you take data from one source, perform some computations, combine the result with another data source, perform some more computations, etc.);
- mis-aligned data: “monthly data” can be “data at the end of the month”, “data at mid-month”, “data smoothed across the month” – furthermore, corporate events might occur within the month;
- Market capitalization requires the “number of shares”, which fluctuates daily (because of options, for instance): data sources update this more or less continuously;
- Currency problems (not read);
- Models: as data providers, they try to add some value to the data they provide, by performing some computations, based on models; they must

include enough variables in those models but not too many.

They favour a model with:

- the market return
- a factor (“yield”), for which they provide several formulas, each corresponding to a given “style” – they state the problems posed by each factor;
- the sector;
- the region (considering the country would lead to too many classes).

They do not mention the problem of missing data, of outliers, of errors and sanity checks, of unsatisfied normality or linearity assumptions in their regressions.

Active Return is Ambiguous

M. Partridge at al.

UBS Investment Research, August 2003

There are several definitions of “active return” (*i.e.*, “difference” between the return of your portfolio and that of a benchmark), but the most widely used have a few problems:

- They are not transitive: if they say that portfolio A is better than portfolio B and that portfolio B is better than portfolio C, they need not say that portfolio A is better than portfolio C;
- They can be incoherent and state that portfolio A is better than portfolio B *and* that portfolio B is better than portfolio A;
- They do not give the same result if you use monthly or daily data: they can say that portfolio A is better than portfolio B if you look at monthly historical prices and the opposite if you look at daily prices (these are fixed portfolios, not investment strategies: the portfolios are not rebalanced).

The definitions are as follows (active return, index dif-

ference, compounded return, log-return, index ratio):

$$\begin{aligned}\alpha_{\text{active}}(A - B) &= \sum_t \left(\frac{A_{t+1}}{A_t} - \frac{B_{t+1}}{B_t} \right) \\ \alpha_{\text{diff.}}(A - B) &= \prod_t \frac{A_{t+1}}{A_t} - \prod_t \frac{B_{t+1}}{B_t} \\ &= \frac{A_{\text{end}}}{A_{\text{begin}}} - \frac{B_{\text{end}}}{B_{\text{begin}}} \\ \alpha_{\text{comp.}}(A - B) &= \prod_t \left(1 + \frac{A_{t+1}}{A_t} - \prod_t \frac{B_{t+1}}{B_t} \right) \\ \alpha_{\text{log}}(A - B) &= \sum_t \log \frac{A_{t+1}}{A_t} - \sum_t \log \frac{B_{t+1}}{B_t} \\ &= \log \left(\frac{A_{\text{end}}}{A_{\text{begin}}} / \frac{B_{\text{end}}}{B_{\text{begin}}} \right) \\ \alpha_{\text{ratio}}(A - B) &= \left(\prod_t \frac{A_{t+1}}{A_t} \right) / \left(\prod_t \frac{B_{t+1}}{B_t} \right) - 1 \\ &= \frac{A_{\text{end}}}{A_{\text{begin}}} / \frac{B_{\text{end}}}{B_{\text{begin}}}\end{aligned}$$

The log returns or the index ratio have no problems (except, of course, being non-additive accross portfolios), and should be used instead of the others. The article pairs the pathologies and the indices (table 10 page 19).

The conclusion could be: if you want to add returns month after month, choose the log-returns (but do not add the log-returns of individual stocks to hope to get that of a portfolio), if you want to “add” the returns of stocks to get that of a portfolio, use the active returns (but *never* add them month after month). If you hesitate, choose the log-returns.

Wavelet compression, determinism and time series forecasting

I. Kaplan, 2003

The author presents a new way of assessing the noisiness (or volatility) of a time series: the percentage of compression (say, on a 64-element moving window) obtained by *lossless* wavelet compression.

Let us first recall what wavelet compression is. We start with a time series and we want to approximate it with a “simpler” function (yes, it sounds like regression). We first try to approximate it by a constant (a horizontal line); then, we take the residuals, cut them into two parts (the first half of the series and the last half) and try to approximate each part by a constant. And we iterate.

At each step, instead of approximating the data with a horizontal line, we can use a more complicated function (a line, a single sine wave – there are other less classical functions, called wavelets, with better theoretical properties).

This can be interpreted as: at each scale, a good forecast of x_n is $\frac{1}{2}(x_{n-1} + x_{n+1})$.

The idea of *lossless* compression is to start with an integer-valued time series, allow only integer coefficients and retain all the coefficients.

One can measure the “complexity” or the “compressibility” by counting the number of bits in the resulting set of *integer* coefficients (the binary code of an integer n requires $\lceil \log_2 n \rceil$ bits). Low values means low noise and high predictability.

Remark: lossy compression removes the low-amplitude noise and thus cannot estimate the overall amount of noise.

Remark: the author notes that the compressibility is reliably approximated by the number of bits of the first difference, which is easier to compute ($\text{sum}(\log(\text{diff}(x))/\log(2))$, in R).

Signal processing for everyone G. Strang (2001)

There are three kinds of Fourier transforms:

- The Fourier series expansion, that turns a (periodic) function into a sequence of coefficients;
- The Fourier transform, that turns a function (in L^2) into another function;
- The Discrete Fourier Transform (DFT), that turns a discrete signal (a sampled function, a sequence) into a periodic function (a function on the circle \mathbf{S}^1),

$$(x_n)_{n \in \mathbf{Z}} \mapsto X(\omega) = \sum_n x_n e^{-in\omega}.$$

The sampled signal and its DFT contain the same information, they are just two different ways of looking at the same data; when we look at the sampled signal, we say that we are in the *time domain*, when we look at its DFT, we are in the *frequency domain*.

In the real world, you never study a continuous signal: you sample it at discrete points and study the resulting sequence – hence our interest in the DFT. But we might lose information if the sampling frequency is too low: for instance, the following sampled signal

could come from one of the following continuous signals

this is called *aliasing*. We usually assume that the signal has no components with a frequency higher than half the sampling rate (or, equivalently, that we sample at a frequency higher than twice the highest frequency in the signal – this is called the *Nyquist frequency*: anything above that is lost by the sampling).

It would be nice if we could recover the signal from its samples, if we could interpolate it – under the assumption that the signal has no component of frequency higher than the sampling frequency, this is reasonable. One would expect a formula of the form $x(t) = \sum a_n g_n(t)$ where the a_n are coefficients computed in a complicated way from the sampled function and the g_n are functions – actually, things are even simpler: the coefficients in *Shannon’s formula* are the sampled values themselves,

$$x(t) = \sum_n x(nT) \cdot \text{sinc} \frac{t - nT}{T/\pi}$$

where sinc is the *sine cardinal* function,

$$\text{sinc } t = \frac{\sin t}{t}.$$

A *filter* is a way of transforming a sampled signal into another sampled signal. To study a filter, one first applies it to simple signals such as: a constant, a linear function, an impulse, an alternating sequence or a pure sinusoidal signal $x_n(\omega) = e^{in\omega}$. The filters may (or not) have the following properties: linear, time-invariant, of finite length, low-pass (the low frequencies are (mostly) preserved, the high-frequencies are (mostly) discarded), high-pass, causal (they do not peer into the future), they can preserve constant signals, linear signals, etc.

