

Optimal classification trees
D. Bertsimas and J. Dunn (2015)

Decision trees are often built in a (suboptimal) greedy way, unconstrained (to detect strong splits hidden behind weak ones) and pruned (to account for the complexity penalty).

The problem of finding the optimal tree of depth at most D can be formulated as mixed integer program:

- Binary variables for each node, indicating if there is a split;
- Binary variables to select the variable used for the split;
- Binary variables indicating non-empty leaves;
- Binary variables indicating, for each observation and each node, whether it goes to the left or to the right;
- Binary variables indicating the majority class in each leaf

(and many constraints).

For the hyperparameters:

- Progressively increase the tree depth, using CART or a shallower tree as a warm start;
- The complexity penalty can be formulated as a hard constraint on the number of nodes: progressively increase the number of nodes;
- Idem for the minimum number of observations in each leaf.

This can be generalized to multivariate decision trees (hyperplane splits, instead of axis-aligned ones), with greedy (single-split-optimal-tree based) warm start (or greedy logistic regressions).

**Learning optimal and fair decision trees
for non-discriminative decision-making**
S. Aghaei et al.

Another MIP formulation of the optimal decision (or regression) tree; also allowing fairness penalties.

Implementation in `ODTlearn`.

**Learning optimal classification trees
using a binary linear program formulation**
S. Verwer and Y. Zhang

Reformulation of the optimal decision tree MIP without constraints for each observation in the training set: just sum the constraints for the rows having the same feature values.

**Optimal constraint-based decision tree
induction from itemset lattices**
S. Nijssen and E. Fromont

DL8 uses frequent itemset mining to build optimal decision trees on binary data (every path, or a decision tree, can be mapped to an itemset): the best decision tree on a subset of the data is obtained by considering all possible ways of partitioning it in two, and recursively determining the best tree for each partition.

**Learning optimal decision trees
using caching branch-and-bound search**
G. Aglin et al.

Implementation improvements for DL8, in `PyDL8.5`

Optimal policy trees
M. Amram et al.

The optimal decision tree MIP can be generalized to build an optimal *policy* tree,

$$\text{Minimize}_{\tau: \mathcal{X} \rightarrow \{0,1\}} \sum_i \Gamma_{i,\tau(x_i)}$$

after estimating the counterfactuals with a doubly robust (DR) estimator

$$\Gamma_{it} = \frac{y_i - \hat{y}_{it}}{\hat{p}_{it}} \mathbf{1}_{z_i=t} + \hat{y}_{it}.$$

Optimal prescriptive trees
D. Bertsimas et al.

Joint (MIP) tree model for counterfactual estimation (locally constant or piecewise linear) and optimal treatment assignment.

Generalized random forests
S. Athey et al. (2016)

Generalized random forests fit a quantity $\theta(x)$ identified as the solution of local moment equations

$$\mathbb{E}[\psi_{\theta(x)}(X) | X = x] = 0.$$

The tree is built recursively, splitting a (parent) node P into (children) C_1, C_2 , maximizing

$$\Delta(C_1, C_2) = \frac{|C_1| \cdot |C_2|}{|P|^2} \left\| \hat{\theta}_{C_1} - \hat{\theta}_{C_2} \right\|^2,$$

which can be approximated with a Taylor expansion

$$\begin{aligned} A_P &= \text{Mean}_{i \in P} \nabla \psi_{\hat{\theta}_P}(x_i) \\ \rho_i &= -A_P^{-1} \psi_{\hat{\theta}_P}(x_i) \\ \tilde{\Delta}(C_1, C_2) &= \sum_{j \in \{1,2\}} \frac{1}{|C_j|} \left(\sum_{i \in C_j} \rho_i \right)^2. \end{aligned}$$

The final estimate is not obtained by averaging estimates from each tree, but by using the ensemble to compute similarity weights $\alpha_i(x)$ between the new sample x and training samples i and putting them in the empirical estimating equation

$$\hat{\theta}(x) = \underset{\theta}{\text{Argmin}} \left\| \sum_i \alpha_i(x) \psi_{\theta}(x_i) \right\|_2.$$

R implementation in `grf`.

evtree: evolutionary learning of globally optimal classification and regression trees in R
T. Grubinger et al. (2014)

Decision trees are usually built greedily: they are only locally optimal – genetic algorithms can search for a globally optimal tree.

Parties, models, mobsters: a new implementation of model-based recursive partitioning in R
A. Zeileis and T. Hothorn

Model-based recursive partitioning (MOB) is a “decision” tree with models (e.g., linear models) in the leaves. They can use different variables for the models $y \sim x_1 + \dots + x_m$ and the splits z_1, \dots, z_ℓ . The tree is built recursively:

- Fit the model to the current node;
- Test for parameter instability (SupLM fluctuation test) to select the variable to split on;
- Use exhaustive search to select the split point;
- Split the node, and iterate until the desired depth;
- Prune the tree by looking at the AIC or BIC improvement.

R implementation in `partykit`.

Generalized M-fluctuation tests for parameter instability
A. Zeileis and K. Hornik (2007)

Given observations $Y_i \stackrel{\text{indep}}{\sim} F_{\theta_i}$, we can test

$$H_0 : \forall i \theta_i = \theta_0$$

$$H_1 : \theta_i \text{ varies over time}$$

using a score function ψ , *i.e.*, a function such that

$$\mathbb{E}_{Y \sim F_\theta} [\psi_\theta(Y)] = 0,$$

e.g.,

$$\psi_\theta(y) = \frac{\partial \text{loss}(y; \theta)}{\partial \theta}$$

where the loss is the log-likelihood or the residual sum of squares.

Since $\hat{B}_n^{-1/2} W_n(\cdot, \hat{\theta}_n) \xrightarrow{d} W^0(\cdot)$, where

- n is the number of observations;
- $\hat{\theta}_n$ is estimated using the whole sample:

$$\sum_{i=1}^n \psi_{\hat{\theta}_n}(Y_i) = 0;$$

$$\cdot W_n(t, \theta) = \frac{1}{\sqrt{n}} \sum_{i=1}^{\lfloor nt \rfloor} \psi_\theta(Y_i);$$

$$\cdot B(\theta) = \text{Var}_{Y \sim F_\theta} [\psi_\theta(Y)];$$

$$\cdot \hat{B}_n = \frac{1}{n} \sum_{i=1}^n \psi_{\hat{\theta}_n}(Y_i) \psi_{\hat{\theta}_n}(Y_i)^\top;$$

$$\cdot W^0(t) = W(t) - tW(1) \text{ Brownian bridge};$$

$$\cdot W \text{ is a standard Brownian motion,}$$

we can use

$$\text{SupLM} = \sup_{t \in \Pi} \frac{\|\text{efp}(t)\|_2^2}{t(1-t)}$$

$\text{efp}(t) = \hat{B}_n^{-1/2} W_n(t, \hat{\theta}_n)$ (empirical fluctuation process)

$\Pi \subset [0, 1]$ interval with suspected break

as test statistic (and approximate p -values). For linear regression,

$$\psi_B(y_i, x_i) = x_i(y_i - x_i^\top \beta).$$

Approximate asymptotic p-values for structural change tests
B.E. Hansen (1997)

P -values for the limiting distribution

$$\sup_{t \in \Pi} \frac{\|W^0(t)\|_2^2}{t(1-t)}.$$

ctree: conditional inference trees
T. Hothorn et al.

Decision tree using statistical tests (adjusted for multiple testing) to select the splits (instead of heuristic, overfitting-prone criteria).

Fast optimal leaf ordering for hierarchical clustering
Z. Bar-Joseph et al. (2001)

Approximation trees: statistical stability in model distillation
Y. Zhou et al.

To explain a blackbox model (e.g., a random forest), distill it into a decision tree using pseudo observations (real observations plus Gaussian noise, for a user-chosen bandwidth – *i.e.*, samples from a KDE of the data). Choose the number of pseudo observations so that the trees be stable – use a statistical test on the Gini index (which is used to select the splits). Choose the tree depth by comparing the variance of the observations in a leaf with the variance of the blackbox model.

Constructing optimal L_∞ star discrepancy sets
F. Clément et al. (2024)

The L^∞ star discrepancy of a finite set $P \subset [0, 1]^d$ is

$$d_\infty^*(P) = \sup_{q \in [0, 1]} \left| \frac{|P \cap [0, q]|}{|P|} - \lambda([0, q]) \right|$$

where λ is the Lebesgue measure. It suffices to consider $q \in \bar{\Gamma}(P)$.

$$\bar{\Gamma}(P) = \bar{\Gamma}_1(P) \times \dots \times \bar{\Gamma}_d(P)$$

$$\bar{\Gamma}_i(P) = \Gamma_i(P) \cup \{1\}$$

$$\Gamma_i(P) = \{x_i : x \in P\}$$

Strong laws for L and U statistics
J. Aaronson et al. (1996)

U-statistics are averages of kernels of random samples, *i.e.*, they are of the form

$$U_n(X_1, \dots, X_n) = \text{Mean}_{\substack{I \subset [1, n] \\ |I|=r}} f(X_I)$$

where f is a symmetric function of r variables, *e.g.*, $f(x_1) = x_1$ for the mean, or $f(x_1, x_2) = \frac{1}{2}(x_1 - x_2)^2$ for the variance.

L-statistics are linear combinations of order statistics, *i.e.*, they are of the form

$$L_n(X_1, \dots, X_n) = \sum_{i=1}^n \mu \left(\left[\frac{i-1}{n}, \frac{i}{n} \right] \right) X_{n;i},$$

e.g.,

density	statistic $L(F) = \int_0^1 F^{-1} d\mu$
$J(u)$	$M_1(F) = E[X]$
$J(u) = \alpha u^{\alpha-1}$	$P_\alpha(F) = \int x dF^\alpha(x)$
$J(u) = 4u - 2$	$g_1(F) = E X - X' $.

Relevance-based importance: a comprehensive measure of variable importance in prediction
M. Czaronis et al. (2024)

The adjusted fit, from a relevance grid model, defines function

$$\begin{aligned} \mathcal{P}(\text{predictors}) \& \longrightarrow \mathbf{R} \\ \theta & \longmapsto \text{Fit}_{\theta,t}^{\text{adj}} \end{aligned}$$

for each observation t ; the *relevance-based importance* $\text{RBI}_{t,k}$ is the corresponding Shapley value for predictor k .

Learning optimal Bayesian networks: a shortest path perspective
C. Yuan and B. Malone (2013)

One can find the causal graph minimizing

$$\text{Score}(G) = \sum_i \text{Score}(x_i, \text{Pa}_i)$$

with dynamic programming, adding successor nodes (leaves) one by one (finding a path from \emptyset to V in the "order graph" – the Hasse diagram of the nodes)

$$\text{Score}(V) = \min_{X \in V} [\text{Score}(X \setminus \{X\}) + \text{BestScore}(X, V \setminus \{X\})]$$

$$\text{BestScore}(X, V) = \min_{P \subset V} \text{Score}(X, P)$$

or with A^* , with a heuristic relaxing the acyclicity constrain

$$h(U) = \sum_{X \in V \setminus U} \text{BestScore}(X, V \setminus \{X\})$$

(better heuristics exist).

$$\begin{array}{c} V \\ | \\ \text{BestScore}(X, V) \\ | \\ V \cup \{X\} \end{array}$$

Learning optimal Bayesian networks using A^* search
C. Yuan et al. (2011)

FastText.zip: compressing text classification models
A. Joulin et al.

Linear models for text classification with n -gram features are easy to train, perform well, but are very large:

- Use product quantization (PQ: k -means on subsets of the coordinates) or orthogonal product quantization (OPQ: PQ after applying a learned rotation), separating norm and direction of the vectors (the norms span 3 orders of magnitude), and retrain the layers after quantization;
- Prune the vocabulary (largest weightes, ensuring there is at least an n -gram in each document); keep the n -grams selected in a **set** (a Bloom filter degrades performance);
- Use Vowpal Wabbit's hashing trick to store the weights.

Enriching word vectors with subword information
P. Bojanowski et al.

Represent words as bags of character n -grams ($3 \leq n \leq 6$); use skipgram to learn the subword representations and add them.

Bag of tricks for efficient text classification
A. Joulin et al.

fastText is a linear model for text classification, using

- Word and n -gram embeddings as features;
- A low-rank constraint

$$\text{Maximize}_{A,B} \text{Mean}_n y_n \log \text{softmax}(BAx_n)$$

- If there are many classes, a hierarchical softmax based on the Huffman coding tree.

Optimized product quantization

T. Ge et al.

Product quantization (k -means on M subsets of the coordinates, for approximate nearest neighbour (ANN) search) after a learned orthogonal transformation:

- Alternatively estimate the cluster centers (k -means) and the orthogonal matrix (Procrustes);
- Initialize with the following heuristic (approximation of the exact solution for Gaussian data):
 - Compute the PCA and sort the eigenvalues in decreasing order;
 - Start with M empty buckets;
 - Sequentially pick the largest eigenvalue and assign it to the bucket with the minimum product of eigenvalues (unless it is already full);

this gives k^M codewords.

Diffusion forcing: next token prediction meets full sequence diffusion

B. Chen et al.

Combine Bayesian updates

with diffusion

$$x^0 \xrightleftharpoons[\text{denoising}]{+\text{noise}} x^k$$

or conditional diffusion

trying to forecast the added noise $\varepsilon_t = x_t^{k_t} - x_t^0$ from z_{t-1} , $x_t^{k_t}$ and k_t .

One can sample on a grid, time \times noise, with an arbitrary (time-dependent) noise schedule – noise can be seen as a form of masking.

Classifier-free diffusion guidance

J. Ho and T. Salimans (2021)

Classifier guidance is a diffusion model whose score is combined with the gradient of a classifier – but we cannot use an off-the-shelf classifier: it has to be trained on noisy data (this is reminiscent of GANs). Instead, jointly train a conditional and an unconditional diffusion model, and combine their scores

$$(1 + w)\varepsilon_\theta(z, c) - w\varepsilon_\theta(z).$$

Gene regulatory network inference in the presence of selection bias and latent confounders

G. Luo et al.

With interventional data ($I_X \rightarrow X$ and/or $I_Y \rightarrow Y$), it is possible to distinguish between

with conditional independence tests.

DeepSeek-R1: incentivizing reasoning capability in LLMs via reinforcement learning

DeepSeek-R1-Zero uses RL (GRPO) on DeepSeek-V3-Base to enhance its reasoning capabilities:

- Prompts: unspecified (math, leetcode, etc.);
- Reward: only accuracy (correct final answer) and format, as specified by the prompt: `<think>...</think>` and `<answer>...</answer>`.

During training, the model spends more and more time thinking, but the `<think>` section becomes less and less readable (it mixes Chinese and English).

DeepSeek-R1 uses 4 steps:

- SUPervised fine-tuning (SFT) with high-quality data, e.g., readable answers from DeepSeek-R1-Zero;
- RL, as above;
- SFT, with 600k reasoning samples (ask the model to generate several answers, and have DeepSeek-V3 select the best) and 200k non-reasoning samples from (DeepSeek-V3, unspecified prompts);
- RL, for alignment (unspecified prompts and rewards).

DeepSeekMath: pushing the limits of mathematical reasoning in open language models

Z. Shao et al.

Start with a code model, and fine-tune it on a large mathematical corpus:

- Train a FastText classifier on OpenWebMath;
- Apply it to CommonCrawl;
- Use the results to identify websites with math contents;
- Add the corresponding pages to the FastText training data (adding arxiv papers does not bring any improvement); re-train;
- To avoid benchmark contamination, exclude pages containing a 10-gram from one of the benchmarks;
- Apply the new model to CommonCrawl.