Linear Time-Invariant (LTI) filters are linear filters that do not change the frequency of pure sine waves, *i.e.*, $x_\omega \mapsto H(\omega)x_\omega$, *i.e.*, a sine wave is only changed in its amplitude and phase, *i.e.*, the filter is diagonalizable in the basis of pure sine waves. The function $H : \mathbf{S}^1 \rightarrow \mathbf{C}$ that describes the changes in amplitude and phase is called the *frequency response*.

We can now examine a few filters. First, the Moving Average (MA) is a lowpass filter,

the Moving Difference is a high-pass filter,

A linear filter can be seen as a convolution; in the frequency domain (recall that it means that we replace the sampled signal by its Discrete Fourier Transform), this becomes a multiplication – multiplication by the frequency response $H(\omega)$.

The article then becomes more complex and explains how to *build* filters. Ideally, we would like to have filters that look like

but this is impossible with finite-length filters: the best filter we can design will show ripples around the transition band, either very high but localized ripples (Gibbs phenomenon) or (better), ripples of the same moderate amplitude everywhere (equiripple filter, Remez algorithm).

The last part (two thirds) of the article focuses on *wavelet transforms*, that can be implemented as a *filter bank*.

The signal is divided into high and low frequencies, the low frequencies are divided into... (we do not divide the high frequencies further: they contain mainly noise – uninteresting information – but we could: we would get *wavelet packets*).

Bayesian model selection in social research **A.E. Raftery (1995)**

(This is the article accompanying the `bicreg` code – a very good and readable introduction to bayesian methods.)

Bayesian testing has the following advantages:

- It works with large samples. In classical hypothesis testing, the choice of the significance, α , is based on empirical remarks for samples of 30 to 100 observations that suggest $\alpha = 0.01$ to 0.05 ;

but what if our sample is larger? We should decrease α (we never do), but how do we balance significance and power?

- It is simpler: instead of having to consider two numbers, significance (α) and power (β , which is often forgotten), we only have one (the Bayes factor).
- It allows multiple tests, e.g., for model selection; with p -values, we have to transform the p -values, using the Bonferroni correction (designed by someone who assumed the observations were independent and who did not understand the notion of percentage but well-suited for people with a 4-operation (no “power” operation) calculator) or the Sidak one (that assumes that the observations could be independent): this is pretty awkward.
- It handles model uncertainty, we do not have to choose a single best model if none stands out.
- It can compare non-nested models.
- It is symmetric: the answer of classical hypothesis testing is either “we reject H_0 ” or “we do not reject H_0 yet”; the answer of bayesian hypothesis testing is “there is weak/strong/very strong evidence for H ”.

The main problem with hypothesis testing is the choice of the prior distributions. However it only contributes as $O(1/n)$ of the final result: for large samples, it is not important.

We can compare two models with:

$$\frac{P(\text{Model}_1|\text{data})}{P(\text{Model}_2|\text{data})} = \frac{P(\text{data}|\text{Model}_1)}{P(\text{data}|\text{Model}_2)} \times \frac{P(\text{Model}_1)}{P(\text{Model}_2)}$$

i.e.,

$$\text{posterior odds} = \text{Bayes factor } B_{12} \times \text{prior odds}.$$

They also detail (with heuristic non-mathematical arguments) the BIC approximation:

$$\log P(\text{data}|\text{model}) = \text{maximum likelihood} - \frac{d}{2} \log n + O(1)$$

where d is the number of parameters in the model and n the number of observations. This yields

$$2 \log B_{12} \equiv \chi_{\text{LRT},12}^2 - \text{df}_{12} \log n$$

where $\chi_{\text{LRT},12}^2$ is the likelihood ratio test statistic (aka *deviance*, it is the difference of the loglikelihoods of the models) and $\text{df}_{12} = d_1 - d_2$.

Actually, we have two definitions of BIC, that only differ by an additive constant:

$$\text{BIC} = \chi_{\text{LRT}}^2 \text{ with the saturated model} - d \log n$$

$$\text{BIC}' = \chi_{\text{LRT}}^2 \text{ with the null (empty) model} - d \log n$$

Here are a few rules of thumb to interpret the Bayes factor or the BIC difference:

BIC difference	Bayes factor	Evidence
2–6	3–20	positive
6–10	20–150	strong
> 10	> 150	very strong

One can convert BIC differences into p -value thresholds, but this depends on the sample size (e.g., strong evidence: $n = 20$, $\alpha = 0.05$; $n = 100$, $\alpha = 0.01$; $n = 10000$, $\alpha = 0.001$ – they give a complete table).

The article also details Occam’s window for model selection (strong version: retain the data-supported and parsimonious models; symmetric version: retain the data-supported models – the symmetric variant performs better).

The bayesian (*i.e.*, BIC-based) approach may also be useful when we want to select *one* best model: it works better (out-of-sample) than p -values or stepwise regression.

The conclusion mentions the model uncertainty problem and BMA – which surpasses bootstrap (bagging).

I have not read the comments after the article.

While reading articles about bayesian methods, you may stumble upon the following vocabulary.

- Non-informative prior: When choosing the prior distribution, we sometimes want to include as little information as possible in it (because we do not have this information). We may choose, for instance, a Cauchy distribution with a large dispersion parameter.
- Improper prior: Sometimes, we would even like to choose a “uniform distribution on \mathbf{R} ”: this is not a probability distribution, but it may work. A non- L^1 “density” function is called an improper prior. (Actually, it does not work that well: prefer a proper prior.)
- Conjugate prior: The conjugate family of priors is a family of probability distribution functions for which the computations are tractable – this depends on the problem at hand, more precisely on the likelihood function – if you do not do the computations by hand, forget about this notion.

Stock return predictability: a bayesian model selection perspective
K.J.M. Cremers

The author tackle the variable selection problem (for a 15-variable regression model of stock returns) with a bayesian approach.

Contrary to other articles that dismiss the issue of choosing the prior distributions by taking a “diffuse” one, this article examines

- the interpretation of those prior distributions, as

the investor’s belief (or not) in the predictability of the returns;

- the effects of these prior distributions on the results: there are no major qualitative differences, in both the skeptic and confident case, the posterior distribution suggests the returns are predictable from half a dozen variables.

They also performed out-of-sample tests: choosing the best model brings no reliable forecast, while a Bayesian Model Average (BMA) has a very small predictive power.

This could be improved by removing some restrictions (normality, linearity, parameter stability) and introducing lagged variables.

Choosing factors in a multifactor asset pricing model: a bayesian approach
J. Ericsson and S. Karlsson

Bayesian modeling goes as follows: you have a model whose parameters you want to “estimate”; you start with an a priori distribution of the parameters; you use the data to compute the a posteriori distribution of the parameters given the data. You can have several different models if you choose an a priori probability for each of them. The differences with the *frequentist* approach are:

- You have (and use) an a priori distribution on the parameters and/or models (if you do not have this information you may cheat and use a *diffuse prior*);
- The result is not an estimation of the parameters (that would be a single number) but the distribution of these parameters – the classical estimates may be obtained from this distribution, by taking the expectation (unbiased estimator) or the mode (Maximum Likelihood Estimator) – but the whole distribution provides more information.