Also evaluate on miniF2F (convert an informal proof into a formal one, checked with Isabelle) and on GSM8K (math with tool use: Python, SymPy).

In PPO,

$$J = \mathbb{E}_{\substack{q \sim \text{queries} \\ o \sim \pi_{\text{old}}(\cdot|q)}} \text{Mean}_{1 \leq t \leq |o|} \frac{\pi_{\theta}(o_t|q, o_{<t})}{\pi_{\text{old}}(o_t|q, o_{<t})} - \beta \text{KL}(\pi_{\theta} \parallel \pi_{\text{ref}})$$

GRPO (group relative polici optimization) replaces the advantage A with the average reward from π_{old} ,

$$A_i = \frac{r_i - \text{mean}(\mathbf{r})}{\text{std}(\mathbf{r})}$$

and uses

$$\text{KL}(\pi_{\theta} \parallel \pi_{\text{ref}}) = \frac{\pi_{\text{ref}}(\cdots)}{\pi_{\theta}(\cdots)} - \log \frac{\pi_{\text{ref}}(\cdots)}{\pi_{\theta}(\cdots)} - 1.$$

DeepSeek-V3 technical report

DeepSeek-V3 combines:

- MoE (top-k and shared experts);
- No auxilliary loss to ensure load balancing between experts replaced by a bias term for each expert;
- Sequence-wise auxilliary loss;
- Multi-head laent attentio (MLA): joint low-rank compression of K and V to reduce the size of the KV cache;
- Multi-token predictin;
- FP8 mixed precision (FP8, BF16, FP32);
- Context length extension (first 32k, then 128k);
- Many parallelism and communication improvements).

Training required 2 months on 2048 GPUs (\$5m).

Softmax is not enough (for sharp out-of-distribution)

P. Veličković et al.

“Softmax” should have been called “softargmax”.

A function is *sharp* if it only depends on a constant number of inputs, e.g., max. Softmax cannot approximate shaprness with increasing problem size: use a temperature-adjusted softmax instead, with the temperature depending on the entropy of the initial probability distribution.

Data-driven discovery of dynamical systems in pharmacology using large language models

S. Holt et al.

LLM-based, CMA-ES-like optimization to find the ODE (Python code) best fitting the data; the LLM can also request more features (from a list). Iterate:

$$\begin{aligned} f &= \text{LLM}(\text{descriptions, past attempts}) \\ \ell &= \text{Min}_{\theta} \text{loss}[f(\text{Data}; \theta)]. \end{aligned}$$

Rethinking early stopping: refine, then calibrate **E. Berta et al.**

(Multiclass) classifiers minimize two quantities:

- Refinement error (whether the classes are in the correct order);
- Calibration error (whether the probabilities are correct).

They are not simultaneously minimized during training. Stop training when the refinement loss stops decreasing,

$$\text{Min}_g \text{Mean}_{(X,Y) \sim \text{Data}} \text{loss}[g(f(X), Y)]$$

where g is the relibration – temperature scaling is good enough.

Towards safe reinforcement learning via constraining conditional value at risk **C. Ying et al.**

CVaR-PPO (aka CPPO) adds a CVaR constraint to the PPO loss, transforms it using the formulation of CVaR as an optimization problem, and replaces the hard constraint with its Lagrangian relaxation.

FinRL-DeepSeek: LLM-infused risk-sensitive reinforcement learning for trading agents **M. Benhenda**

RL trading agent, using technical indicators and LLM-derived signals (trade recommendation from news, confidence in this recommendation, risk assessment, each as a numeric score in $[0, 10]$), trained with CVaR-PPO.

On causal discovery in presence of deterministic relations **L. Li et al.**

Deterministic relations create independence and wreak havoc in constraint-based causal discovery algorithms: for instance, if $X \rightarrow Y$ is deterministic, then y is constant when conditioned on X , and therefore independent from everything: $* \perp\!\!\!\perp Y \mid X$. Similarly,

GES can be modified to account for deterministic relations:

- Identify deterministic variables (by looking at the variance of the residuals of regressions) and ignore independence relations coming from determinism;
- Use a (RKHS) ridge-adjusted BIC as score (because the variance matrix is singular in presence of determinism).

**Generalized score functions
for causal discovery
B. Huang et al. (2018)**

Using linear models in GES can introduce spurious relations, e.g., in

$$\begin{array}{ll} X_1 = \varepsilon_1 & X_1 \\ X_2 = X_1 + X_1^2 + \varepsilon_2 & \downarrow \\ X_3 = X_2 + X_2^2 + \varepsilon_3 & X_2 \\ & \downarrow \\ & X_3 \end{array}$$

the influence of X_1 on X_3 cannot be blocked by a linear function of X_2 , and can miss relations, e.g.,

$$\begin{array}{ll} X_1 = \varepsilon_1 & X_1 \\ X_2 = (\sin X_1 + \varepsilon_2)^2 & \downarrow \\ & X_2 \end{array}$$

Use a kernel conditional independence test to rule out potential parents of a node.

For the score function, use the (ridge-regularized) CV-log-likelihood or marginal likelihood of an RKHS regression (regression on

$$\begin{bmatrix} \kappa(x_1, x) \\ \vdots \\ \kappa(x_n, x) \end{bmatrix} \in \mathbf{R}^n$$

instead of $\phi(x) \in \mathcal{H}$).

**Universality, characteristic kernels
and RKHS embeddings of measures
B.K. Sriperumbudur et al.**

A kernel on X is a positive definite function $\kappa : X \times X \rightarrow \mathbf{R}$. I defines a subspace

$$\text{Span}\{\kappa(\cdot, x), x \in X\} \subset \mathcal{F}(X, \mathbf{R}).$$

It is *universal* if

$$\mathcal{H}_0 = \overline{\text{Span}\{\kappa(\cdot, x), x \in X_0\}} = \mathcal{F},$$

for some $X_0 \subset X$ and some Hilbert space $(\mathcal{F}, \|\cdot\|)$ of functions on X .

It is *characteristic* if

$$\begin{cases} \text{Borel}(X) & \longrightarrow \mathcal{H} \\ P & \longmapsto \int_X \kappa(\cdot, x) dP(x) \end{cases}$$

is injective.

Examples include:

- $\mathcal{C}^0(X)$ and $\|\cdot\|_\infty$;
- $\mathcal{C}^0(X)$ and compact convergence;
- $\mathcal{C}_0(X)$ (continuous functions vanishing at infinity) and $\|\cdot\|_\infty$;
- L^0 and $\|\cdot\|_p$

**DoWhy-GCM: an extension of DoWhy
for causal inference in graphical causal models
P. Blöbaum et al.**

dowhy was limited to effect estimation

$$\mathbb{E}[Y \mid \text{do}(T = 1)];$$

with **dowhy-gcm**, it can answer causal queries: counterfactuals, direct and indirect effects, causal strength, root cause analysis, etc.

**Can large language models
infer causation from correlation?
Z. Jin et al.**

Can an LLM learn the PC algorithm, *i.e.*, infer causation from correlations (independence and conditional independence relations, expressed as text)? No. Fine-tuning does not help much.

**Causal inference using LLM-guided discovery
A. Vashishtha et al.**

Do not ask the LLM to find the whole causal graph (it would struggle to distinguish direct from indirect relations) but only the partial order it induces (the *transitive reduction*, aka Hasse diagram it induces).

You can compare DAGs with the L^1 distance between their transitive reductions.

Use a triplet prompt to infer this order: provide 3 variables and ask for their causal graph.

Applications include

- Post-processing the output of the PC algorithm, to orient the remaining unoriented edges;
- Constraints (transitive closure) for the PC or GES algorithms.

**Causal order: the key to leveraging
imperfect experts in causal inference
A. Vashishtha et al. (2024)**

Building a causal graph by asking pairwise questions to an LLM creates spurious edges – with pairwise queries alone, the LLM cannot distinguish between direct and indirect effects.

The not build a DAG, but just a *partial order*: it can be used

- To obtain a valid adjustment set (the ancestors of a node in a topological order);
- As constraints or prior for classical causal discovery algorithms.

Do not use pairwise queries, but triplet queries (either all triplets, or $k = 10$ triplets for each pair if the graph is large), aggregated with a majority vote: this creates fewer cycles.

The *topological divergence* between a partial order \preceq and a DAG defined by its adjacency matrix is the num-

ber of edges incompatible with the order,

$$D(\preceq, A) = \sum_{i \not\preceq j} A_{ij}.$$

***From causal to concept-based
representation learning***

G. Rajendran et al.

With no additional assumptions or data, we cannot recover latent factors Z from observed data $X = f(Z)$. If Z is a causal representation, and if we have interventions on all latent variables Z_j , it is identifiable – but that is a lot of interventions. A *concept* is a projection AZ of the latent factors; concepts are identifiable through conditioning.

***CLadder: assessing causal reasoning
in language models***

Z. Jin et al.

Dataset to check if LLMs already know do-calculus and can answer queries on the three rungs of the causality ladder (association, intervention, counterfactuals), without resorting to commonsense.

***Deep proxy causal learning and its application
to confounded bandit policy evaluation***

L. Xu et al. (2024)

PCL estimates causal effects in presence of unobserved confounders using proxies.

$$\text{ATE}(a) = \mathbb{E}_U[\mathbb{E}[Y | A = a, U]]$$

$$h \text{ s.t. } \mathbb{E}[Y | A = a, Z = z] = \int h(a, w) \rho_W(w | A = a, Z = z) dw$$

$$\text{ATE}(a) = \mathbb{E}_W[h(a, W)]$$

The “bridge function” h can be found with 2-stage regression.

***Causal reasoning and large language models:
opening a new frontier for causality***

E. Kıcıman et al.

LLMs are good, but have unpredictable failures.

***Shaking the foundations: delusions in
sequence models for interaction and control***

P.A. Ortega et al.

In imitation learning, the model takes its own actions as evidence about the world: this leads to self-delusion.

Actions are causal interventions: do not model $P[O|A]$, but $P[O|\text{do}(A)]$.

***On information transfer
in control dynamical systems***

S. Sinha and U. Vaidya (2018)

The directed information is

$$I(X \rightarrow Y) = H(Y_1, \dots, Y_T) - \sum_{1 \leq t \leq T} H(Y_t | Y_{<t}, X_{\leq t}).$$

The transfer entropy is

$$T_{X \rightarrow Y} = H(Y_t | Y_{<t}) - H(Y_t | Y_{<t}, X_{<t}).$$

A dynamical system

$$x_{t+1} = f(x_t, y_t) + \text{noise}$$

$$y_{t+1} = g(x_t, y_t) + \text{noise}$$

defines a conditional probability distribution $\rho(y_{t+1}|y_t)$. Similarly, if we freeze x ,

$$x_{t+1} = x_t$$

$$y_{t+1} = g(x_t, y_t) + \text{noise}$$

defines $\rho_{\mathcal{F}}(y_{t+1}|y_t)$. The information transfer is

$$T_{x \rightarrow y}_t^{t+1} = H(\rho(y_{t+1}|y_t)) - H(\rho_{\mathcal{F}}(y_{t+1}|y_t)).$$

***Context is key: a benchmark for forecasting
with essential textual information***

A.R. Williams et al.

Cik is a benchmark for *multimodal* probabilistic time series forecasting models (models also provided with a textual context for each time series), such as UniTime, Time-LLM, LagLlama, Chronos, Moira, TimeGEN.

The CRPS (continuous ranked probability score)

$$\text{CRPS}(F, x) = \int_{-\infty}^{+\infty} (F(y) - \mathbf{1}_{y \geq x})^2 dy \quad (\text{dim} = 1)$$

$$= \mathbb{E}_{X \sim F} |X - x| - \frac{1}{2} \mathbb{E}_{X, Y \sim F} |X - Y|$$

(the energy score uses $\|\cdot\|_2^2$ instead of $|\cdot|$) is a proper scoring rule generalizing the MAE to assess *probabilistic* forecasts – cross-entropy

$$- \text{Mean} \log f(x) = H(\text{data}, F)$$

$$H(p, q) = - \mathbb{E}_{X \sim p} \log q(x)$$

is often a better choice if the forecasted density is available.

The RCRPS (region-of-interest CRPS) is a weighted and penalized CRPS: to give more weight to some forecasting horizons and penalize (problem-specific) constraint violations.

Regions of reliability in the evaluation of multivariate probabilistic forecasts
É. Marcotte et al. (2023)

A *scoring rule* is a function S measuring how unlikely an event $y \sim \text{Data}$ is, wrt a forecasted distribution F ; it is *proper* if

$$\mathbb{E}_{y \sim \text{Data}} S(y, F)$$

is minimal for $F = \text{Data}$.

In practice, however, we do not have a ground truth distribution, but only a finite sample from it: for some combinations of

d : dimension

n : ground truth sample size

m : forecast sample size

the statistical power of most scoring rules to detect

- Differences in mean;
- Positive correlations;
- Skewness;
- Difference in marginal variance;
- etc.

is low – you need to increase n and m .

Time-MoE: billion-scale time series foundation models with mixture of experts
X. Shi et al.

Transformer (with SwiGLU, RMSNorm, no biases, ROPE, multi-resolution forecasting, MoE), trained on 300B data points.

Towards transparent time series forecasting
K. Kacprzyk et al.

TO make time series forecasting (from static features) “transparent”, let the user interactively see the impact of changing some of the inputs on:

- The shape of the forecast (a sequence of segments, labeled increasing/constant/decreasing and convex/linear/concave);
- Some properties of the forecast (mean, slope, maximum, minimum).

Fit a model with clubic splines (piecewise polynomials) $\mathbf{R}^k \rightarrow \mathbf{R}^T$.

Forecast evaluation for data scientists: common pitfalls and best practices
H. Hewamalage et al.

Long list of error measures for time series forecasting, with their suggested use and pitfalls.

- Use a simple baseline (naive, seasonal naive);
- Forecast plots $t, \hat{y} \sim \text{time}$ are misleading;
- Beware of non-stationarity (seasonality, trend, unit root (stochastic trend), heteroskedasticity, structural breaks) and non-normality (symmetry, tails, outliers, intermittency (zero-inflation));
- Beware of ddata leakage.

Chronos: learning the language of time series
A.F. Ansari et al.

T5-based foundation time series forecasting model, processing time series that have been mean-scaled (divide by the average absolute value) and quantized (uniform binning), trained with data augmentation: TSMixup, KernelSynth (Gaussian processes with kernels from the automated statistician).

The effectiveness of discretization in forecasting: an empirical study on neural time series models
S. Rabanset et al.

Binning input and output data tends to improve the performance of deep learning time series forecasting models (MLP, CNN, RNN).

Maximum entropy bootstrap for time series: the meboot R package
H.D. Vinod and J. López-de-Lacalle

The *maximum entropy bootstrap*, for potentially non-stationary time series,

- Separates the order of the observations from their distribution;
- Resamples the observations, using a piecewise uniform distribution (more precisely, a piecewise maximum entropy distribution, with a pre-specified mean on each interval, to allow values slightly more extreme than observed);
- Keep the order (sic).

Maximum entropy ensembles for time series inference in economics
H.D. Vinod (2006)

The uncertainty of machine learning predictions in asset pricing
Y. Liao et al. (2025)

There are many types of bootstraps:

- Classical: resampling with replacement;
- Residual: fit a model and esample the residuals;
- Wild: idem, after multiplying the residuals by $N(0, 1)$ (for heteroskedastic data);
- Blocks: blocks of constant sizes;
- Stationary: blocks of random length, from a geometric (exponential) distribution;
- Parametric: $X \sim F_{\hat{\theta}}$;
- Smooth: $X \sim \text{kde}$;
- etc.