This article is less badly written than the preceeding. They consider the variable selection problem in the linear regression of a stock return (or the returns of N stocks) with respect to several economic variables and several benchmark returns. The bayesian approach (with diffuse priors) gives a probability for each of these models. The interesting point is not (as the authors claim) the ability to choose the best model, but the ability to detect *model uncertainty*: indeed, the probability of the best model can be pretty low. I can see several causes to that model uncertainty:

- Some of the models are *very* similar or, at least, give similar predictions, and we do not have enough data to distinguish between them (this is the theoretical foundation of Bayesian Model Averaging);

- The best models are different but wrong, by the same amount (this is reality).

The article also details the 15 factors used in the study.

Thick Modeling
C.W.J. Granger and Y. Jeon

Extremely confusing article whose authors may not be as competent as they ought to be:

- In their “portfolio example”, they do not say where the data is, where the model is, which parameters are estimated. Actually, they consider several stocks, each known by the time series of its returns (this is the data). They assume that the returns are normal and independent and that their covariance structure is simple and can be described by three parameters (this is the model). They also define the quantity of interest: the composition of the optimal portfolio one can build with these stocks.

But their confusion goes further: this is not Bayesian Model Averaging (we would need *several* models) but a classical bayesian method: we have an a priori distribution of the model parameters, we use the data to compute their a posteriori distribution and then the a posteriori distribution of the quantity of interest.

- They confuse “noise” (what appears in a model) and “residuals” (what appears at the end of a regression – the residuals are an *estimation* of the noise).
- They seem to think that Maximum Likelihood can be used to compare models: you only use it when facing a *single* model (or for tests, with *nested* models).
- They suggest to perform Bayesian Model averaging with an equally-weighted trimmed-mean, as if they had never heard of MCMC.

***FlexMix: a general framework
for finite mixture models
and latent class regression in R***
F. Leisch (JSS 2004)

The EM (Expectation Maximization) algorithm is used to fit models with missing data, such as finite mixture models (for instance $z \sim x \cdot y$, where only x and y are known and z is qualitative). It works as follows:

- Choose an a priori estimate of the model parameters;
- (E-step) Replace the missing values by their expected values, assuming that the model parameters are correct;

- (M-step) Estimate the parameters by MLE (Maximum Likelihood Estimation), assuming that the missing values have the value inferred at the previous step;
- (E-step) ...
- (M-step) ...
- etc.

There are already some R packages to do that:

- `mclust` (for mixtures of gaussians);
- `fpc` (for mixtures of regressions);
- `mmlcr` (for mixtures of latent-class regression).

FlexMix encompasses the general linear models (Poisson regression, etc.) and is more configurable: you can provide your own model and write your own M-step.

iPlots
S. Urbanek and M. Theus (DSC 2003)

Interactive graphics should provide *colour brushing* and *linked highlighting*: the authors provide a framework to do so, for simple graphics (histograms, barcharts, scatterplots), implemented with SJava (but the user need not know anything about Java). It might be easier to use than GGobi (and prettier), but it lacks its multi-dimensional capabilities.

Synergy, issue 3, 2000

The Coil Contest is the European equivalent of the KDD Contest (but the KDD Contest is still alive). The conclusions of that issue are that for real-world problems, they suggest to try different algorithms (“look beyond your pet algorithm”) and to use a rigorous methodology (you can afford a crappy algorithm, but not a crappy methodology).

This issue also contains an article about wavelets, focusing on the combination of wavelets and “soft” algorithms (fuzzy logic, neural networks, genetic algorithms).

Do not expect to learn anything reading this – they provide interesting real-life examples, though – even one with high-frequency financial data.

***Using Perl for Statistics: Data Processing and
Statistical Computing***
G. Baiocchi (JSS, 2004)

This long and detailed article presents Perl as a glue language for statistics, navigating between remote data (web), statistical libraries (R, various Perl modules) and presentation tools (L^AT_EX), performing tasks such as data retrieval, transformation, validation and recoding. They suggest using Windows (why?) and Emacs (or SciTE, which also exists under Windows).

They list and assess the quality of various Perl statistical modules: reproductibility, reliability, benchmarking – the main problem is the Random Number Generator (RNG): avoid the default one and prefer MT or TT800.

They also mention matrix handling modules, PDL (a Perl package allowing one to manipulate matrices as easily as if they were scalars – like Matlab or R –, whose large graphical capabilities are not mentionned) and even Win32::OLE (to talk to the R DCOM server).

As many people claim to be a Perl guru after just a few hours, as the articles covers a lot of subjects, one could have feared that the author does not master some of them – this is not the case. It seems to be a good presentation of Perl, aimed at statisticians.

Kernlab – an S4 package for kernel methods in R

A. Karatzoglou et al. (JSS, 2004)

There are three R packages dealing with kernel methods: **e1071** (which uses libsvm), **klaR** (which uses SVMlight) and **kernlab**, with which you can add new kernels in R (with no need to dive into C or C++ code) and new algorithms (though many are already implemented).

The article starts by recalling the notion of S4 classes (with S3 objects, the class is merely an attribute, only used for method dispatching; with S4 classes, all objects of a given class have the same “slots” and methods are attached to the class – but if you just want to use S4 classes, the main difference is that \$ became @) and namespaces. It then lists the kernels and algorithms:

- SVM regression, classification (with 2 or more classes, but also with just one class: “novelty detection” or “outlier detection”);
- *Relevance Vector Machine* (a bayesian, weighted SVM regression);
- “*Gaussian processes*” (?);
- A Google-type ranking algorithm based on a network constructed with the kernel distance;
- kernel PCA, kernel CCA, clustering based on a kernel PCA.

The package also provides an *interior point quadratic optimizer* (most optimization algorithms (e.g., the *simplex* algorithm) examine the boundary of a convex subset of a high-dimensional space, because we know that the solution is on this boundary; but in high dimension, the boundary is huge and some algorithms are trying to take a “shortcut” *through* the convex: they are called “interior point” algorithms).

Wavelets in Statistics: a review

A. Antoniadis (1997)

This document is rather old and assumes that the reader is familiar with the theory behind wavelets (Besov spaces, etc.). Yet, the conclusion was enlightening, presenting “recent or future” developments (with no details):

- Non-parametric tests;
- Regression with irregularly spaced points (“*lifting scheme*”: one can define wavelets adapted to the sample points), non gaussian noise;
- Jump detection;
- *Wavelet packets*.

State Space Modeling in Macroeconomics and Finance using S+FinMetrics

E. Zivot et al. (2002)

This is the documentation of the SsfPack part of S+FinMetrics, containing a lot of examples (Recursive Least Squares (RLS), CUSUM test (the cumulative sum of the residuals should have zero mean and a variance proportional to time; we can plot those cumulative sums of residuals and the confidence intervals), ARMA), with code – but it is rather useless if you do not have S-Plus and S+FinMetrics.

Searching for alpha, the importance of revenues and cash flow estimate revisions in stock selection

J. Gaudaut et al. (Citigroup, 2004)

Analysts can provide us with a few estimations for each stock:

- estimated earnings (very commonly used);
- estimated revenue;
- estimated cash flow.

The changes in those estimates (“revisions”) can help us select outperforming stocks. Actually, it suffices to look at the *breadth*, *i.e.*, the number of revisions. This strategy works better with the cash flow, continental Europe and low-capitalization values, but is sector-dependant.