To compute prediction confidence intervals for deep learning models on panel data, use a variant of the wild bootstrap:

$$\begin{aligned}\hat{y}_{it} &= \hat{g}(x_{i,t-1}) && \text{forecast} \\ \varepsilon_{it} &= y_{it} - \hat{y}_{it} && \text{residual} \\ \eta_t &\sim N(0, 1) && \eta_t, \text{ not } \eta_{it} \text{ or } \eta_i \\ y_{it}^* &= \hat{y}_{it} + \eta_t \varepsilon_{it}\end{aligned}$$

and fine-tune the model (starting from the trained one) for k epochs.

Applications include worst-case (uncertainty-aware) portfolio optimization

$$\text{Maximize}_w \text{Min}_{\mu \in \text{CI}} w' \mu - \frac{\lambda}{2} w' V w.$$

The stationary bootstrap **D.N. Politis and J.P. Romano**

Resample blocks of random lengths, from a geometric distribution.

Proceedings of the 7th annual AI in finance conference **Wolfe, 2025**

LLM applications in finance include:

- Comparison of ChatGPT-generated answers with human ones in conference calls – differences correlate with abnormal volumes;
- Denoising reported earnings;
- Human-free surveys, with synthetic personas (mimicking human participants);
- Making discretionary investing systematic;
- Identifying (and betting against) retain investor biases (technical analysis, from StockTwits).

Regimes **A. Mulliner et al. (2025)**

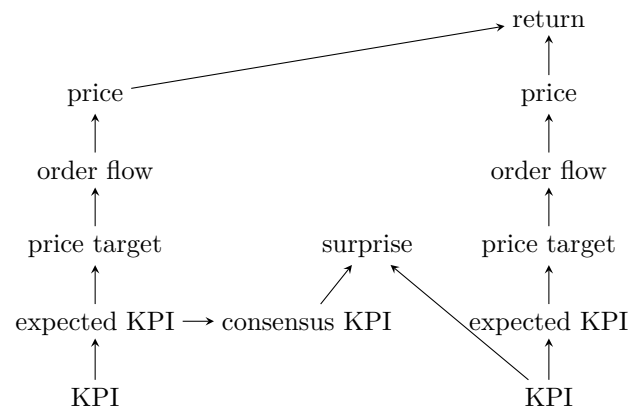

- Take a few macro-economic variables (S&P 500, 10y-3m, 3m, oil, copper, VIX, stock-bond correlation);
- Compute the (Euclidean) distance between today's state and past states;
- Buy (sell) assets with positive (negative) average returns in similar past situations.

One can also look at the most dissimilar past states, and take the opposite actions. [It works better with the Mahalanobis distance; a learned Mahalanobis distance gives similar results out-of-sample but overfits in-sample.]

Dynamic asset allocation using machine learning: seeing the forest for the trees **C. Mueller-Glissmann and A. Ferrario**

A *student tree* is a complex model (e.g., a random forest) distilled into a tree (on real data + noise).

Working backwards from returns **A. Kelleher and A. Mittal**

Mathematical models in epidemiology **F. Brauer et al. (2019)**

Automatic posterior transformation for likelihood-free inference **D.S. Greenberg et al. (2019)**

The Bayesian approach to statistics estimates the posterior $p(\theta|x)$ from the prior $p(\theta)$ and the likelihood $p(x|\theta)$.

Approximate Bayesian computation (ABC, aka likelihood-free inference) only assumes that we know the prior $p(\theta)$ and that we can sample from $p(x|\theta)$ – but we do not know the likelihood.

One can model the posterior as $q_{F(x,\phi)}(\theta) \approx p(\theta|x)$, where q_ψ is a family of tractable distributions and F is a neural net, trained with generated pairs (θ, x) ,

$$\text{Maximize}_{\phi} \sum_i \log q_{F(x_i, \phi)}(\theta_i).$$

Since we are interested in the posterior $p(\theta|x_0)$ at a specific point x_0 , we may want to restrict the θ samples to “informative” values (sampling θ from $q_{F(x_0, \phi_{n-1})}(\theta)$ instead of $p(\theta)$ to estimate ϕ_n) – this gives a biased posterior, but it can be fixed.

Deep symbolic regression: recovering mathematical expressions from data via risk-seeking policy gradients **B.K. Petersen et al.**

Symbolic regression usually uses genetic programming. Instead, use RL to train an RNN model, to generate a symbolic expression tree in pre-order traversal (depth-first, left-to-right). The RNN is not only fed the previous token, but also the parent and sibling nodes. The reward is the normalized root mean square error. The constant token is replaced with the constant maximizing the reward (using BFGS). The REINFORCE policy gradient (with baseline, for variance reduction) would maximize the expected sum of rewards – instead, we

want to maximize the maximum reward: this can be achieved by maximizing the conditional expected reward

$$\mathbb{E}_{\tau \sim p_\theta} [R(\tau) \mid R_\tau \geq R_\varepsilon(\theta)].$$

Why do tree-based models still outperform deep learning on tabular data?
L. Grinsztajn et al.

Neural networks:

- Are biased towards overly smooth functions;
- Are more affected (than tree-based methods) by uninformative features;
- Are rotation-invariant (rotating the input does not affect training).

KwikBucks: correlation clustering with cheap-weak and expensive-strong signals
S. Silwal et al. (2023)

Given a graph (V, E) , *correlation clustering* finds a clustering C minimizing

$$\sum_{(i,j) \notin E} C_{ij} + \sum_{(i,j) \in E} (1 - C_{ij}).$$

KwikCluster picks a vertex at random, forms a cluster by adding its neighbours, removes it, and iterates. Alternatively, find a *maximum independent set* and assign (in parallel) the other nodes to their first neighbour in that set – these are 3-approximations.

This can be generalized to budgeted correlation clustering – we have a limited number of queries to the exact graph, and an unlimited number to an approximation of the graph.

Spectral sparsification of graphs: theory and algorithms
J. Baston et al. (2009)

The *Laplacian quadratic form* of a weighted graph (V, w) is

$$Q_G(x) = \sum_{(u,v) \in E} w_{uv} (x_u - x_v)^2.$$

The *cut* of a subset of nodes $S \subset V$ is

$$\text{Cut}_G(S) = \sum_{\substack{u \in S \\ v \notin S}} w_{uv} = Q(\mathbf{1}_S).$$

Two weighted graphs are *cut-similar*, resp. *spectrally similar* if

$$\begin{aligned} \forall S \quad \sigma^{-1} \cdot \text{Cut}_{\tilde{G}}(S) &\leq \text{Cut}_G(S) \leq \sigma \cdot \text{Cut}_{\tilde{G}}(S) \\ \forall S \quad \sigma^{-1} \cdot Q_{\tilde{G}}(S) &\leq Q_G(S) \leq \sigma \cdot Q_{\tilde{G}}(S). \end{aligned}$$

The *effective resistance* between two nodes u, v is

$$R_{uv} = \left(\min_{x: x_u=1, x_v=0} Q_G(x) \right)^{-1}$$

(the equivalent resistance if you replace each edge with a resistor of resistance $1/w$).

The hypercube is a spectral approximation (a spectral sparsifier) of the complete graph on 2^n vertices (set the weights on the hypercube to $n/2\sqrt{\log n}$).

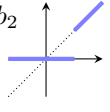

One can obtain spectral sparsifiers:

- By sampling q edges (with replacement) with probabilities $p_e \propto w_e R_e$ and assigning them weights $w_e/q p_e$;
- Or as a union of random spanning trees.

Spectral sparsification of graphs
D.A. Spielman and S.H. Teng (2010)

Gemma Scope: open sparse autoencoders everywhere all at once on Gemma 2
T. Lieberum et al.

To explain an LLM, train a *sparse autoencoder* (SAE, sparse and nonnegative) on its activations (after the MLP, or the activations on the residual stream – for all layers)

$$\begin{aligned} x \mapsto y &= \sigma(W_1 x + b_1) \mapsto \hat{x} = W_2 y + b_2 \\ \sigma(z) &= \text{JumpReLU}_\theta(z) = z \odot \mathbf{1}_{z \geq \theta} = \begin{array}{c} \text{---} \end{array} \\ \theta &= 10^{-3} \end{aligned}$$

Transcoders (which reconstruct the output of an MLP from its input, using a sparse hidden layer) do not work that well.

Jumping ahead: improving reconstruction fidelity with JumpReLU sparse autoencoders
S. Rajamanoharan et al.

To train an SAE, with discontinuous JumpReLU activations and ℓ^0 sparsity penalty, use straight-through estimation for the gradients

$$\frac{\partial \text{JumpReLU}}{\partial \theta} * k_\varepsilon, \quad \frac{\partial \mathbf{1}_{z \geq \theta}}{\partial \theta} * k_\varepsilon$$

where k_ε is a (rectangle) kernel of bandwidth ε ; for the ℓ^0 penalty, use the pre-activations:

$$\|y\|_0 = \mathbf{1}_{W_1 x + b_1 \geq 0}.$$

Scaling and evaluating sparse auto-encoders
L. Gao et al.

The SAE with top- k activations ($k = 32$) does not require an ℓ^0 or ℓ^1 penalty, but may suffer from a large number of dead neurons: add an auxiliary loss, the reconstruction error from the top k_{aux} (512). You can use several values of k , e.g., $\ell(k) + \ell(4k)/8$, and change k at test time.

$$\begin{aligned} y &= \sigma(W_1(x - b_2) + b_1) \\ \hat{x} &= W_2 y + b_2 \end{aligned}$$

**Improving dictionary learning
with gated sparse autoencoders**
S. Rajamanoharan et al.

The L^1 penalty in SAE

$$\begin{aligned}x &= x - b_2 \\ y &= \text{ReLU}(W_1 x + b_1) \\ \hat{x} &= W_2 y + b_2\end{aligned}$$

causes shrinkage. Instead, *gated SAEs* use

$$\begin{aligned}x &= x - b_2 \\ g &= W_0 x + b_0 \\ y &= \mathbf{1}_{g \geq 0} \odot \text{ReLU}(W_1 x + b_1) \\ \hat{x} &= W_2 y + b_2 \\ (W_1)_{ij} &= e^{r_i} \cdot (W_0)_{ij}.\end{aligned}$$

**Transcoders find
interpretable LLM feature circuits**
J. Dunefsky et al.

Circuit analysis looks for sparse subgraphs corresponding to specific behaviours. Transcoders approximate a densely activating MLP layer with a wider, sparsely activating layer.

$$\begin{aligned}z &= \text{ReLU}(W_1 x + b_1) \\ \hat{y} &= W_2 z + b_2.\end{aligned}$$

Train with a faithfulness loss $\|\hat{y} - y\|^2$ and a sparsity penalty $\|z\|_1$.

To find interpretable circuits, pick the top k activations; among their children, pick the top k activations; among the resulting k^2 graphs, pick the top k ones; and continue.

**Sparse feature circuits: discovering and editing
interpretable causal graphs in language models**
S. Marks et al.

Neurons or attention heads are polysemantic. Instead, use sparse autoencoders and look for sparse feature circuits. After interpreting them, you may decide to remove some of them (e.g., gender, for fairness).

**Scaling monosemanticity: extracting
interpretable features from Claude 3 Sonnet**
A. Templeton et al.

Applications of sparse autoencoders (SAE) to interpret LLMs include identifying features activated when

- The model gives instructions to build chemical, biological or nuclear weapons;
- The user probes the model's goals and values, or tries to jailbreak it;
- The model is trained to be a sleeper agent;
- etc.

**Sparse cross-coders
for cross-layer features and model diffing**
J. Lindsey et al.

Adjacent layers are almost parallel: apply dictionary learning to them jointly (a cross-coder is a multi-layer transcoder).

Tokenizarion is NP-complete
P. Whittington et al.

The problem of compressing a dataset to at most δ symbols is NP-complete.

**Neural relational inference
for interacting systems**
T. Kipf et al. (2018)

GNN over a *latent* graph, to discover and model particle interactions (e.g., basketball players).

Can a transformer represent a Kalman filter?
G. Goel and P. Bartlett

Yes, explicitly, up to a small additive error.

**ZipIt! Merging models
from different tasks without training**
G. Stoica et al.

To merge models (same architecture but different training data and/or tasks), permutation-based methods assume they have exactly the same features, up to permutation, and try to recover that permutation, for each layer:

$$\text{Maximize}_{\sigma \in \mathfrak{S}_n} \sum_i \text{Cor}(z_i^1, z_{\sigma(i)}^2)$$

where z_i^2 are the features, for neuron i , in layer ℓ , which contains n neurons.

$$W_\ell^* = \frac{1}{2} W_\ell^1 + \frac{1}{2} P_\ell W_\ell^2 P_{\ell-1}^\top$$

Instead, concatenate the features, $z_i^1 \| z_i^2$, and average highly correlated ones: this accounts for redundancy in each model, and features unique to each model.

**LongNet:
scaling transformers to 1,000,000,000 tokens**
J. Ding et al.

Dilated attention is exponentially sparser as distance grows.

Consistency models
Y. Song et al.

The diffusion SDE

$$dx_t = \mu(x_t, t)dt + \sigma(t)dW_t$$

defines a probability flow ODE

$$\dot{x}_t = \mu(x_t, t) + \frac{1}{2}\sigma(t)^2\nabla\log p_t(x_t);$$

the score function $s_\theta(x, t) \approx \nabla\log p_t(x)$ is learned from data. Diffusion models solve this ODE, mapping $(x_{t+1}, t+1)$ to x_t . Consistency models instead directly map (x_t, t) to x_0 (or, rather, x_ε); they are trained from trajectories, and try to enforce the constraints

$$\begin{aligned} f(x_t, t) &= f(x_s, s) \\ f(x_\varepsilon, \varepsilon) &= x_\varepsilon. \end{aligned}$$

Diffusion models as masked autoencoders
C. Wei et al.

Diffusion model conditioned on masked input for image inpainting.

**Hyena hierarchy:
towards larger convolutional language models**
M. Poli et al.

Convolutions can be efficiently computed with the FFT

$$\begin{aligned} (h * u)_t &= \sum_{n=1}^{L-1} h_{t-n} u_n \\ (h * u) &= \begin{bmatrix} h_0 & h_{-1} & \cdots & h_{-L+1} \\ h_1 & h_0 & \cdots & h_{-L+2} \\ \vdots & & \ddots & \\ h_{L-1} & h_{L-2} & \cdots & h_0 \end{bmatrix} \begin{bmatrix} u_1 \\ u_1 \\ \vdots \\ u_{L-1} \end{bmatrix}. \end{aligned}$$

The filter h can be implicit, $h_t = \gamma_\theta(t)$, where γ_θ is described by a neural net (with sine activations to capture frequency information, and possibly multiplied by a “shaping factor”, e.g., exponential decay) or comes from a state space model (SSM)

$$\begin{aligned} x_{t+1} &= Ax_t + Bu_t \\ y_t &= Cx_t + Du_t \end{aligned}$$

i.e.,

$$\begin{aligned} y_t &= \sum_{n=0}^t (CA^{t-n}B + D\mathbf{1}_{t=n})u_n \\ h_t &= \begin{cases} XA^tB + D\mathbf{1}_{t=0} & \text{if } t \geq 0 \\ 0 & \text{otherwise} \end{cases} \end{aligned}$$

where A, B, C, D are learned (the memory extent is determined by the spectral radius of A).

Hyena is a subquadratic replacement for self-attention: it first computes projections of the input (v, x^1, \dots, x^N)

(to mimick transformers, use 3, and call them value, key and query) and iterates

$$\begin{aligned} z_t^1 &= v_t \\ z_t^{n+1} &= x_t^n (h^n * z_t^n)_t \\ y_t &= z_t^{N+1} \end{aligned}$$

**Hungry hungry Hippos: towards language
modeling with state space models**
T. Dao et al.

The H3 state space model outputs

$$Q \odot \text{SSM}_{\text{diag}}(\text{SSM}_{\text{shift}}(k) \odot V)$$

where the shift SSL uses

$$A = \begin{bmatrix} 0 & & 0 \\ 1 & \diagdown & \\ & 1 & 0 \\ 0 & & 1 & 0 \end{bmatrix}$$

and the diagonal SSM uses a diagonal A .

**Designing losses for data-free training of
normalizing flows on Blotzman distributions**
L. Felardos et al.

Normalizing flows approximate a target distribution by learning a bijective transformation from some reference distribution (e.g., Gaussian).

$$\begin{array}{ccccc} \text{Gaussian} & q_N & \longrightarrow & p_G & \text{Generated} \\ & q_F & \longleftarrow & p_B & \text{Target} \end{array}$$

One can minimize $\text{KL}(p_G \| p_B)$: this only requires the unnormalized target density, but leads to mode collapse. Minimizing $\text{KL}(q_F \| q_N)$ requires data, which can be sparse.

Instead of data, one can use samples from the generated distribution, with importance sampling. For better convergence, the importance weights p_B/p_G should be close to 1.

As loss function, use

$$\text{Var}_{x \sim \text{generated}} \log \frac{p_B(x)}{p_G(x)}$$

or, more precisely,

$$\text{Mean}_i \left(r(x_{G,i}^\dagger) - k^\dagger \right)_+^2$$

where

$$\begin{aligned} r(x) &= \log \frac{p_B(x)}{p_G(x)} \\ k &= \text{Mean } r(x_{G,i}) \\ \dagger &= \text{stop-gradient.} \end{aligned}$$

**Action matching:
learning stochastic dynamics from samples**
K. Neklyudov et al.

If particles are described by the ODE $\dot{x}_t = v_t(x_t)$, their density satisfies $\dot{q}_t = -\nabla \cdot (q_t v_t)$. Under mild conditions, $v_t = \nabla s_t$ for some “action” s_t . It can be recovered by minimizing

$$\mathcal{L}_{\text{AM}}(s) = \mathbb{E}_{x \sim q_0} [s_0(x)] + \mathbb{E}_{x \sim q_1} [s_1(x)] + \int_0^1 \mathbb{E}_{x \sim q_t} \left[\frac{1}{2} \|\nabla s_t(x)\|^2 + \frac{\partial s_t}{\partial t} \right] dt$$

This can be generalized to SDEs (entropic action matching)

$$dx_t = v_t(x)dt + \sigma_t dW_t$$

and unbalanced action matching (creation or destruction of probability mass).

**The training process of many deep networks
explores the same low-dimension manifold**
J. Mao et al.

The *intensive PCA* (InPCA) of a distance matrix $D = (d(y_i, y_j))_{ij}$ is the eigendecomposition of the centered distance.

$$\begin{aligned} L &= I - \frac{1}{n} \mathbf{1} \\ W &= -\frac{1}{2} LDL \\ W &= U \Lambda U^\top \\ X &= U \sqrt{|\Lambda|} \end{aligned}$$

Coordinates corresponding to negative (resp. positive) eigenvalues have a negative (positive) contribution to distances.

**ZipLoRA: any subject in any style
by effectively merging LoRAs**
V. Shah et al

LoRA update matrices are sparse, but aligned LoRA matrices interfere when naively merged,

$$\Delta W = \lambda \Delta W_{\text{context}} + (1 - \lambda) \Delta W_{\text{style}}.$$

Instead, learn which column of which LoRA to keep,

$$(m'_1 \otimes \mathbf{1}) \odot \Delta W_1 + (m'_2 \otimes \mathbf{1}) \odot \Delta W_2.$$

Riemannian residual neural networks
I. Katsman et al. (2023)

Residual networks

$$x_{i+1} = x_i + \ell_{i+1}(x_i)$$

can be generalized to Riemannian manifolds

$$x_{i+1} = \exp_{x_i} \ell_{i+1}(x_i)$$

where the vector field ℓ_i is defined with a standard neural net

$$n_i : \mathbf{R}^D \longrightarrow \mathbf{R}^D$$

after embedding \mathcal{M} into a higher-dimensional vector space $\mathcal{M} \hookrightarrow \mathbf{R}^D$,

$$\ell_i(x) = \text{proj}_{T_x \mathcal{M}} n_i(x).$$

**RMT:
retentive networks meet vision transformers**
Q. Fan et al.

A retentive block is an attention block with exponential decay

$$\begin{aligned} \text{Ret}(X) &= (QK^\top \odot D)V \\ Q &= (XW_Q) \odot \Theta \\ K &= (XW_Q) \odot \bar{\Theta} \\ V &= XW_V \\ \Theta_n &= e^{in\theta} \\ D_{nm} &= \gamma^{n-m} \mathbf{1}_{n \geq m} \end{aligned}$$

It can be generalized to 2-dimensional data (Manhattan self-attention, MaSA).

Transformers from an optimization perspective
Y. Yang et al. (2022)

Unfolded optimization aims to replace the feed-forward layers of a neural network $y = f(x)$ with a gradient step from an optimization problem

$$\underset{y}{\text{Minimize}} \ g(y; x),$$

one layer at a time.

**Tokenformer: rethinking transformer scaling
with tokenized model parameters**
H. Wang et al.

Alternate standard attention

$$X \mapsto \text{Att}(XW_Q, XW_K, XW_V)$$

with token-parameter attention

$$X \mapsto \text{Att}(XW_Q, W_K, W_V).$$

Were RNNs all we needed?
L. Feng et al.

GRU and LSTM can be simplified, by removing the influence of the hidden state h_{t-1} on the gates.

LSTM and minLSTM

The gradients can be computed with the *parallel prefix scan* algorithm.

$$\begin{aligned} h_k &= a_k \odot h_{k-1} + b_k \\ \mathbf{a}^* &= \text{cumsum}(\log \mathbf{a}) \\ \mathbf{c} &= \log \text{cumsum} \exp(\log \mathbf{b} - \mathbf{a}^*) \\ \mathbf{h} &= \mathbf{a}^* + \mathbf{c} \end{aligned}$$

Efficient parallelization of a ubiquitous sequential computation F.A. Heinsen

The recurrence $x_t = a_t x_{t-1} + b_t$ can be computed with two cumulated sums (which can be computed in parallel),

$$\mathbf{x} = \left(\prod^{\text{cum}} a_t \right) \odot \left(x_0 + \sum^{\text{cum}} \frac{b_t}{\prod^{\text{cum}} a_t} \right),$$

i.e.

$$\begin{aligned} \log x_t &= a_t^* + \log(x_0 + b_t^*) \\ a_t^* &= \sum_t^{\text{cum}} \log a_t \\ b_t^* &= \sum_t^{\text{cum}} \exp(\log b_t - a_t^*) \end{aligned}$$

For numeric stability, prefer

$$x_t = \exp[a_t^* + \text{tail}(\text{LCSE}(\text{cat}(\log x_0, \log b_t - a_t^*)))].$$

Prefix sums and their applications G.E. Blelloch

Cumsum, cummax, cummin can be computed in parallel.

The recurrence $x_i = (x_{i-1} \otimes a_i) \oplus b_i$ can be computed in parallel.

$$\begin{aligned} (a, b) \cdot (a', b') &= (a \otimes a', b \otimes a' \oplus b') \\ \mathbf{x} &= \text{pr}_2(\text{cum}(\mathbf{a}, \mathbf{b})) \end{aligned}$$

This can be generalized to higher order recurrences (replace x_i with $(x_i, x_{i-1}, \dots, x_{i-k})$); applications include $x_i = a_i + b_i/x_{i-1}$, Fibonacci numbers, etc.

Byte latent transformer: patches scale better than tokens A. Pagnoni et al.

Train a small transformer to forecast the next byte, from the current and previous bytes, with *hash* n -gram embeddings, $3 \leq n \leq 8$. Use it to split the input into variable-length *patches* (whenever the entropy of the next byte is above some threshold or increases too much). Feed those patches to a large transformer, to forecast the next patch. Decode the patches into bytes, with a small transformer, still using the entropy to decide when patches end.

The model scales better than tokenizer-based transformers, and excels at character-level tasks.

Switch transformers: scaling to trillion parameter models with simple and efficient sparsity W. Fedus et al.

MoE (mixture of experts) selecting just one expert, with a load-balancing loss to use all experts.

Train short, test long: attention with linear biases enables input length extrapolation O. Press et al.

Position encoding (PE) adds a sine (or learned) positional encoding to the first layer. *RoPE* multiplies keys and queries with a sine encoding, at each layer; the values are left untouched. *T5 bias* adds a learned, distance-dependent bias to the pre-softmax attention, at each layer (the values are left as is). *ALiBi*

adds a penalty proportional to the distance to the pre-softmax attention.

$$\text{softmax} \left(q_i K_{:,i}^\top - m \begin{bmatrix} i-1 \\ \vdots \\ 2 \\ 1 \\ 0 \end{bmatrix} \right)$$

RoFormer: enhanced transformer with rotary position embedding J. Su et al.

xLSTM: extended long short-term memory M. Beck et al.

In the LSTM, replace

$$\begin{aligned} c_t &= \sigma(f_t) c_{t-1} + \sigma(i_t) z_t \\ h_t &= o_t \psi(c_t) \end{aligned}$$

with

$$\begin{aligned}c_t &= \exp(f_t)c_{t-1} + \exp(i_t)z_t \\h_t &= o_t \frac{c_t}{n_t} \\n_t &= \exp(f_t)n_{t-1} + \exp(i_t).\end{aligned}$$

To make it more transformer-like, replace the scalar c with a matrix, and use matrix products. (To avoid numeric overflow, keep track of $m = \log n_t$, and divide everything by e^m .)

***A Wigner-Eckart theorem
for group equivariant convolution kernels***
L. Lang and M. Weiler (2021)

The Peter-Weyl theorem states that if G is a compact group and X a homogeneous space, then $L^2(X, K)$ ($K = \mathbf{R}$ or \mathbf{C}) is a direct sum of unitary irreducible representations, each with multiplicity at most its dimension; for $X = G$ and $K = \mathbf{C}$, the multiplicity is the dimension.

***Coordinate-independent
convolutional networks***
M. Weiler et al.

***Nomic Embed: training a reproducible
long context text embedder***
Z. Nussbaum et al.

Open-source 8192-context-length embedding model, with *task-specific prefixes*, to break the symmetry of the encoder (we want a different model for questions and answers, such that the embeddings match). Tricks include: RoPE, SwiGLU, Flash Attention, AdamW, gradient accumulation, etc.

***Self-guiding exploration
for combinatorial problems***
Z. Iklassev et al.

To solve combinatorial problems (e.g., TSP) with an LLM:

- “List all possible methods to solve this problem. Return them separated by newlines”;
- For each method, “list all the steps to use this method”;
- For each step, “Is the problem easily solvable? Return ‘yes’ or ‘no’”; if not, go to the previous step;
- “Give feedback on the proposed solution”;
- “Integrate all previous findings and provide the final answer”.

Stealing part of a production language model
N. Carlini et al.

With access to the logits of an LLM, one can recover the dimension of the last weight matrix. The final layer is a projection from the hidden latent dimension to a *higher* dimensional logit vector: the dimension of the

span of the logit vectors is the dimension of the last layer; estimate it by looking at the singular value of the matrix Q of logits. The SVD, $Q = U\Sigma V^\top$ also gives the weight matrix, $W = U\Sigma$ (up to symmetries). The attack still works without direct access to the logits, but is more expensive.

***Let’s do a thought experiment: using
counterfactuals to improve moral reasoning***
X. Ma et al. (2023)

To help LLMs to better in moral reasoning tasks:

- Ask for moral counterfactual questions for each scenario;
- Answer; discuss moral implications; highlight moral conflicts;
- Summarize and conclude.

***Tree of thoughts: deliberate problem solving
with large language models***
S. Yao et al.

Don’t ask for the next step, as in CoT (chain of thoughts), but for several possible next steps; explore the tree with BFS (ask the LLM to pick the best k children among those generated; some tasks (e.g., creative writing) are fine with $k = 1$).

***ChatDB: augmenting LLMs
with databases as their symbolic memory***
C. Hu et al.

Give your LLM access to an SQL database, where it can store (and later retrieve) information.

Learning to tokenize for general retrieval
W. Sun et al.

Sparse retrieval relies on inverted indices (TF-IDF, BM25, etc.). Dense retrieval compares queries and document embeddings. Generative retrieval replaces the dense embeddings with discrete ones – lists of “tokens”.

***Retrieval augmented generation
for large language models: a survey***
Y. Gao et al. (2023)

RAG can suffer from low precision, low recall, irrelevance, hallucinations:

- Preprocess the chunks: remove irrelevant or duplicate information (e.g., boilerplate text, special characters); rewrite to eliminate ambiguity; adjust chunk size;
- Align query and documents: given a document, ask for corresponding queries and use them to compute the embedding; conversely, given a query, ask for (hallucinated) documents answering it, and query the vector database with them;
- Add metadata to the retrieved documents;
- Use a customized (domain-specific) embedding;
- Re-rank;

- Reduce noise in the retrieved documents and compress them (reduce the context length): remove irrelevant context, highlight pivotal paragraphs; ask the LLM to rewrite the context;
- Hybrid search (vector + keywords);
- Recursive retrieval: first retrieve small chunks, to capture key information, then larger blocks for more context;
- Ask the LLM to “step back and reason about the general underlying concepts or principles”;
- Let the LLM populate its own database;
- Ask the LLM to assess the relevance of the retrieved documents;
- Rewrite the query; try several formulations;
- Compute the embeddings on small chunks, but retrieve larger chunks (e.g., abstracts vs full papers);
- etc.

Time is encoded in the weights of finetuned language models
K. Nylund et al.

The time vectors are $W_t - W$, where W are the model weights and W_t the weights after finetuning on data from period t . Use them to shift the model’s attention to another period, e.g., $W + (W_{t_1} - W_{t_0})$.

“Do anything now”: characterizing and evaluating in-the-wild jailbreak prompts on large language models
X. Shen et al. et al. (2023)

Get your jailbreak prompts from Reddit and Discord.

Patch n’ Pack: NaBiT, a vision transformer for any aspect ratio and resolution
M. Dehghani et al.

Instead of resizing images before giving them to a ViT, pack patches from several images, and have the network output a sequence of labels, one for each input image.

Domain adaptation for time series under feature and label shifts
H. He et al.

Align the two domains (feature shift: time and frequency features, Sinkhorn divergence), then correct (label shift).

Baldur: whole-proof generation and repair with large language models
E. First et al.

LLM to generate formal proofs (software verification with Isabelle) and fix them in case of errors.

Prompt programming for large language models: beyond the few-shot paradigm
L. Reynolds and K. McDonell

Few shot prompts help locate already learnt tasks: well-crafted 0-shot prompts can do better.

Safety alignment should be made more than just a few tokens deep
X. Qi et al.

Safety alignment of LLMs with RLHF is shallow: it just trains the model to identify harmful requests and to *start* the answer with a refusal (“I cannot”, etc.). Those models are susceptible to *prefilling attacks* (provide the beginning of the answers, e.g., “Sure, here is” and let the model complete it).

JaxPruner: a concise library for sparsity research
J.H. Lee et al. (2024)

Implementation of pruning and sparse training algorithms.

A* search without expansions: learning heuristic functions with deep Q-networks
F. Agostinelli et al.

Deep Q network as heuristic for A* search (aka best-first search).