New accounting standards changes are likely to increase the earnings estimates volatility and hence its usefulness; the other estimates may help.

Option Pricing under Model and Parameter Uncertainty using Predictive Densities

F.O. Bunnin et al. (2000)

This article (which I have not read) gives another example of Bayesian Model Averaging (BAM).

The theoretical price of an option is the expectation of its discounted payoff. To perform this computation, we assume that:

- We know the model describing the price of the underlying (usually the Black–Scholes model, which is known to be wrong);
- We know that the model parameters are constant (this is precisely the reason why the Black–Scholes model is wrong: the parameters are not constant (“clustered volatility”));
- We know those parameters (while different estimations of the volatility, such as the implied or the historical volatility, give different results).

With BAM, we can simultaneously consider several models (with constant or stochastic volatility) and take into account the uncertainty on the parameters; as a result, we get a distribution of theoretical prices.

Bayesian Model Averaging: A Tutorial **J.A. Hoeting et al. (1999)**

This article is a more comprehensive, detailed presentation of Bayesian Model Averaging (BMA) and its algorithms.

Here are a few means of averaging over the set of all models:

- Do not consider all the models but just the “best” and those close to it (a slightly different variable selection, a different error structure, etc.).
- *Occam’s window* suggests not to consider all the models but only the parsimonious and data-supported ones, *i.e.*, the models $M \in \mathcal{M}$ such that

- $\text{pr}(M|\text{Obs}) > (1 - \varepsilon) \max_{N \in \mathcal{M}} \text{pr}(N|\text{Obs})$
- there is no smaller model $N \subsetneq M$ that better fits the data, *i.e.*, such that $\text{pr}(N|\text{Obs}) > \text{pr}(M|\text{Obs})$.

Those models are enumerated by a Branch and Bound (B&B) algorithm (for small, simple problems).

- For larger problems, one can use the Markov Chain Monte Carlo (MCMC) algorithm to sample from the set of all models – this is called *Markov Chain Monte Carlo Model Composition* (MCMCMC or MC³).
- Orthogonalized model mixing (?).

The integrals (the posterior probability of the models) can be computed by

- explicit formulas for some (simple) classes of models;
- approximations (Laplace method);
- replacing $\text{pr}(y|M, \text{Obs})$ by $\text{pr}(y|M, \hat{\theta}_{\text{MLE}}, \text{Obs})$.

One may remark that these ideas allow us to compare completely unrelated models. If a model is embedded in the other, we can use a Likelihood Ratio (LR) test or the AIC, if not we can use the BIC approximation. Here, we have other approximations (actually, the Laplace approximation often coincides with the BIC one).

For linear regression, the choice of a model comprises:

- choice of variables;
- transformations: Box–Cox, ACE (Alternating Conditionnal Expectation: a family of non parametric transformations), broken lines (ACE often yields broken lines);
- outliers, using a model of the form $y = bx + \varepsilon$ where ε is a mixture of $N(0, \sigma^2)$ with probability $1 - p$ and $N(0, K^2 \sigma^2)$ with probability p , with p the proportion of outliers and $K \gg 1$ the variance-inflation parameter.

They also detail survival analysis and graphical models.

But how do we fix the prior model probabilities? One can set

$$\text{pr}(M) = \prod_j \pi^{\delta_j} (1 - \pi)^{1 - \delta_j}$$

where π is the probability of including a variable (with $\pi < \frac{1}{2}$, we put a penalty on larger models) and $\delta \in \{0, 1\}$ denotes the presence or absence of variable j in model M . Another solution is to ask an expert of the domain to forge “imaginary data”.

There are other approaches to model averaging:

- Bootstrap both the data and the model selection (the results are poorer than those of BMA);
- “Minimax Multiple Shrinkage Stein Estimator” (?);
- Bagging;
- Stacking (?);
- Boosting (weighted bagging).

The article concludes with two very detailed real-life examples and is followed by a few comments.

**Methodology for Bayesian Model Averaging:
an Update
J.A. Hoeting (2002)**

When performing a regression (or any other statistical analysis), we are confronted to the choice of a model (e.g., the choice of a few variables to use as predictive variables, among dozens of variables). Oftentimes, the data do not suggest a *single* best model. To overcome that *model uncertainty*, one can do the computation (e.g., we may want to compute a forecast) for each model, compute the “probability of each model given the data”, and average over the models.

More formally, let

$M \in \mathcal{M}$: the models

Obs : the observed data

y : the parameter to be estimated,

or the variable to be predicted

$\text{pr}(M)$: prior probability of model M

$\text{pr}(\theta|M)$: prior distribution of parameter θ in model M

$$\text{pr}(y|\text{Obs}) = \sum_{M \in \mathcal{M}} \text{pr}(y|\text{Obs}, M) \cdot \text{pr}(M|\text{Obs}) \quad (1)$$

$$\text{pr}(M|\text{Obs}) = \frac{\text{pr}(\text{Obs}|M) \cdot \text{pr}(M)}{\sum_{N \in \mathcal{M}} \text{pr}(\text{Obs}|N) \cdot \text{pr}(N)} \quad (2)$$

$$\text{pr}(\text{Obs}|M) = \int_{\theta \in \Theta} \text{pr}(\text{Obs}|M, \theta) d\theta. \quad (3)$$

To use such an approach, one has to overcome some problems:

- How to choose the prior probabilities?
- How to compute the integrals?
- How to deal with the large number of models?

For the first point, I have no clue; for the second, one uses ad hoc, model-dependent approximations; for the third, one uses Monte Carlo Markov Chains (MCMC) to sample in the set of models.

BMA can be applied, for instance, to the following sets of models:

- Linear models, with a different choice of variables, a different choice of transformations, a different selection of outliers;
- Non-parametric regression models;
- Spacial models (but I do not know anything about spacial models...);
- Generalized Linear Models (GLM);
- Graphical models;
- Classification trees (this is very similar to *bagging*);

- Survival analysis.

The article mentions a few S-Plus packages to perform BMA (apparently, they do not work under R in a straightforward way (they use undocumented internal S-Plus functions) and they have not been ported to R); a more comprehensive list is on the BMA home page, <http://www.research.att.com/~volinsky/bma.html>.

To sum up, the advantages of BMA are:

- Takes model uncertainty into account (if there is no model uncertainty, it is useless; it is more useful when there are many variables, many useless variables and multicollinearity problems);
- Better forecasts;
- Less over-optimistic confidence intervals (more classical model selection procedures use the same data twice: first to select the model, then to estimate the quantities of interest).

**Time Series in Finance:
the array database approach
D. Shasha**

A time series database should have the following desirable properties:

- Handling of regular time series, with missing values;
- Converting a time series to a given frequency, taking its *type* into account (for *level* time series, just take the latest value; for *flow* time series, take the sum since the last timestamp), in both directions (lower frequency: sampling, higher frequency: interpolation) – this also includes turning an irregular time series into a regular one;
- Perform basic computations (cumulative sum, moving average, correlation, regression, acf, etc.) and user-defined ones;
- Sequences are first-class objects, *i.e.*, you can play with them as easily as if they were numbers;
- *Bitemporality*: each event has two timestamps, the time at which it is valid and the time at which it was entered into the database; in other words, the database keeps track of how the errors were corrected. Thus, when backtesting (*i.e.*, when doing tests with historical data), we can use either the “historical data we should have had at the time, had the database been error-free and up-to-date” or the “historical data we actually had at the time, including the errors and the delays” – the former could in fact assume that we had the information before everyone else, which is not very realistic...

They detail several systems: FAME (Forecasting, Analysis and ModEling), S-Plus, SAS and KSQL (K is an array language – it makes me think of stored procedures in R under PostgreSQL).

The document also presents many concrete and detailed use cases; it ends with a large (but perhaps a bit outdated) bibliography on sequence similarity, subsequence matching, pattern matching.

Evanesce Implementation in S-Plus FinMetrics Module Insightful Corp., 2002

Copulas are a mean of describing the dependance relation between two random variables (X, Y) abstracting the peculiarities of the distribution of X and Y – we only focus on the dependance relation. The idea is to transform X and Y so that their distribution be uniform in $[0, 1]$. A *copula* is the joint distribution of the transformed variables.

This document lists more than a dozen copulas. Let us mention the simplest ones.

- Gaussian copulas (obtained when (X, Y) is gaussian, with correlation ρ);
- Mixture-of-gaussians copulas;
- Extreme value copulas: this is a *max-stable* family of copula; they verify

$$\forall u, v \quad C(u^t, v^t) = C(u, v)^t;$$

the Gumbel copula

$$C(u, v) = \exp - ((-\log u)^\delta + (-\log v)^\delta)^{1/\delta}$$

is one of them;

- Archimedean copulas,

$$C(u, v) = \phi^{-1}(\phi(u) + \phi(v))$$

for some function ϕ – this reduces the study to functions of a single variable. The Gumbel copula is archimedean.

They only present the notion of copulas for *pairs* of variables: actually, it can be generalized in higher dimensions. This is especially easy for families of copulas defined by a function of a single variable such as the archimedean copulas:

$$C(u_1, \dots, u_n) = \phi^{-1}(\phi(u_1) + \dots + \phi(u_n)).$$

You might also want to read *Taken to the limit: simple and not so simple loan loss distribution*, P.G. Schönbucher, http://www.wilmott.com/pdfs/040404_schon.pdf.

Orla, a data flow programming system for very large time series G. Zumbach and A. Trapletti (Olsen & Associates)

Flow programming languages (see *Advanced Programming Language Design*, by R. A. Finkel, for a description of the main families of programming languages and their characteristic features) are quite rare outside electronics. The authors have developed a framework based on the flow programming paradigm to process time series. Their data is stored in a “time series data base” (aka *temporal database*) that can be queried in a very simple way, close to:

```
SELECT FX(USD,*)
BETWEEN 2004-01-01 AND now;
```

(actually, it does not look like SQL, but it is as straightforward – they call that syntax SQDADL (Sequencial Data Description Language).

Iterative Incremental Clustering of Time Series J. Lin et al.

Clustering algorithms such as *k*-means (that tries to find spherical clusters) or EM (that tries to find elliptical clusters – more precisely, it is a model-based clustering algorithm that assumes the data is a mixture of (say) gaussians – in R, it is implemented in the *mclust* module) require a *good* first estimate of the cluster centers, that is progressively refined.

Instead of considering the whole data set right away (it may have a lot of variables), one may perform a clustering on the first coefficients of the Haar wavelet transform; then on the coefficients of levels 1 and 2, using the preceding results as initial estimates; etc.

The results are better than with a “batch” algorithm (we are less likely to find in a local extremum) – and it is faster.

To vary or not to vary? Weights, breaks, factors and sampling frequencies in predictive return models R. Masih (Goldman Sachs, 2004)

Factors vary with time. They suggest two ways of accommodating those changes.

First, you can take the same factor at several frequencies (daily, weekly, monthly) and use all of them in the same regression (MIDAS: MIXed Data Sampling).

Second, you can take several simple models (linear regression with a single predictive variable, for all the possible variables) and combine the models, with “bayesian methods” (they are very vague about those).

They also speak of “breaks”, but I know neither how they find them nor how they use them.

**Quantitative Portfolio Strategy
Peculiarity of the Japanese Stock Market
T. Suwabe (Goldman Sachs, 2004)**

Investor sentiment, defined as

$$\text{NIS} = \frac{\text{Buy volume} - \text{Sell volume}}{\text{Total volume}},$$

estimated with intraday data, is correlated with future return.

Incidentally, they also define the notion of “factor return” (the coefficients of a factor, in a regression, when you do the same regression at various times); remark that they are autocorrelated in Europe and the US but not in Japan or in Asia; remark that Japanese returns have a negative autocorrelation that tends quickly to zero while the NIS has positive autocorrelation and tends slowly to zero.

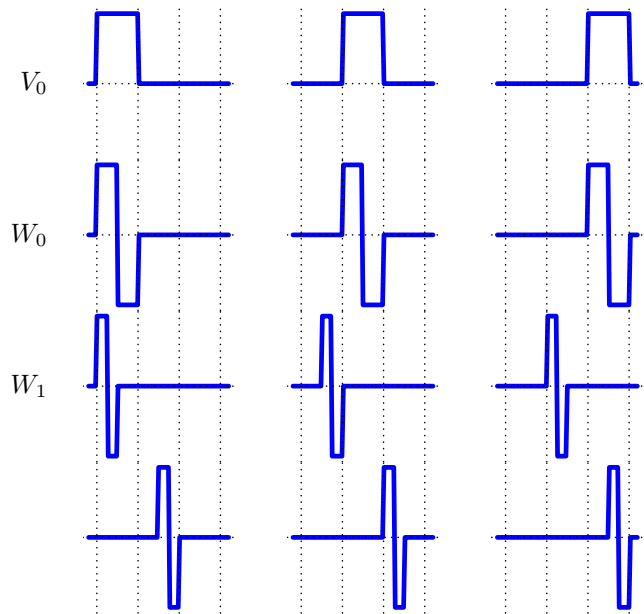

**Wavelets, Approximation and
Statistical Applications
W. Härdle et al., 1997**

The following figure represents a wavelet transform: the curve in the first plot is the signal to be described; the rectangles (or vertical segments) represent the coefficients; the lower left part tells us that in the left part of the interval, high frequencies dominate; the top right part tells us that in the right part of the interval, low frequencies dominate.

This is very similar to the decomposition of periodic functions into Fourier series, but we have one more dimension: the frequency spectrum is replaced by a frequency-location plot (an other advantage is that there is almost no Gibbs effect – very convenient when the signals are not periodic or stationary...)

The general idea is the following: find an orthonormal basis of L^2 whose elements can be interpreted in terms of “location” and “frequency”. For example (this is called the Haar basis):

This gives a decomposition

$$L^2 = V_0 \oplus \bigoplus_j W_j$$

where V_0 is generated by the father wavelet ϕ and its translations and the W_j are generated by the mother wavelet ψ , its translations and rescalings.

$$\begin{aligned} \phi &= \text{father wavelet} \\ \psi &= \text{mother wavelet} \end{aligned}$$

The choice of the basis depends on the applications: will you be dealing with smooth (\mathcal{C}^∞) functions? continuous but non-differentiable functions, with a fractal nature? functions with jumps? The convergence speed of the Wavelet decomposition will depend on the adequacy of the basis and the data studied.

More technically, the construction of a basis goes as follows.