Dynamic clustering of contextual multi-armed bandits
T.T. Nguyen and H.W. Lauw (2014)

DynUCB:

- Fits a LinUCB model for each user;
- Clusters the coefficients of those models (k -means);
- Selects the action using the average model in each cluster.

Nonparametric bandits with covariates
P. Rigole and A. Zeevi (2018)

For the (non-contextual) 2-arm bandit, UCB is asymptotically optimal and its regret is $O(\log n)$. For a contextual 2-arm bandit, bin the context vectors (using a grid) and use UCB on each cell; the regret is polynomial – there exist bandits for which this cannot be improved.

Nonparametric stochastic contextual bandits
M.Y. Guan and H. Jiang (2018)

(Under reasonable assumptions), k -NN-UCB has sub-linear regret.

A practical method for solving contextual bandit problems using decision trees
A.N. Elmachetoub et al.

For each possible action, fit a decision tree on a bootstrap sample, and use it as a Thompson sample: predict the reward, and pick the action with the highest reward.

***The epoch-greedy algorithm
for contextual multi-armed bandits***
J. Langford and T. Zhang

Iterate:

- One exploration step (random arm);
- $\lceil \varepsilon_n \rceil$ exploitation steps, where ε_n is an average regret bound for each exploration step, for the policy optimal (from a finite set \mathcal{H} of candidate policies) on the exploration data only.

***Gambling in a rigged casino:
the adversarial multi-armed bandit problem***
P Auer et al. (1998)

Exp3 solves the fixed-horizon multi-arm bandit (MAB) problem with k arms as

$$p_i(t) \propto \exp \eta \sum_{\tau < t} \hat{r}_{i\tau}$$

$$\hat{r}_{it} = \begin{cases} \frac{r_{it}}{\hat{p}_{it}} & \text{if arm } i \text{ was chosen at time } t \\ 0 & \text{otherwise} \end{cases}$$

$$\hat{p}_{it} = (1 - \varepsilon)p_{it} + \frac{\varepsilon}{k}$$

Exp4 uses the same idea to choose between experts (each providing a probability distribution on arms).

***Approximate planning in large POMDPs
via reusable trajectories***
M. Kearns et al.

Given a POMDP you can sample from, with a finite action space, build *trajectory trees*:

- Nodes: state, observation pairs
- Children for all actions, with the edge labeled by the corresponding reward;
- Depth H (there is an exponential number of nodes in each tree).

Use those trees to evaluate policies: a deterministic (resp. stochastic) policy defines a (distribution on) path(s).

Sequential testing
R. Nowak (2011)

Consider the null and alternative hypotheses

$$H_0 : X_i \stackrel{\text{iid}}{\sim} p_0$$

$$H_1 : X_i \sim p_1$$

(they have to be simple); choose α and β , the desired type I and type II error rates; compute the thresholds

$$a = \log \frac{\beta}{1 - \alpha} < 0$$

$$b = \log \frac{1 - \beta}{\alpha} > 0$$

and the cumulated sums

$$\Lambda_k = \sum_{i=1}^k \log \frac{p_1(x_i)}{p_0(x_i)}.$$

The *sequential probability ratio test* (SRPT) accepts H_p (resp H_0) as soon as $\Lambda_k > b$ (resp $\Lambda_k < a$).

***Doubly robust policy evaluation
and optimization***
M. Dudík et al. (2014)

The *direct method* (DM, aka controlling for confounders, backdoor adjustment) estimates the value of a (MAB) policy from an estimate $\hat{r}(s, a)$ of the reward conditioned on the state (state = context = exogenous variables) s and action a

$$V = \text{Mean}_t \sum_a \pi(a, s_t) \hat{r}(s_t, a);$$

it has low variance but potentially high bias.

Importance sampling (IS) uses the (known) data collection policy π_0

$$V = \text{Mean}_t \frac{\pi(a_t, s_t)}{\pi_0(a_t, s_t)} r_t$$

(there is no bias, but the variance is high if π and π_0 are very different).

The *inverse propensity* score (IPS, or inverse propensity weighting, IPW) method uses some estimator $\hat{\pi}_0$ of the collection policy,

$$V = \text{Mean}_t \frac{\pi(a_t, s_t)}{\hat{\pi}_0(a_t, s_t)} r_t.$$

The *doubly robust* (DR) estimator uses \hat{r} (DM) as a baseline, and corrects it with the propensity score

$$V = \text{Mean}_t \sum_a \pi(a, s_t) \hat{r}(s_t, a) + \frac{\pi(a_t, s_t)}{\hat{\pi}_0(a_t, s_t)} (r_t - \hat{r}(s_t, a_t)).$$

***Open bandit dataset and pipeline: towards
realistic and reproducible off-policy valuation***
Y. Saito et al. (2021)

Besides DM, IPW, DR, *off-policy evaluation* (OPE) of contextual MAB policies include

- Self-normalized IPW

$$V = \frac{\text{Mean}_t w(a_t, s_t) r_t}{\text{Mean}_t w(a_t, s_t)}, \quad w(a, s) = \frac{\pi(a, s)}{\hat{\pi}_0(a, s)}$$

- Switch estimator: DR when $w \leq \tau$, DM when the importance weights are too large;
- DR with optimistic shrinkage

$$V = \text{Mean}_t \hat{r}(s_t, \pi) + \hat{w}(a_t, s_t, \lambda) [r_t - \hat{r}(s_t, a_t)]$$

$$\hat{w}(a, s, \lambda) = \frac{\lambda}{w(a, s) + \lambda} w(a, s)$$

- Cross-fitting.

***TimesNet: temporal 2D-variation modeling
for general time series analysis***
H. Xu et al.

To account for inter- and intra-period variations, and multi-periodicity, stack (with residual connection) several TimesBlocks:

- Compute the FFT of the 1D input (if there are several channels, average the amplitudes of each frequency) to identify the top k frequencies
- For each of those frequencies, reshape the 1D input to 2D (*i.e.*, stack them), with 0-padding if needed;
- Apply an inception block;
- Reshape to 1D.

***Generative probabilistic forecasting
with applications in market operations***
X. Wang and L. Tong.

A weak autoencoder only recovers its input in distribution.

***Generative time series modeling
with Fourier flows***
A.M. Alaa et al.

Normalizing flows in the frequency domain

***Predict, refine, synthesize:
self-guiding diffusion models
for probabilistic time series forecasting***
M. Kollovieh et al.

TSDiff is an unconditional diffusion model for time series with S4 layers. To make it conditional, *diffusion guidance* uses Bayes rule

$$\nabla_{x_t} \log p(x_t|c) = \nabla_{x_t} \log p(x_t) + \nabla_{x_t} \log p(c|x_t)$$

which only requires an auxiliary classifier (for forecasting, $c = x^{\text{obs}}$).

The *continuous ranked probability score* (CRPS) is the quantile (pinball) loss integrated from 0 to 1; it can be used to evaluate probabilistic forecasts.

***Score matching through the roof:
linear, nonlinear, and latent variables
causal discovery***
F. Montagna et al.

The score function $\nabla \log p$ can be used to test for conditional independence:

$$X \perp\!\!\!\perp Y | Z \iff \frac{\nabla^2}{\nabla X \nabla Y} \log p(X, Y, Z) = 0.$$

This leads to a generalization of the PC and PCI algorithms: AdaScore.

***Sensitivity analyses
for unmeasured confounders***
L. D’Agostino McGowan (2022)

Sensitivity analysis answers the question “how strong should a missing confounder be to change the sign of $E[Y|\text{do}(T=1)]?$ ”

R implementation in `tipr`.

***Learning domain-specific
causal discovery from time series***
X. Wang and K. Kording

Supervised learning for causal discovery (for time series, with a transformer).

***Granger causality detection with
Kolmogorov-Arnold networks***
H. Lin et al.

Granger causality testing with KAN (stacked GAMs), with a sparsity penalty for the first layer, fitted with proximal gradient descent to ensure sparsity.

KAN: Kolmogorov-Arnold networks
Z. Liu et al.

Stacked GAMs.

KAN: Kolmogorov-Arnold networks
Z. Liu et al.

A KAN is a neural net with GAM layers: the weights are replaced by learnable nonlinearities (splines of order 3 on G intervals).

***NeuralFactors: a novel factor learning
approach to generative modeling of equities***
A. Gopal

Train a VAE to forecast future stock returns from current stock characteristics

$$\begin{aligned} \text{stock}_{it} &\mapsto \alpha_{it}, \beta_{it}, \sigma_{it}, \nu_{it} \\ z_{t+1} &\sim T(\mu_z, \sigma_z, \nu_z) \\ r_{i,t+1} &\sim T(\alpha_{it} + \beta_{it}^\top z_{t+1}, \sigma_{it}, \nu_{it}) \end{aligned}$$

and use it for synthetic data, covariance estimation, risk analysis, portfolio construction.

A T-SNE embedding of the β_i reveals industrial sectors.

Improving investment strategies with GNNs
G. Farmanfarmaian

Gated GCNs use GRU in the depth dimension.

GraphGPS alternates MPNN layers with global attention layers.

The *turbulence index* (of the market, at a given data) is the Mahalanobis distance to the average return vector.

The structure of the supply chain graph is not useful in forecasting future (monthly) returns, but global information (e.g., from a virtual node) is.

***A geometric approach
to asset allocation with investor views***
A.V. Antonov et al. (2024)

Given a prior on the distribution of asset returns

$$x \sim p_{\text{prior}} = N(\mu_0, V_0)$$

and investor views $x \sim p_{\text{views}} = N(\mu_1, V_1)$, compute a posterior distribution

$$\underset{p=N(\mu, V)}{\text{Argmin}} d(p, p_{\text{prior}}) \text{ such that } d(p, p_{\text{view}}) \leq d_0$$

or

$$\underset{p=N(\mu, V)}{\text{Argmin}} d(p, p_{\text{prior}}) + \lambda d(p, p_{\text{view}}) \leq d_0.$$

This readily generalizes to degenerate views.

Markowitz portfolio construction at seventy
S. Boyd et al. (2024)

Long list of constraints and penalties you may want to add to your portfolio optimization (turnover, risk budget, costs, etc.).

Replace the hard constraints with penalties to ensure the problem is always feasible (but report constraint violations); fine-tune the scale of the penalties on historical data.

Use robust optimization to account for the uncertainty in μ and Σ .

Some constraints are not convex:

- Integral number of shares (lot shares);
- Maximum number of assets;
- Minimum position size;

Do not write the target volatility constraint as $w' \Sigma w \leq \sigma^2$, but $\|L^\top w\|_2 \leq \sigma$, where $\Sigma = L^\top L$ is the Choleski decomposition. If Σ comes from a factor model, $\Sigma = FvF^\top + \Delta$, use

$$\begin{aligned} w' \Sigma w &= \|\ell^\top w\|_2^2 + \|\Delta^{1/2} w\|_2^2 \\ &= \left\| \begin{pmatrix} \ell^\top w \\ \Delta^{1/2} w \end{pmatrix} \right\|_2^2 \end{aligned}$$

where $v = \ell^\top \ell$.

***Constrained max drawdown: a fast and robust
portfolio optimization approach***
A. Dorador

The Markowitz portfolio optimization problem (minimizing risk with a minimum return constraint) can be linearized: replace the risk with

$$\sum_t \left| \sum_i (r_{it} - \bar{r}_i) w_i \right|$$

or

$$\text{Min}_t \sum_i r_{it} w_i$$

(add $0 \leq w \leq \frac{1}{2}$ to avoid the 1-asset portfolio). To limit the number of assets (e.g., $\forall i w_i \neq 0 \implies w_i \leq 0.05$), use the big-M transform (with $M = 0.5$).

***Can GANs learn the stylized facts
of financial time series***
S. Kwon and Y. Lee

GANs struggle to reproduce simple statistical models (Heston, Ornstein-Uhlenbeck, jump diffusion, etc.)

Time-series foundation model for value-at-risk
A. Goel et al. (2024)

Fine-tuned foundation time series models (e.g. TimeFM) are competitive with conventional econometric models (GARCH, GAS).

***Automated regime detection
in multidimensional time series data
using sliced Wasserstein k-means clustering***
Q. Luan and J. Hamp (2023)

Sliced Wasserstein k -means clustering on (the delay emneddings of) time series.

***Risk parity portfolios with skewness risk:
an application to factor investing
and alternative risk premia***
B. Bruder et al. (2016)

Define risk parity portfolios using skewness as a risk measure, and assuming asset returns follow a Gaussian mixture distribution.

A tale of tail covariances (and diversified tails)
J. Rosensweig (2023)

The *tail covariances* are $E[XY^{2k-1}]$ and $E[X^{2k-1}Y]$ (higher moments depend more on the tail of the distributions than their centers).

***Multistage stochastic programs
with the entropic risk measure***
O. Dowson et al.

$$\text{Ent}_\gamma[X] = \gamma^{-1} \log E[e^{\gamma X}]$$

***Industry classification based on supply chain
network information using GNNs***
D. Wu et al.

Infer the industry of unlisted firms from the supply chain network.

The corporate chronicles
Wolfe research

How markets react to corporate events (40+ types: earnings, clients, products, corporate structure, listing, dividends, buybacks, legal, bankruptcy, regulations, shareholder activism, etc.)

Factor crowding, tail dependence, and dynamic allocation
Wolfe research (2021)

Define crowding as

Utilization(short leg) – Utilization(long leg).

More generally, regress utilization against factor quantile, size quantile and volatility quantile; use the coefficients of the factor quantiles as crowding for each quantile.

Measuring stock-level exposure to bitcoin
Wolfe research (2021)

Use the grayscale bitcoin trust (GBTC) instead of bitcoin, to have market-like closing prices. Find stocks exposed to bitcoin in two ways:

- Exposure: return \sim market + industry + BTC, with Huber loss, and elastic net penalty
- NLP: cryptocurrency related words in management presentations and conference calls.

Text-based network industries and endogenous product differentiation
G. Hoberg and G. Phillips (2009)

Take the product description from the 10K filings, only keep nouns and proper nouns (they are capitalized 90% of the time), discard geographic words, and words appearing in more than 25% of the documents; compute pairwise cosine similarity to get each company's neighbours.

Either use this weighted graph to compute a fixed industry classification (apply some clustering algorithm on data from 1997) or truncate the graph (to have the same number of connected pairs as in the SIC-3 classification).

Deep generators on commodity markets; application to deep hedging
N. Bourson et al.

Synthetic time series: TSGAN, CTOGAN, SIGGAN, CEGEN.

Higher-order graph attention network for stock selection with joint analysis
Y. Qiao et al.

Stack LSTM (stock characteristics), motif-based GAT (from a graph built from sector, industry, Wiki data, etc.), MLP.

Simple formulas for standard errors that cluster by both firm and time
S.B. Thompson (2009)

In a panel regression $y_{it} = x'_{it}\beta + \varepsilon_{it}$, if there is correlation among i, t and (i, t) (up to lag L)

$$E[\varepsilon_{it}\varepsilon_{is}|x_{it}x_{is}] \neq 0$$

$$E[\varepsilon_{it}\varepsilon_{jt}|x_{it}x_{jt}] \neq 0$$

$$E[\varepsilon_{it}\varepsilon_{js}|x_{it}x_{js}] \neq 0 \text{ if } |t - s| < L$$

then

$$\text{Var } \hat{\beta} = \hat{V}_I + \hat{V}_{T,0} - \hat{V}_{W,0} + \sum_{1 \leq \ell \leq L} (V_{T,\ell} + V'_{T,\ell}) - \sum_{1 \leq \ell \leq L} (\hat{V}_{w,\ell} + \hat{V}'_{w,\ell})$$

where

$$\hat{V}_I = H^{-1} \sum_i \hat{c}_i \hat{c}'_i H^{-1}$$

$$\hat{V}_{T,\ell} = H^{-1} \sum_t \hat{s}_t \hat{s}'_{t+\ell} H^{-1}$$

$$\hat{V}_{w,\ell} = H^{-1} \sum_{it} \hat{u}_{it} \hat{u}'_{i,t+\ell} H^{-1}$$

$$\hat{u}_{it} = x_{it} \hat{\varepsilon}_{it}$$

$$\hat{c}_i = \sum_t \hat{u}_{it}$$

$$\hat{s}_t = \sum_i \hat{u}_{it}$$

$$\hat{\varepsilon}_{it} = y_{it} - x_{it} \hat{\beta}$$

$$H = \sum_{it} x_{it} x'_{it}$$

Estimating standard errors in finance panel data sets: comparing approaches
M.A. Petersen (2006)

Commonly used estimators of the standard error in panel regressions are biased:

- Newey-West has a small bias;
- Fama-MacBeth only accounts for correlation between firms;
- Clustered standard errors only account for correlation over time.