1. Choose a father wavelet ϕ .
2. Set $\phi_j k(x) = 2^{j/2} \phi(2^j x - k)$, for $j \in \mathbf{N}$ and $k \in \mathbf{Z}$ – this is f translated by k and shrunk j times.
3. Set $V_j = \text{Vect} \{ \phi_{jk}, k \in \mathbf{Z} \}$ and check that:

4. $(\phi_{0k})_{k \in \mathbf{Z}}$ is an orthonormal system (a Hilbert basis of V_0 ;
5. $\forall j \in \mathbf{Z} \quad V_j \subset V_{j+1}$;
6. $\overline{\bigcup_{j \geq 0} V_j} = L^2$.
7. Then, set $W_j = V_{j+1} \ominus V_j$ so that $L^2 = V_0 \oplus \bigoplus_{j \geq 0} W_j$.
We then want to find a mother wavelet $\psi \in W_0$ such that if we set
8. $\psi_{jk}(x) = 2^{j/2} \psi(2^j x - k)$,
9. then $(\psi_{jk})_{k \in \mathbf{Z}}$ is a basis of W_j .
10. Then (finally), we have a basis of L^2 :

$$\begin{array}{ccccccc}
 \cdots & \phi_{0,-2} & \phi_{0,-1} & \phi_{0,0} & \phi_{0,1} & \phi_{0,2} & \cdots \\
 \cdots & \phi_{1,-2} & \phi_{1,-1} & \phi_{1,0} & \phi_{1,1} & \phi_{1,2} & \cdots \\
 \cdots & \phi_{2,-2} & \phi_{2,-1} & \phi_{2,0} & \phi_{2,1} & \phi_{2,2} & \cdots \\
 & & & \vdots & & &
 \end{array}$$

When conditions 4, 5 and 6 are satisfied, we say that we have found a MultiResolution Analysis (MRA).

For the forgetful reader, they recall some basic facts about Fourier Analysis – if we just want to *use* wavelets, we do not need it: it is used to check that the abovementioned properties are satisfied, when you build your own wavelet basis.

The book then gives a first construction of wavelet bases, from a Riesz basis (it is not that hard, but we do not really need to know what it is): we get the Battle–Lemarié father wavelets.

Apart from the first one (the Haar father wavelet), they are not compactly supported.

The book then goes on to the Daubechies's construction of wavelet bases (based on Fourier analysis). This time:

- father and mother wavelets have a compact support;
- the first moment of the father wavelet are vanishing.

Let us list the main (families of) wavelet bases mentioned in the book:

- Haar;
- Battle–Lemarié;
- Daubechies;
- Coiflets (the father wavelet has vanishing moments);
- Symlets (more symmetric than the Daubechies wavelets).

(There are two technical chapters on Sobolev and Besov spaces, which I have not read.)

Let us now mention some statistical applications of wavelets:

- Approximation of possibly irregular functions and surfaces (there is a reduced Gibbs phenomenon, but you can circumvent it by using *translation-invariant wavelets*).
- Smoothing.
- Density estimation: just try to estimate the density as a linear combination of wavelets, then remove/threshold the wavelets whose coefficients are too small (usually, the threshold is chosen as 0.4 to 0.8 times the maximum coefficient; we also use *block thresholding*: we do not remove single coefficients but whole blocks of coefficients). For instance, density estimation of financial returns: we can clearly see the fat tails. Kerlel methods do not perform that well, unless they use adaptive bandwidth.
- Regression: this is very similar, we try to find a function f (linear combination of wavelets, we threshold the smaller coefficients) such that

$$\forall i \quad y_i = f(x_i) + \text{noise}.$$

If $x_i = i/n$ with $n = 2^k$ for some $k \in \mathbf{Z}$, it works out of the box otherwise, you have to scale and bin the data.

- Gaussian White Noise Estimation: find a function f such that

$$dY(t) = f(t) dt + \varepsilon dW(t) \quad t \in [0, 1].$$

- Jump detection.
- Time series.
- Diffusion Models (?).
- Image compression, indexing, reconstruction, etc.

Problems:

- The authors do not seem to know the symbols \forall and \exists – they systematically omit them, hoping that the reader will pick the right one;
- The book is rather old and therefore does not mention recent developments – it is good as an introduction to the subject, but should be complemented by other documents.

For more about wavelets, check <http://www.wavelet.org/> and its tutorials.

Computational Methods for Time Series **G. Kitagawa, T. Higuchi, S. Sato**

Linear State Space Models (SSM) are used to model non-stationnary time series; but when the series have jumps, outliers or involve non-gaussian distributions, we can turn to *non-linear state space models*:

$$x_n \sim Q_n(\cdot|x_{n-1})$$

$$y_n \sim R_n(\cdot|x_n).$$

The extended Kalman filter used in this context is only an approximation (a Taylor series, in fact) and it still assumes that the distributions are gaussian. If we do not want this approximation or if our distributions are really non gaussian, we can use the exact formulas:

$$p(x_n|y_{n-1}) = \int p(x_n|x_{n-1})p(x_{n-1}|y_{n-1}) dx_{n-1}$$

$$p(x_n|y_n) = \frac{p(y_n|x_n)p(x_n|y_{n-1})}{\int p(y_n|x_n)p(x_n|y_{n-1})}.$$

We have integrals when we go from n to $n+1$, but actually, we want to go from 1 to $N+1$ – we have integrals of integrals of... of integrals: all in all, we have to integrate over a high-dimensional space. We resort to *Monte Carlo integration*. This is called a *Particle Kalman Filter* (the idea is similar to that of using Monte Carlo simulations to price exotic options).

We usually estimate the model parameters by Maximum Likelihood (MLE), but this assumes that those parameters are constant – often, this is not a reasonable assumption. To solve this problem, we can augment the model by adding the parameters to the list of hidden variables: this is called a *Self-Organizing SSM*.

The articles also explains how the computations can be parallelized, how the particles can be exchanged between the different runs (*cross-over*).

Pattern Recognition of Time Series Using Wavelets **E. A. Maharaj**

The wavelets coefficients of time series can be used to estimate the “difference” (the distance) between two time series. One can devise a test to check if the coefficients of two series are significantly different: compute

$$\frac{(\text{wavelet coefficients of the first series})^2}{(\text{coefficients of the other})^2}$$

and compare it with the distribution obtained by randomly swapping the coefficients of the two series (they did the test with 256 and 1024 coefficients). One could use the resulting p -value to compute a distance between time series.

Personnal remarks:

- One might use that to *cluster* time series (into sectors, industries, countries, etc. – the interpretation will be left to more economically-inclined people).
- The coefficients may be similar but with delays (one could replace the distance between x and y by the minimum distance between delayed versions of x and delayed versions of y).
- Those delays can vary with time (a few days in normal market situations, much less in a crash – here, I should tell more about time warp distance and dynamic programming – the idea is the following: compute a time-warp distance for each level of the wavelets decomposition, then combine these distances).

Random and Changing Coefficient Models **G.C. Chow, Handook of Econometrics (1984),** **volume 2, chapter 21,**

A survey article, with too many formulas to be enlightening. A section presents various tests on those models (such as “are the coefficients random or constant?”).

The Kalman Foundations of Adaptive Least Squares **J.H. McCulloch, 2004**

The model underlying a regression looks like

$$y = \beta x + \text{noise}.$$

But in a financial context, the observations are ordered $(x_1, y_1), (x_2, y_2), \dots, (x_n, y_n)$ and the coefficient β may (slowly) change with time. The model is then

$$\beta = \text{random walk}$$

$$y_t = \beta_t x_t + \text{noise}.$$

This is a State Space Model, but a non-linear one.

$\beta_{t+1} = \beta_t + \text{noise}$	(hidden)
$x_t = \text{noise}$	(observed)
$y_t = \beta_t x_t + \text{noise}$	(observed)

It is called a *Random Coefficient Model* (there are variants where β is stationnary) and the corresponding non-linear Kalman filter is called *Adaptive Least Squares* (ALS). This is a generalization of the Recursive Least Squares alluded to above.

The article is full of formulas and thus not very readable.

Here are some simpler alternatives to ALS:

- *Local Regression*, *i.e.*, for each point we do a weighted regression with a null weight for future observations (because we do not know them yet) and an exponentially decreasing weight for past observations; the difference with ALS is that we have to choose the rate of decrease of the weights.
- A broken-line regression (it sounds appealing, especially if we look at real data, but unfortunately it is not robust at all).

***What Investors Can Learn
from a Very Alternative Market***

**R.N. Kahn, Financial Analysts Journal 60 5,
p. 17–21.**

The article stresses the “importance of rigorous scientific analysis to successful investing”.

“Investors (or baseball team managers) are irrational in systematic and predictable ways:

- social interaction (herding);
- heuristic simplification (generalization from personal experience, extrapolating from recent events);
- self-deception (attributing positive outcomes to one’s skill and negative outcomes to bad luck).”

The low liquidity of the baseball market makes the resulting inefficiencies easier to spot and exploit.

(These ideas are presented and developed in the book *Moneyball*, by M. Lewis (2003).)

***Statistical Algorithms for Models
in State Space using SsfPack 2.2***

**S.J. Koopman, N. Shephard, J.A. Doornik
Econometrics Journal (1999) 2, p. 113–166**

This article presents SsfPack, an Ox library for State Space Model estimations (Ox is a C-like language for matrix and time-series analysis, commercial, closed-source and Windows-only – there is a limited Linux version, available only to academic users). The SPlus module “FinMetrics” uses SsfPack.

The article contains a lot of examples and has a distinctive bayesian flavor.

The first part presents various time series models that may be expressed in state-space form: ARMA, structured model with seasonal and *cycle* components

$$\begin{pmatrix} x_{t+1} \\ y_{t+1} \end{pmatrix} = \begin{pmatrix} \cos \theta & \sin \theta \\ -\sin \theta & \cos \theta \end{pmatrix} \begin{pmatrix} x_t \\ y_t \end{pmatrix} + \text{noise},$$

regression models (*recursive least squares* – we want to find β such that $y_t = \beta x_t + \text{noise}$: take a first, random, estimation $\hat{\alpha}_0$ of β , consider the first observation (x_1, y_1) , refine the estimate $\hat{\alpha}_1$, consider the second observation, etc.), non-parametric cubic spline models (not read).

The second part presents the implemented algorithms: simulation, Kalman filter, smoother (in a filter, you only use the information available up to time t to predict the hidden variable at time t , in a smoother, you use all the information, even that posterior to the prediction), a posteriori sampler (I think – it was not that clear), likelihood computation

$$-\frac{nN}{2} \log(2\pi) - \frac{1}{2} (\log |F_t| + v'_t F_t^{-1} v_t)$$

(where n is the number of observations, N the number of observed variables, $|\cdot|$ the determinant, v_t the residuals, F_t the variance of the residuals) – there is also a “concentrated or profile log-likelihood”.

***“We’re going to be a 90 % Linux shop by 2006”*
Linux Journal 127, November 2004, p. 48-50**

These words are from Morgan Stanley.

***Scientific Visialization with PoVRay*
Linux Journal 127, November 2004, p. 62-67**

PoVRay is a ray tracer, *i.e.*, a program to draw 3D scenes from a textual description. It can draw isosurfaces, *i.e.*, surfaces of the form $f(x, y, z) = k$, where f is specified by an equation or a binary df3 file (8-bit by default, but a patch extends this to 32-bit data and another patch to HDF files, that contain several functions). It is being used for meteorogological data.

***Maximum likelihood estimation of
mean-reverting processes*
J.C.G. Franco**

MLE of a mean-reverting Ornstein-Uhlenbeck process (OU is a continuous analogue of an AR(1) time series, the MR version is used to model exchange rates or the price of products with a fixed cost of production) requires either maximizing a function of 3 variables or solving a (non-linear) system of 3 equations. This article mixes these two approaches and reduces the problem to that of maximizing a function of a single variable.

***Swingtum – A Computational Theory of
Fractal Dynamic Swings and Physical Cycles
of Stock Market in a Quantum Price-Time
Space*
H. Pan**

The market reacts to 4 types of fluctuations:

- dynamic swings (they have a fractal nature, have multilevel trends, as Elliott waves for instance);
- physical cycles (year, month, week);
- abrupt momentum (news impact, chart patterns);
- random walk (the rest, what we cannot predict);

Nothing really concrete:

- If the prices depend on several “forces”, then the price variation is the “sum” of these “forces” (he takes into account a stock “mass” , *i.e.*, inertia);
- The prices are piecewise log-periodic,

$$p \sim \sin \log t,$$

i.e., the rise is steeper than the fall (or conversely) and the waves start and end at random instants;

- Hilbert transforms are important (I have no idea why).
- “Multidimensionnal embedding” (yes, these words are mentioned without any further explanation).

Yet, if we remove all the nonsense from this gibberish, the article suggests to do exactly what we are doing: look at the data, all the data, cluster it (empirically or not, your clustering may/should be hierarchical) and try to find a model (using the rational and irrational beliefs investors are actually using, because their actions depend on that and the market responds to those actions).

***Bubbles, Crashes and Intermittency
in Agent-Based Market Models***
I. Giardina and J.-P. Bouchaud
arXiv:cond-mat/0206222

A very readable article on the same subject. They present a simplified model of financial markets:

- There are only two assets, a stock and a bond (risk-free asset).
- Each agent has a predefined set of strategies. He looks at the last m returns, compares them with the risk-free returns, obtains a history binary vector of length m ; a strategy is a function $\{0,1\}^m \rightarrow \{\text{buy}, \text{sell}\}$ (chartists do that). The strategies are chosen at random with a bias, P (“polarization”) towards “trend-following” or “contrarian” strategies.
- There is also a “do nothing” strategy.
- If the prices become too high or too low, the agents revert to fundamental analysis.
- If an agent decides to invest, he only invests a fraction g of his assets.
- Each strategy is rated with the number of “successes” it would have yielded in the past (weighted moving average).
- The prices depend on the number of actors willing to buy/sell and on the market stiffness λ .

The consequences:

- The system has three states: oscillating (bubbles and crashes), intermittent (irregular bubbles and crashes) and stable.
- Only two parameters are important: polarization P and g/λ .
- There are multiscale fluctuations (even though the model is not multiscale).
- There is volatility clustering and long-term dependence.
- A Tobin tax of a few basis points would have no effect; A Tobin tax of a few percents have a stabilizing effect.