The square-and-add Markov chain
P. Diaconis et al.

Adding $\pm 1 \bmod p$ is a random walk on \mathbf{F}_p , which converges (slowly) to a uniform distribution; $X_{n+1} = 2X_n \pm 1 \bmod p$ converges faster; $X_{n+1} = X_n^2 \pm 1$ (in \mathbf{F}_q) looks trickier.

2. Classical portfolio optimization methods include Markowitz, risk parity, and hierarchical risk parity.

3. The first chapters cover classical topics:

- Mean-variance optimization with or without a risk-free asset; tangent portfolio;
- 2-fund separation theorem;
- CAPM;
- Multifactor model (APT);
- Shrinkage or random matrix theory (RMT) to estimate the variance matrix;
- Returns estimation: historical, Black-Litterman, Jackknife (bias correction), penalized regression, bootstrap (for confidence intervals);
- Portfolio optimization with CVaR constraint

and Bayesian methods

- Black-Litterman;
- gfbm (geometric fractional Brownian motion): geometric Brownian motion with the Wiener process replaced with a fractional Brownian motion W^H , with Hurst exponent H , defined as a Gaussian process (GP) with covariance function

$$E[W_t^H W_s^H] = \frac{1}{2}(|t|^{2H} + |s|^{2H} - |t - s|^{2H}),$$

with a beta prior on the Hurst exponent H

- Metropolis-Hastings
- Kalman filter, particle filter
- Hierarchical Bayesian models
- Bayesian optimization, GP regression, GP classification

5. Besides VaR and CVaR (technically, tail conditional expectation, expected shortfall and conditional value at risk are different, but they coincide if the distribution of X is smooth and $E[X^-] < \infty$),

$$\text{TCE}_\alpha = E[Y | Y \geq \text{VaR}_\alpha(Y)]$$

$$\text{ES}_\alpha = \frac{1}{1 - \alpha} \int_\alpha^1 \text{VaR}_u(Y) du$$

$$\text{CVaR}_\alpha = \inf_{a \in \mathbf{R}} a + \frac{E[(Y - a)^+]}{1 - \alpha}$$

also consider

- Gini shortfall

$$\rho(Y) = E[Y_\alpha] + \beta E[|Y'_\alpha - Y''_\alpha|], \quad \beta < \frac{1}{2}$$

where $Y_\alpha = Y | Y \leq \text{VaR}_\alpha$ and Y'_α and Y''_α are iid copies of Y_α ;

- Spectral risk measures,

$$- \int_0^1 q_X(u) \phi(u) du,$$

with $\phi \geq 0$, $\phi \searrow$, $\int |\phi| = 1$, e.g., the exponential spectral risk measure, with

$$\phi(u) = \frac{ke^{-ku}}{1 - e^{-k}}.$$

6. Factor models can be:

- Statistical (PCA-like);
- Macroeconomic (time series);
- cross-sectional (à la Fama-French).

This chapter also contains a proof of a (rigorous version of) the fundamental law of portfolio management.

8. The *optimal control* problem

$$\begin{aligned} &\text{Find} && u \\ &\text{To maximize} && \int_0^T F(x_t, u_t, t) dt + g(x_T) \\ &\text{Such that} && \dot{x} = f(x_t, u_t, t), x(0) = x_0 \end{aligned}$$

leads to the Hamilton-Jacobi-Bellman (HJB) equation

$$-\frac{\partial V}{\partial t} = \max_u F(x, u, t) + \nabla_x V \cdot f(x, u, t)$$

where $V(x_t, t) = \int_t^T F dt + g$.

A **viscosity solution** V of $F(x, V(x), \nabla V(x)) = 0$, $x \in \Omega$ is a function V satisfying

- (i) For all $\phi \in \mathcal{C}^1(\Omega)$, if $V - \phi$ has a local maximum at x_0 , then $F(x_0, V(x_0), \nabla \phi(x_0)) \leq 0$;
- (ii) For all $\phi \in \mathcal{C}^1(\Omega)$, if $V - \phi$ has a local minimum at x_0 , then $F(x_0, V(x_0), \nabla \phi(x_0)) \geq 0$.

The *Merton problem* looks for the proportion π of wealth to invest in a risky asset (assuming a geometric Brownian motion, with drift, volatility and risk-free rate known) to maximize expected CRRA utility

$$\begin{aligned} U(x) &= \frac{x^{1-\gamma}}{1-\gamma} \\ dX &= rX dt + (\mu - r)\pi X dt + \sigma \pi X dW; \end{aligned}$$

it is constant (it does not depend on time and wealth):

$$\pi^* = \frac{\mu - r}{\gamma \sigma^2}.$$

One can add transaction costs, or change the utility function.

9. Applications of Markov decision processes (MDP) include

- Multi-period portfolio optimization, with transaction costs or regime switching;
- Option hedging.

To make MDPs aware of risk, one could alter the reward; alternatively, one could directly alter the Bellman equation, either replacing the expected reward with the expected utility of reward, or by adding a variance penalty (risk-sensitive MDPs).

10. Optimal control and reinforcement learning (RL) study the same problem (OC tends to use continuous state and time, while RL prefers discrete time).

$$\dots s_t \xrightarrow{\text{agent}} a_t \xrightarrow{\text{environment}} s_{t+1}, r_{t+1} \xrightarrow{\text{agent}} a_{t+1} \dots$$

A RL model keeps estimates of one or more of the following:

- Policy $\pi(a|s)$;
- Value function $V(s)$;
- Action value function $Q(s, a)$;
- Model $\hat{p}(s'|s, a)$, $\hat{r}(s, a, s')$.

11. *Physics-informed neural nets* can fit a PDE $Df_\theta = 0$ (Black-Scholes or, more generally, the Fokker-Planck PDE of some SDE – the shape of the PDE is known, but some of its parameters are not) to data:

$$\text{Minimize}_{\theta} \text{Mean}_i \|f_\theta(x_i, t_i) - u_i\|^2 + \text{Mean}_j \|Df_\theta(x_j, t_j)\|^2.$$

They can also be used for SDEs, $dX = \mu dt + \sigma dW$, by minimizing

$$\left(\frac{dX}{dt} - \mu\right)^2 \quad \text{and} \quad [(X_{t+\Delta t} - X_t)^2 - \sigma^2 \Delta t]^2;$$

one can also add jumps.

12. Build the MST or TMFG of the correlation matrix of the asset returns, and invest in low-centrality assets (on average), while avoiding investing in nearly assets.

13. Hierarchical risk parity can be applied to other matrices, e.g.:

- Compute the sensitivity B of asset returns \mathbf{r} to risk factors \mathbf{f} : $\mathbf{r} = B\mathbf{f} + \varepsilon$ (with a linear model, or a sparse neural net – use automatic differentiation to compute B);
- Compute the distances between the assets in sensitivity space;
- Use that distance matrix to build a hierarchical risk parity portfolio.

Portfolio optimization based on neural network sensitivities from assets dynamics respect common drivers
A.R. Dominguez

Relevance
M. Czaronis et al.

The OLS forecast can be written as a “relevance-weighted” average of past observations,

$$\hat{y} = \bar{y} + \frac{1}{N-1} \sum_{i=1}^N r_{it}(y_i - \bar{y})$$

where the relevance between observations is

$$r_{ij} = \text{similarity}_{ij} + \frac{1}{2}(\text{informativeness}_i + \text{informativeness}_j)$$

$$\text{similarity}_{ij} = -\frac{1}{2}(x_i - x_j)'V^{-1}(x_i - x_j)$$

$$\text{informativeness}_i = (x_i - \bar{x})'V^{-1}(x_i - \bar{x}).$$

If you only use the subset $I \subset \llbracket 1, N \rrbracket$ of most relevant observations, use

$$\hat{y} = \bar{y} + \frac{\lambda^2}{|I|-1} \sum_{i \in I} r_{it}(y_i - \bar{y})$$

$$\lambda^2 = \frac{1}{N+1} \sum_{i=1}^N r_{it}^2 \Big/ \frac{1}{|I|+1} \sum_{i \in I} r_{it}^2.$$

Relevance-based prediction: a transparent and adaptive alternative to machine learning
M. Czaronis et al.

Relevance-based prediction

$$\begin{aligned} \hat{y} &= x'_{\text{new}} \hat{\beta} \\ &= \bar{y} + \frac{1}{N-1} \sum r_i (y_i - \bar{y}) \\ &= \sum w_i y_i \end{aligned}$$

expresses OLS forecasts as (data-dependent) linear combinations of observations

$$\begin{aligned} r_i &= \text{sim}(x_{\text{new}}, x_i) + \frac{1}{2} [\text{info}(x_{\text{new}}) + \text{info}(x_i)] \\ \text{sim}(x_1, x_2) &= -\frac{1}{2}(x_1 - x_2)'V^{-1}(x_1 - x_2) \\ \text{info}(x) &= (x - \bar{x})'V^{-1}(x - \bar{x}). \end{aligned}$$

We can also recover R^2 as

$$\begin{aligned} R^2 &= \frac{1}{N-1} \sum \text{info}(x_i) \text{fit}_i \\ \text{fit}_i &= \text{Cor}(w, y)^2 \end{aligned}$$

The virtue of transparency: how to maximize the utility of data without overfitting
M. Czaronis et al. (2024)

Use partial sample regression (relevance-based prediction on a subset of high-relevance observations) on a grid, with various relevance thresholds r^* (deciles) and all possible subsets of variables; use the adjusted fit as weights to combine the forecasts (as in BMA, Bayesian model averaging)

$$\begin{aligned} \hat{y} &= \sum w_i y_i \\ \text{fit} &= \text{Cor}(w, y) \\ \text{asymmetry} &= \frac{1}{2} [\text{Cor}(w^+, y) - \text{Cor}(w^-, y)]^2 \\ \text{adjusted fit} &= \# \text{variables} \times (\text{fit} + \text{asymmetry}) \end{aligned}$$

where w^+ and w_- are the weights if we use the observations with $i \geq r^*$ and $r_i < r^*$ (so that $w^+ = w$).

A transparent alternative to neural networks with an application to predicting volatility
M. Czaronis et al. (2024)

Relevance grid numeric example: predicting volatility from 14 variables (do not use all the subsets of predictors, just 100 random ones).

Any deep ReLU network is shallow
M.J. Villani and N. Schoots

A ReLU network is a locally linear function on a partition into polytopes. Any such function can be represented by a ReLU network, and 3 hidden layers are enough. This transformation can be automated, and the resulting network may be easier to interpret (Shapley, etc.)

Provably faster gradient descent via long steps

B. Grimmer

Gradient descent, with periodic long steps (which may increase the loss function), speeds up convergence (from $1/2T$ to $1/5T$)

Can large language models infer causation from correlation

Z. Jin et al.

Ask an LLM to discover and run the PC algorithm, *i.e.*, discover and use

- $A \perp\!\!\!\perp B | C \implies$ no A - B edge;
- $A \perp\!\!\!\perp B$ and $A \not\perp\!\!\!\perp B | C \implies A \overset{A}{\underset{B}{\rightrightarrows}} C$;
- All colliders can be found in that way.

(given all the relevant conditional independence statements, with no noise). The performance is bad.

Full parameter fine-tuning for large language models with limited resources

K. Lv et al.

To reduce memory usage when training large models, replace the traditional

- Forward pass, keeping all the activations;
- Backward pass, keeping all the gradients;
- Parameter update

with

- Forward pass
- For each layer, starting from the last:
 - Compute the gradients;
 - Update the parameters;
 - Free all the layers after the current one (they are no longer needed).

Language models can solve computer tasks

G. Kim et al. (2023)

When asking an LLM to generate keyboard and mouse actions, iterate:

- “Review your previous answer and find problems with it”;
- “Based on the problems found, improve your answer”.

[This is similar to LLM-based optimization.]

Deep symbolic regression for physics guided by unit constraints: towards the automated discovery of physical laws

W. Tenach et al. (2023)

Physical-unit-aware symbolic regression, with deep reinforcement learning, for low-noise data (0.1% to 10%): dimensional analysis drastically reduces the search space.

Language model cross-over: variation through few-shot prompting

E. Leyerson et al.

CMA-ES on sentences, with an LLM to do the sampling. For instance,

- For symbolic regression, try “here are 10 expressions that approximate the dataset”, followed by 9 lines of Python code;
- Stable diffusion prompts, to generate images (the objective function could be the dominating colour, or anything that can be computed automatically);
- Modifying the sentiment of a sentence (without changing its meaning);
- Reinforcement learning (generate Python code to control a robot).

Inference-time intervention: eliciting truthful answers from a language model

K. Li et al. (2023)

Find a “truthfulness” direction, for some attention heads (with a probe, *i.e.*, a classifier trained on the network activations), and shift activations in that direction at inference time.

System 2 attention (is something you might need too)

J. Weston and S. Sukhbaatar

Instead of giving all the context to an LLM, proceed in two steps:

- Ask the LLM to remove irrelevant parts of the context;
- Answer the query.

Graph neural prompting with large language models

Y Tian et al.

Combine knowledge graph and LLMs with soft prompts.

LLaMA-adaptor: efficient fine-tuning of language models with zero-init attention

R. Zhang et al.

Fine-tune LLMs by learning a prompt prefix, not as tokens, but directly in the latent space, not in the first layer, but in higher layers, with zero-initialized attention (multiply the attention to the added prefix with a gating factor, initialized at zero).

***GPT is becoming a Turing machine:
here are some ways to program it***
A. Jojic et al.

Simulate iterative behaviour (loops) by providing a repetitive execution path as example.

Faithful chain-of-thought reasoning
Q. Lyu et al.

CoT is not faithful: the explanations need not entail the conclusion. Instead, ask the LLM to generate the reasoning and the answer in a formal language (Python, Datalog, PDDL, depending on the task: math, relational inference, robot planning) and verify it.

***Scaling down to scale up:
a guide to parameter-efficient fine-tuning***
V. Lialin et al.

There are many parameter efficient fine-tuning (PEFT) methods:

- *Adapters* are small fully-connected layers (or MoE layers), added (for instance) after transformers;
- *Soft prompts* are prompt prefixes added, not as input tokens, but in latent space (either only for the input layer, or for all layers);
- Selective methods only fine-tune some of the parameters, e.g., only the last layers, or only the biases, or a sparse subset of parameters (subset of important rows and columns, learned mask);
- Reparametrization methods alter the weights W , e.g., $W \leftarrow W + AB'$ (LoRA), $W = W + A \otimes B$ or $W = W + \text{fastfood}(A)$.

Those can be combined.

***Fastfood – approximating kernel expansions
in loglinear time***
Q. Le et al. (2013)

The *fastfood* transform

$$V = \frac{1}{\sigma\sqrt{d}} DH_d G \Pi H_d B$$

where

- $\Pi \in \{0, 1\}^{d \times d}$ is a permutation matrix;
- $H_2 = \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}$, $H_{2\ell} = \begin{bmatrix} H_\ell & H_\ell \\ H_\ell & -H_\ell \end{bmatrix}$;
- B is diagonal with ± 1 entries;
- G is diagonal, Gaussian;
- D is diagonal;

approximates Gaussian matrices $Z \sim N(0_{n \times d}, \sigma^2)$.

***Abusing images and sounds for indirect
instruction injection in multi-modal LLMs***
E. Bagdasaryan et al.

With multimodal LLMs, prompt injection is no longer limited to text: you can alter images or sounds to modify the LLM's behaviour, as if you were altering the prompt.

***HuggingGPT: solving AI tasks with ChatGPT
and its friends in Hugging Face***
Y. Shen et al.

Provide HuggingFace models as tools to ChatGPT.

***WizardLM: empowering large language models
to follow complex instructions***
C. Xu et al.

To generate instruction data, start with an initial set of instructions (e.g., “1+1=?”) and ask the LLM to generate new ones, in several directions: adding constraints, deepening, concretizing, increasing the reasoning steps, complicating the input, etc.

***Removing RLHF protections in GPT-4
via fine-tuning***
Q. Zhan et al.

Fine-tune with prompts violating the OpenAI ToS and responses from an uncensored Llama2 70B.

***Measurable Taylor's theorem:
an elementary proof***
G. Viggiano

In the Taylor expansion

$$f(x) = \sum_{j=0}^k \frac{f^{(j)}(c)}{j!} (x-c)^j + \frac{f^{(k+1)}(\xi)}{(k+1)!} (x-c)^{k+1}$$

for $f \in \mathcal{C}^{k+1}$, ξ can be chosen to be a measurable function of x continuous at c .

***Machine learning
for partial differential equations***
S.L. Brunton and J.N. Kutz (2023)

1. To learn a PDE from observational data, PDE-FIND uses

$$u_t = \Theta(u, u_x, u_{xx}, uu_x, \dots) \xi$$

where Θ is a library of candidate terms, e.g.,

divergence	$\nabla \cdot u$
vorticity	$\nabla x u$
shearing	$u_x + v_y$
stretching	$u_x - v_y$

and ξ is a sparse vector.

2. The **Koopman operator** of a discrete, nonlinear finite-dimensional dynamical system

$$x_{t+1} = F(x_t) \quad x_t \in \mathcal{X}$$

is the linear, infinite-dimensional transformation

$$K : \begin{cases} \mathbf{R}^{\mathcal{X}} & \longrightarrow \mathbf{R}^{\mathcal{X}} \\ g & \longmapsto Kg = g \circ F. \end{cases}$$

It satisfies

$$(Kg)(x_t) = g(F(x_t)) = g(x_{t+1}).$$

Learn K satisfying those constraints; diagonalize it,

$$K\phi_k = \lambda_k\phi_k$$

(“intrinsic measurement coordinates”) and reduce the dimension. The non-linear system has become linear – it is easy to solve.

3. If u is a solution of the linear PDE $Lu = f$, then it can be computed from the **Green’s function** of the PDE, *i.e.*, the solution G of $L^\dagger G(\cdot, \xi) = \delta_\xi$, where L^\dagger is the adjoint of L and δ_ξ is the Dirac delta, as follows:

$$\begin{aligned} u(x) &= \langle \delta_x, u \rangle \\ &= \langle L^\dagger G(\cdot, x), u \rangle \\ &= \langle G(\cdot, x), Lu \rangle \\ &= \langle G(\cdot, x), f \rangle \\ &= \int G(\xi, x) f(\xi) d\xi. \end{aligned}$$

The PDE can also be solved by looking for an eigen-decomposition of L :

$$L\phi_n = \lambda_n\phi_n.$$

If a solution u can be represented as a sum of eigenfunctions (Sturm-Liouville theory), then

$$u = \sum \frac{\langle \phi_n, f \rangle}{\lambda_n} \phi_n.$$

Neural operators generalize that to nonlinear PDEs.

Numerically stable parallel computation of (co)variance
R. Schubert and M. Gertz

Do not compute the variance of $\text{Var } X = E[X^2] - E[X]^2$, but (Welford)

$$\begin{aligned} \mu_{k+1} &= \frac{k}{k+1}\mu_k + \frac{1}{k+1}x_{k+1} \\ S_{k+1} &= S_k + \frac{k}{k+1}(x_{k+1} - \mu_k)^2. \end{aligned}$$

Fundamentals of causal inference with R
B.A. Brumback (2022)

Effect measures include:

$p_0 = E[Y(0)]$	
$p_1 = E[Y(1)]$	
$\frac{p_1}{1-p_1}, \frac{p_0}{1-p_0}$	odds
$RD = p_1 - p_0$	risk difference
$RR = p_1/p_0$	relative risk
$RR^* = \frac{1-p_0}{1-p_1}$	relative risk
$OR = \frac{p_1}{1-p_1} \bigg/ \frac{p_0}{1-p_0}$	odds ratio
$NNT = 1/RD$	number needed to treat
$AF = 1 - 1/RR$	attributable fraction
$CP = \frac{p_1 - p_0}{1 - p_0} = 1 - 1/RR^*$	causal power

Check the R packages: **AER**, **boot**, **car**, **faraway**, **gee**, **geepack**, **Matching**, **resample**.

6. There are several ways of adjusting for a sufficient confounder H .

– Outcome modeling (aka backdoor adjustment), using a model $Y \sim T + H$,

$$E[Y(t)] = \sum_h E[Y|T=t, H=h]P[H=h];$$

– Exposure modeling (aka inverse propensity score weighting), using a model $e : E[T|H] \sim H$,

$$\begin{aligned} E[Y(1)] &= E\left[\frac{TY}{e(H)}\right] \\ E[Y(0)] &= E\left[\frac{(1-T)Y}{1-e(H)}\right] \end{aligned}$$

– Doubly robust standardization

$$\begin{aligned} E[Y(1)] &= E\left[\frac{T}{e(H)}Y - \frac{T-e(H)}{e(H)}\hat{Y}(H, 1)\right] \\ E[Y(0)] &= E\left[\frac{(1-T)}{1-e(H)}Y + \frac{T-e(H)}{1-e(H)}\hat{Y}(H, 0)\right] \end{aligned}$$

– Matching;
– Difference-in-differences (DiD), under the “additive equi-confounding” assumption

$$\begin{aligned} E[Y_1(0)|A=1] - E[Y_1(0)|A=0] &= \\ E[Y_0|A=1] - E[Y_0|A=0] & \end{aligned}$$

(the difference between the treated and the non-treated, if we had not treated them, is the same as

the difference between those two groups before treatment),

$$\begin{aligned} \text{ATT} &= E[Y_1(1) - Y_1(0)|A=1] \\ &= E[Y_1(1)|A=1] - E[Y_1(0)|A=1] \\ &= E[Y_1|A=1] - \\ &\quad (E[Y_0|A=1] - E[Y_0|A=0] + E[Y_1(0)|A=0]) \\ &= E[Y_1 - Y_0|A=1] - E[Y_1 - Y_0|A=0] \end{aligned}$$

(T is time, A is the treatment).

- Front-door adjustment, given a surrogate marker of the effect of T on Y (a mediator)

$$E[Y(t)] = \sum_m P[M=m|T=t] \sum_{t'} E[Y|M=m, T=t']$$

- Instrumental variables

with *principal stratification*

I : treatment assignment

T : treatment

C : compliance

$T(0) = T(1) = 1$ always taker

$T(0) = T(1) = 0$ never taker

$\forall t A(t) = t$ complier

$\forall t A(t) = 1 - t$ defier

assuming there are no defiers (monotonicity assumption), we can compute the complier average causal effect

$$\begin{aligned} \text{CACE} &= E[Y(1) - Y(0)|C=1] \\ &= \frac{E[Y|T=1] - E[Y|T=0]}{P[A=1|T=1] - P[A=1|T=0]} \end{aligned}$$

- Instrumental variables with *structural nested mean models*: assuming $Y - Y(0) \perp\!\!\!\perp I|T$, we can compute the ATT (with the same formula).

The *propensity score* has many uses:

- Inverse propensity weighting;
- Backdoor adjustment: the propensity score is a sufficient confounder,

$$\forall t Y(t) \perp\!\!\!\perp T | H \implies \forall t Y(t) \perp\!\!\!\perp T | e(H);$$

- Stratification: computing the ATE in each quartile;
- Matching: easier to do on the propensity score $e(H)$ than on the original confounders H .

Adding *precision variables* reduces variance.

Mediation analysis measures the importance of a mediator.

Denote the potential outcome $T(t, m)$.

$\text{TE} = T(1, M(1)) - Y(0, M(0))$ total effect

$\text{CDE}(m) = Y(1, m) - Y(0, m)$ controlled direct effect

$\text{CIE}(m) = \text{TE} - \text{CDE}(m)$ controlled indirect effect

$\text{NDE} = Y(1, M(0)) - Y(0, M(0))$ natural direct effect

$\text{NIE} = Y(1, M(1)) - Y(1, M(0))$ natural indirect effect

$\text{TE} = \text{CDE} + \text{CIE} = \text{NDE} + \text{NIE}$

$$\text{PE} = \frac{\text{CIE}(m)}{\text{TE}}$$

$$\text{PM} = \frac{\text{NIE}}{\text{TE}}$$

We can also have time-dependent confounders:

we want to know the optimal value of T_1 and, given T_1 and H , the optimal value of T_2 .

Conformal predictive portfolio selection M. Kato (2024)

Consider a model forecasting future returns Y_t from asset features X_t :

$$\hat{Y}_{t+1} = \hat{f}_t(X_{t+1})$$

where \hat{f}_t is trained on $(X_1, Y_1), (X_2, Y_2), \dots, (X_t, Y_t)$. The returns of a portfolio with weights w are $w'Y_t$; the forecasted returns are $w'\hat{Y}_{t+1}$. Apply conformal prediction (CP) to those portfolio return predictions: for each w , we have a prediction interval

$$\hat{C}_t^w(X_{t+1}) = [\underline{r}_{t+1}^w, \bar{r}_{t+1}^w].$$

Find the portfolio weights minimizing some loss function of those intervals

$$w^* = \underset{w}{\text{Argmin}} \ell(\hat{C}_t^w(X_{t+1})).$$

For instance:

- Start with a finite set of portfolios \mathcal{E} ;
- Compute their prediction intervals at level α : $[\underline{r}_w, \bar{r}_w]$;
- Consider a proportion β of portfolios, $\tilde{\mathcal{E}} \subset \mathcal{E}$, with the highest \underline{r}_w (low risk, measured with the VaR);
- Among those, pick the portfolio with the highest \bar{r}_w .

To account for the time series lack of exchangeability, use full conformal prediction, *i.e.*, fit the model on augmented datasets (add (X_{t+1}, y) for all possible values of y) and on all permuted datasets

$$(X_{\sigma(1)}, y_{\sigma(1)}), \dots, (X_{\sigma(t)}, y_{\sigma(t)}), (X_{\sigma(t+1)}, y)$$

for all $\sigma \in \mathfrak{S}_n$. It is actually sufficient to consider only shifts, *i.e.*, permutations of the form

$$\exists j \in \llbracket 0, t-1 \rrbracket \quad \forall i \in \llbracket 1, t \rrbracket \quad \sigma(i) \equiv i + j \pmod{t}$$

**Exact and robust conformal inference methods
for predictive machine learning
with dependent data**

V. Chernozhukov et al.

Conformal prediction for time series: use full conformal prediction and all shifts of the data.

**Applied causal inference
powered by ML and AI**

V. Chernozhukov et al. (2024)

1. To estimate β_1 in $Y = \beta_1 D + \beta_2 W + \varepsilon$, we can use “partialing out”, *i.e.*,

- Compute the residuals \tilde{Y} and \tilde{D} of $Y \sim W$ and $S \sim W$;
- Fit a linear model $\tilde{Y} = \beta_1 \tilde{D} + \eta$.

$$\begin{aligned} \beta_1 &= \underset{b_1}{\operatorname{Argmin}} \operatorname{E}(\tilde{Y} - b_1 \tilde{D})^2 \\ &= \operatorname{E}[\tilde{D}^2]^{-1} \operatorname{E}[\tilde{D} \tilde{Y}] \end{aligned}$$

2. The average treatment effect and the average predictive effect are usually distinct, because of selection bias,

$$\begin{aligned} \text{ATE} &= \operatorname{E}[Y(1) - Y(0)] \\ \text{APE} &= \operatorname{E}[Y|T=1] - \operatorname{E}[Y|T=0] \end{aligned}$$

but, for randomized control trials, they are equal.

Including covariates can help denoise the ATE estimator.

RCTs are not always possible, for instance because of externalities (positive, as for herd immunity after vaccination, or negative, *e.g.*, the drop in college wage premium as more people go to college).

3. The lasso assumes *approximate sparsity*

$$|\beta_j| \leq A j^{-a} \quad \text{for } a > 1/2.$$

Ridge regression assumes the coefficients are dense (small, approximately of the same magnitude). ElasticNet assumes the true model is sparse+dense.

The L^1 penalty is $\lambda \sum |\beta_i|$ only if the predictors are normalized, $\operatorname{E}[X_j^2] = 1$ (if not, multiply λ by $\hat{\sigma}_j$). Choose the penalty scale as

$$\begin{aligned} \lambda &= 2 \cdot c \cdot \hat{\sigma} \sqrt{n} z_{1-a/(2p)} \quad x = 1.1, a = 0.05 \\ z_{1-a/(2p)} &\approx \sqrt{2 \log(2p/a)}. \end{aligned}$$

The lasso sets $\hat{\beta}_j$ to zero if the marginal benefit of moving it away from zero is smaller than the marginal increase in penalty.

$$\hat{\beta}_j = 0 \quad \text{if} \quad \left| \frac{\partial}{\partial \beta_j} \sum_i (Y_i - \hat{\beta}'_i X_i)^2 \right| < \lambda$$

The **post-lasso** uses the lasso to select the predictors, and then fits an OLS regression (unbiased) on those predictors. Cross-validate the whole post-lasso process, not just the variable selection.

The **lava** method splits the predictors into sparse and dense ones, with L^1 and L^2 penalties respectively.

$$\underset{b=\delta+\xi}{\operatorname{Minimize}} \sum (Y_i - b' X_i)^2 + \lambda_1 \sum \delta_i^2 + \lambda_2 \sum |\xi_i|$$

4. The **double lasso** uses partialing out to infer the effect of T on Y , with high-dimensional confounders W .

- Compute the residuals \tilde{T} , \tilde{Y} of lasso (or post lasso, or any lasso variant) models for $T \sim W$, $Y \sim W$;
- Use a least squares regression $\tilde{Y} \sim \tilde{T}$.

Using the lasso just once (on $Y \sim T + W$, to select the variables) is invalid – the double lasso may select different variables for $Y \sim W$ and $T \sim W$.

5. If we have all the confounders (unconfoundedness, aka conditional ignorability) $\text{CAPE} = \text{CATE}$ and $\operatorname{E}[\text{CAPE}] = \operatorname{E}[\text{CATE}]$.

Conditioning requires you to model $Y|T, X$;

$$\begin{aligned} \delta(x) &= \operatorname{E}[Y(1) - Y(0)|X = x] \\ &= \operatorname{E}[Y|T=1, X=x] - \operatorname{E}[Y|T=0, X=x] \\ \delta &= \operatorname{E}[\delta(X)] \end{aligned}$$

while *propensity score weighting* only requires you to model $T|X$.

$$\begin{aligned} H &= \frac{\mathbf{1}(T=1)}{\operatorname{P}[Y=1|X]} - \frac{\mathbf{1}(T=0)}{\operatorname{P}[Y=0|X]} \\ \delta(X) &= \operatorname{E}[YH|X] \end{aligned}$$

In *stratified RCT*, the propensity score is known.