***Evolution Management in a Complex
Adaptive System***
D.M.D. Smith, 2003

Detailed version of the preceding article – still unreadable but less empty.

***Evolution Management in a Complex
Adaptive System: Engineering the Future***
D.M.D. Smith and N.F. Johnson
arXiv:cond-mat/0409036

The article alluded to by the New Scientist article: unreadable and empty.

Forecasting Stock Markets
New Scientist, 25th September 2004, p. 16

Presentation of agent-based models of stock markets: they have the same properties as the actual stock markets (not new); furthermore, one can easily *control* those markets (this is new). It could have applications beyond finance (meteorology, pollution, terraforming, etc.)

***A Joint Review of Technical and Quantitative
Analysis of Financial Markets Towards a
Unified Science of Intelligent Finance***
H. Pan

This article starts by a presentation of fundamental analysis, technical analysis and quantitative analysis of financial markets.

Fundamental analysis is the study of the accounting variables tied to a given asset: the sources are irregular, not always reliable, the data are published with a certain time lag, the accounting rules differ from country to country (which prevents comparison). Yet, automatic news monitoring could provide some insight (I would like to hear more about the applications of NLP (*Natural Language Processing*) in finance: is it really used?).

Technical analysis is the study of the price and volume times series and the quest of *signs* in those series.

The *Dow theory of trends* states that:

- There are three time scales (year, month, week);
- At each scale, the trends have 3 phases: accumulation (knowledgeable investors buy/sell), public participation (knowledgeable investors wait, the public buys/sells), distribution phase (knowledgeable investors sell/buy).

The *Elliott theory of waves* states that a trend (which can be observed at various scales) looks like that:

(insert a picture)

The ratios of the price differences are believed to be Fibonacci numbers or $k/2^n$ (this is an irrational belief).

The *Gann theory of cycles and angles* represents those waves in a 2-dimensional space, price×time: it can be analysed statically (one looks at the densest regions) or dynamically (given the current region, which is the next most probable region? – this is a Markov chain). Marketing people, undeterred by the perspective of falling in the “abuse of science” trap exemplified by the Sokal affair, see an analogy between “price-time” and “space-time”, and between the movements between the price-time space and the electrons jumping between energy levels – it may impress clients, though.

A technical analyst typically chooses a minimal set of technical indicators:

- A market-mode indicator, indicating if the market is in a trend or in a cycle, such as the “MESA filter” (but we do not know what it is);
- A trend indicator (a moving average);
- A cycle indicator, such as RSI or Sinewave (again, I do not know what it is);
- A volatility indicator, such as the 2σ Bollinger bands;
- A market breadth indicator (again, I do not understand).

A technical analyst also tries to spot *chart patterns*, at various time scales.

Quantitative finance has pointed out the following facts:

- The distribution of returns is not normal, it has fat tails, it sometimes looks *stable* (the Levy stable distributions are a family of distributions such that if X_1, \dots, X_n are iid and follow one of those, then so does their sum $X_1 + \dots + X_n$ – the most prominent examples are the normal and Cauchy distributions) (but this is contradicted by the facts that the second moment is finite, or the fact that the extreme value distribution follows a power law); the longer the time scale, the more normal the distribution looks;
- *Clustered volatility*, i.e., heteroscedasticity of returns, can be accounted for by GARCH models;

- Stock prices have a *fractal* structure;
- Crashes can be modelled as *phase transitions*;
- *Multiagent game models* such as the Minority Game or the Santa Fe Institute Stock Market Model can explain some of these characteristics of the distribution of returns.

The *Swing Market Hypothesis* states that the markets are sometimes efficient, sometimes not; in each of these modes, they can have several regimes. There are 4 types of fluctuations:

- dynamic swings (fractals, i.e., multilevel trends, i.e., Elliott waves, with “power laws” and “log-periodicity”);
- physical cycles (year, month, week);
- abrupt momentum (news impact, chart patterns);
- random walks.

***The good and the bad of value investing:
applying a bayesian approach
to develop enhancement models
R. Bird***

“Value investing” means finding stocks that are misvalued by the market: if they are overvalued, we sell them, if they are undervalued, we buy them. Various ratios try to identify them: the article chose the *book to market*, but any other would do.

The problem is that among those value stocks, most will remain over- or under-valued – they were not real value stocks, their price was that high or that low for good reasons, the variables/methods we used to select them were too coarse to identify those reasons.

One can use *logistic regression* with respect to various fundamental variables to spot them – they do not take all the available variables but only those (less than 30) that were deemed important, according to previous articles. But there are still too many variables to have a reliable model. A simple approach would be to try to select “the best” (or, at least, “a good”) model, both simple and giving good predictions.

Instead, as we are not interested in the interpretation of the model but mainly in its prediction, we can consider several good models and compute their “average forecast” – this is called *bagging*.

Here, they take *all* the models and use the MCMC algorithm to average them – but this requires that we affect a *score* to each model: the article does not tell us how it is computed (actually, they are “just” using *Bayesian Model Averaging*).

(Here, I should recall what “MCMC” means...)

The conclusions of the article are:

- the model changes with time;

- the model depends on the country (this is not surprising, because the accounting rules, and hence the variables, depend on the country).

***Profitability, Earnings and Book Value
in Equity Valuation: A Geometric View
and Empirical Evidence***
P. Chen and G. Zhang

The article compares the model presented in the previous article with actual data. In short,

$$\text{value} \sim \text{Book Value} * f(\text{earnings}),$$

where f is convex, increasing.

***Accounting Information, Capital Investment
Decisions and Equity Valuation:
Theory and empirical Implications***
G. Zhang

One may model the evolution of a company as follows:

$$\begin{array}{ll} \text{Cash flow} & c_t = \kappa_t s_{t-1} \\ \text{Operating Efficiency} & \kappa_t = \text{random walk} \\ \text{Assets} & s_t = \gamma s_{t-1} + i_t \\ \text{Stock depreciation} & \gamma \\ \text{Investment} & i_t \\ \text{Value} & V_t = \sum_{s>t} \text{PV } E[\text{net cash flow}] \\ & = \sum_{s>t} \text{PV } E[c_t - i_t] \end{array}$$

Here, i_t is not specified: it depends on *investment decisions*. To simplify the model, they limit the choices to:

- stop investing;

- invest such that the value of the stocks s_t remains constant;
- invest more (with a growth factor G).

The actual investment decision is then the one that maximizes the value. After playing with the formulas, it becomes

$$\begin{aligned} V_t &= \text{expected value if we maintain the activities} \\ &+ \text{price of the option to stop operations at } t+1 \\ &+ \text{price of the option to expand the operations} \end{aligned}$$

and later, a function of the book value and the earnings. The article examines the convexity of the formula:

- V is convex;
- For steady-state companies, the value only depends on the earnings, not on the book value.

The PB-ROE Valuation Model Revisited
J.W. Wilcox and T.K. Philips, 2004

The P/B ROE valuation model is just another *valuation model* (as the DDM, Discounted Dividend Model). In short:

$$\log(\text{P/B}) = \alpha + \beta \text{ ROE}.$$

They estimate α and β with a classical regression. The fact that The P/B is above (respectively under) its predictive value does not necessarily mean that it is overvalued (respectively undervalued): other factors could account for the discrepancy.