Propensity score weighting gives unbiased estimators, but they may have high variance: also accounting for the link between the confounders X and the outcome Y can “denoise” the estimator.

The ATE can be computed by regressing $Y \sim H$ (clever covariate).

$$\begin{aligned} \phi(t, x) &= \frac{(-1)^t}{\operatorname{P}[T=t|X=x]} \\ H &= \phi(T, X) \\ Y &= \beta H + \varepsilon \\ \text{ATE} &= \operatorname{E}[\beta(\phi(1, X) - \phi(0, X))] \end{aligned}$$

6. Do not condition on colliders.

7. The **do** operation can be represented graphically in two ways, either by removing incoming edges

or by splitting the node in two (SWIG, single world intervention graph, of **fix** intervention).

D-separation implies conditional independence, but the converse requires faithfulness. While the model is almost surely faithful, the neighbourhood of unfaithful models can be large, all the more so in high dimensions.

8. There are many *valid adjustment strategies*:

- Parents of the treatment T ;
- Propensity score;
- Parents of the outcome Y (excluding the descendants of T);
- $\text{Parents}(T) \cup \text{Parents}(Y) \setminus \text{Descendants}(T)$ (robust against perturbations of the DAG);
- $\text{Causes}(T) \cap \text{Causes}(Y)$
- Backdoor criterion: a set S blocking all backdoor (*i.e.*, non-causal) paths, and containing no descendant of T ;
- More generally, any set S such that $Y \perp\!\!\!\perp T | S$ in the SWIG.

10. We want to compute

$$\frac{d}{dt} \mathbb{E}[Y|T = t, X = x]$$

or

$$\frac{d}{dt} \mathbb{E}[Y|\text{do}(T = t), X = x]$$

(which reduces to the first expression if X is a sufficient conditioning set).

The partially linear regression model (PLM) is

$$Y = \beta T + g(X) + \varepsilon \quad \mathbb{E}[\varepsilon|T, X] = 0;$$

the confounders X have an additive, but nonlinear effect.

If \tilde{Y} and \tilde{T} are the residualized Y and T wrt X , then β is the coefficient of the linear model $\tilde{Y} \sim \tilde{T}$; it is given by the first order condition $\mathbb{E}[(\tilde{Y} - \beta\tilde{T})\tilde{T}] = 0$.

$$\beta = \mathbb{E}[\tilde{T}^2]^{-1} \mathbb{E}[\tilde{T}\tilde{Y}]$$

To prevent overfitting, **Double ML** (DML) uses *cross-fitted residuals*: for observations in fold k , \tilde{Y} and \tilde{T} are estimated from models fitted without fold k

To reduce bias, if you have several models to predict T and Y , use the best ones by looking at the CVMSE.

In the *interactive regression model* (IRM)

$$\begin{array}{lcl} \begin{array}{c} X \\ \swarrow \quad \searrow \\ T \longrightarrow Y \end{array} & \begin{array}{l} T = m(X) + \tilde{T} \\ Y = g(T, X) + \varepsilon \end{array} & \begin{array}{l} \mathbb{E}[\tilde{T}|X] = 0 \\ \mathbb{E}[\varepsilon|T, X] = 0 \end{array} \end{array}$$

the treatment is not additively separable, but it is binary. To estimate the average treatment effect

$$\theta = \mathbb{E}[g(1, X) - g(0, X)].$$

combine regression adjustment

$$\hat{\theta} = \mathbb{E}[g(1, X) - g(0, X)]$$

and propensity score reweighting

$$\begin{aligned} \hat{\theta} &= \mathbb{E}[YH] \\ H &= \frac{\mathbf{1}(T=1)}{m(X)} - \frac{\mathbf{1}(T=0)}{1-m(X)} \end{aligned}$$

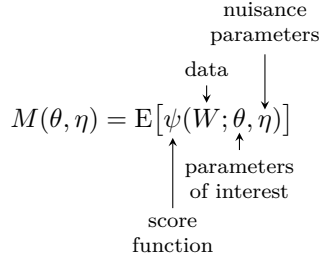

(Horvitz-Thompson transformation): this is the *doubly robust parametrization*

$$\hat{\theta} = \mathbb{E}[g(1, X) - g(0, X) + (Y - g(T, X))H].$$

Propensity scores close to 0 or 1 are problematic: they lead to very large values of H .

More generally, **double machine learning** (DML) uses a *score* function

$$M(\theta, \eta_0) = 0 \iff \theta = \theta_0$$

satisfying the *Neyman orthogonality condition*

$$\left. \frac{\partial M(\theta_0, \eta)}{\partial \eta} \right|_{\eta=\eta_0} = 0$$

i.e., $\hat{\theta}$ is insensitive to small perturbations of η around η_0 : we can use $\hat{\eta}$ instead (from a good machine learning model: lasso, post-lasso, ℓ^1 -penalized neural net, random forest, or ensemble of these). For instance, for the partially linear model (PLM)

$$\begin{aligned} \psi &= (\tilde{Y} - \theta \tilde{T}) \tilde{T} \\ &= [Y - \ell(X) - \theta(T - m(X))](T - m(X)) \\ \eta &= (\ell, m) \text{ nuisance parameters;} \end{aligned}$$

to estimate the ATE in the IRM

$$\begin{aligned} \psi &= [g(1, X) - g(0, X)] + H[Y - g(T, X)] - \theta \\ H &= \frac{T}{m(X)} - \frac{1-T}{1-m(X)} \\ \eta &= (g, m) \end{aligned}$$

(and similar score functions for the GATE or the ATET).

Use *sample splitting*: estimate $\hat{\eta}_k$ on data without the k th fold, then estimate $\hat{\theta}$ using $\hat{\eta}_k$ for observations in the k th fold; you can also get an estimator of $\text{Var} \hat{\theta}$ and confidence intervals.

12a. We can measure the impact of a non-observed confounder:

first, remove the effect of the observed confounders X

then, project \tilde{Y} on \tilde{T} to get

$$\begin{aligned} \beta &= E[\tilde{Y} \tilde{D}] / E[\tilde{D}^2] = \alpha + \phi \\ \phi &= \frac{\delta \gamma}{\gamma^2 + \text{Var}[\varepsilon_T]} = \text{omitted confounder bias.} \end{aligned}$$

Assumptions on the size of δ and γ give bounds on ϕ (alternatively, you can make assumptions on the R^2 of those models).

12b. In presence of an **instrumental variable** (IV)

the effect α of the treatment T on the outcome Y is identifiable

e.g., with the score $\psi = (\tilde{Y} - \alpha \tilde{T}) \tilde{Z}$, leading to

$$\alpha = \frac{E[\tilde{Y} \tilde{Z}]}{E[\tilde{T} \tilde{Z}]}$$

(double machine learning is applicable) or directly, by estimating $\beta\alpha$ and β :

$$\begin{aligned} \beta\alpha &= \frac{E[\tilde{Y} \tilde{Z}]}{E[\tilde{Z}^2]} \\ \beta &= \frac{E[\tilde{T} \tilde{Z}]}{E[\tilde{Z}^2]} \\ \beta\alpha &= \frac{\beta\alpha}{\beta} = \frac{E[\tilde{Y} \tilde{Z}]}{E[\tilde{T} \tilde{Z}]} \end{aligned}$$

(Some of this can be generalized to non-linear IV models.)

12c. *Proxies* of unobserved confounders can also help.

13. With *weak instruments*

$$\begin{aligned} \tilde{Z} &\longrightarrow \tilde{T} \xrightarrow{\alpha} \tilde{Y} \\ \hat{\alpha} &= \frac{E[\tilde{Z} \tilde{Y}]}{E[\tilde{Z} \tilde{T}]}, \quad E[\tilde{Z} \tilde{T}] \approx 0, \end{aligned}$$

use *Neyman's statistic*

$$C(\alpha) = \frac{E[(\tilde{Y} - \alpha \tilde{T}) \tilde{Z}]^2}{\text{Var}[(\tilde{Y} - \alpha \tilde{T}) \tilde{Z}]} \sim N(0, 1)^2 = \chi^2(1)$$

to test for $H_0 : \alpha = \alpha_0$ and derive confidence intervals. This generalizes to other score functions ψ ; in dimension m :

$$\begin{aligned} M(\theta) &= E[\psi(W, \theta, \hat{\eta})] \\ \Omega(\theta) &= \text{Var}[\psi(W, \theta, \hat{\eta})] \\ C(\theta) &= M(\theta)' \Omega(\theta)^{-1} M(\theta) \sim \chi^2(m) \end{aligned}$$

14. “Heterogeneous treatment effects” refers to the CATE, as opposed to the ATE.

$$\begin{aligned} \text{ATE} &= E[Y^{(1)} - Y^{(0)}] \\ \text{CATE} &= E[Y^{(1)} - Y^{(0)} | X = x] \end{aligned}$$

DML works out of the box:

- For models $\hat{\mu}$ and \hat{g} to estimate

$$\mu(Z) = P[T = 1|Z]$$

$$g(Y, Z) = E[Y|T, Z]$$

- Set

$$\hat{Y}_i = H_1(Y_1 - \hat{g}_k(T_i, Z_i)) + \hat{g}_k(1, Z_i) - \hat{g}_k(0, Z_i)$$

$$H_i = \frac{T_1}{\hat{\mu}_k(Z_i)} - \frac{1 - T_i}{1 - \hat{\mu}_k(Z_i)}$$

where $\hat{g}_k, \hat{\mu}_k$ are estimated without the fold containing i ;

- Regress (linearly, if you want confidence intervals) $\hat{Y} \sim X$.

To get valid confidence intervals with random forests, use *honest forests*:

- Use a separate sample to build the tree and to compute the leaf estimates;
- Use smaller subsamples, without replacement, instead of bootstrap samples.

Alternatively, one can look for a *policy* $\pi : X \mapsto \pi(X) \in [0, 1]$ indicating who to treat, maximizing

$$V(\pi) = E[\pi(X)(Y^{(1)} - Y^{(0)})].$$

This does not give a full picture of treatment heterogeneity: if the effects are all negative, $\pi = 0$. Instead, one can look for a quantile-constrained optimal policy

$$\text{Maximize}_{\pi} E[\pi(X)(Y^{(1)} - Y^{(0)})] \quad \text{st} \quad E[\pi(X)] = q.$$

15. Meta learning decomposes the CATE estimation into a sequence of regression problems.

- S (single) learner

$$\hat{g}(T, Z) \approx E[Y|T, Z]$$

$$\hat{\tau}(X) \approx E[\hat{g}(1, Z) - \hat{g}(0, Z)|X]$$

- T (two) learner

$$\hat{g}_1(Z) \approx E[Y|Z, T = 1]$$

$$\hat{g}_0(Z) \approx E[Y|Z, T = 0]$$

$$\hat{\tau}(X) \approx E[\hat{g}_1(Z) - \hat{g}_0(Z)|X]$$

- DR (double robust)

$$\hat{g}_1(Z) \approx E[Y|Z, T = 1]$$

$$\hat{g}_0(Z) \approx E[Y|Z, T = 0]$$

$$\hat{\mu}(Z) \approx E[T|Z]$$

$$\hat{g}(T, Z) = \hat{g}_1(Z)T + \hat{g}_0(Z)(1 - T)$$

$$H = \frac{T}{\hat{\mu}(Z)} - \frac{1 - T}{1 - \hat{\mu}(Z)}$$

$$\hat{Y} = H(Y - \hat{g}(T, Z)) + \hat{g}_1(Z) - \hat{g}_0(Z)$$

$$\hat{\tau}(X) \approx E[\hat{Y}|X]$$

- R-learner

$$\hat{h}(Z) \approx E[Y|Z]$$

$$\hat{\mu}(Z) \approx E[T|Z]$$

$$\check{Y} = Y - \hat{h}(Z)$$

$$\check{T} = T - \hat{\mu}(Z)$$

$$\hat{\tau}(X) = \frac{E[\check{T}^2 \cdot \check{Y}/\check{T}|X]}{E[\check{T}^2|X]}$$

($\hat{\tau}$ is a regression $\check{Y}/\check{T} \sim X$, with weights \check{T}^2);

- X-learner

$$\hat{g}_1(Z) \approx E[Y|Z, T = 1]$$

$$\hat{g}_0(Z) \approx E[Y|Z, T = 0]$$

$$\hat{\mu}(Z) \approx E[T|Z]$$

$$\hat{\delta}_0(Z) \approx E[g_1(Z) - Y|Z, T = 0]$$

$$\hat{\delta}_1(Z) \approx E[g_0(Z) - Y|Z, T = 1]$$

$$\hat{\delta}(Z) = \delta_1(Z)(1 - \hat{\mu}(Z)) + \delta_0(Z)\hat{\mu}(Z)$$

$$\hat{\tau}(X) \approx E[\hat{\delta}(Z)|X].$$

Which model is best depends on the data (imbalance, how complicated \hat{g} and $\hat{\mu}$ are, etc.) – try cross-validation and ensembling.

The optimal (unconstrained) policy only looks at the sign of the CATE

$$\pi^*(X) = \mathbf{1}_{\tau(X) \geq 0}$$

but the misclassification cost is sample-dependent: it is a cost-sensitive classification problem. You may need to penalize the variance of the policy.

16. With longitudinal data, under the conditional parallel trends assumption (parallel trends for $T = 0$ and $T = 1$, once we condition on Z), DML (double/debiased machine learning) can compute the ATET (DiD, difference in differences).

17. If the treatment is assigned (deterministically) by some score $T = \mathbf{1}_{X \geq c}$ (as in regression discontinuity design, RDD), observations close to the threshold are comparable.

$$\tau_{RD} = E[Y(1) - Y(0)|X = c]$$

$$= \lim_{x \rightarrow c^+} E[Y|X = x] - \lim_{x \rightarrow c^-} E[Y|X = x]$$

DAG-GNN: DAG structure learning with graph neural networks
Y. Yu et al. (2019)

One can sample from the linear structural causal model $X = AX + Z, Z \sim N(0, I)$ as

$$X = (I - A)^{-1}Z, \quad Z \sim N(0, I).$$

This can be made nonlinear

$$X = f_2[(I - A)^{-1}f_1(Z)], \quad Z \sim N(0, I)$$

and f_1, f_2 can be learned as an autoencoder

$$\begin{aligned} X &= f_2[(I - A)^{-1}f_1(Z)] && \text{decoder} \\ Z &= f_4[(I - A)f_2(Z)] && \text{encoder.} \end{aligned}$$

The paper uses a VAE.

Gradient-based neural DAG learning

S. Lachapelle et al.

NOTEARS solves the optimization problem

$$\text{Minimize}_{U, V} \text{Mean}_U \|X - XU\|_F^2 + \lambda \|U\|_1 \text{ st } \text{Tr } e^{U \odot U} = d.$$

GraNDAG replaces the linear transformation $X \mapsto XU$ with a neural network, and uses the neural network connectivity matrix

$$C = \left| W^{(L)} \right| \left| W^{(L-1)} \right| \dots \left| W^{(1)} \right|$$

(where $|W|$ is the element-wise absolute value) for the constraint.

CAM: Causal additive models, high-dimensional order search and penalized regression

P. Pühlmann et al. (2014)

CAM is a nonlinear score-based causal discovery algorithm which first looks for a topological order, and only then, the causal graph:

- If there are too many variables (>30), select 10 candidate parents for each node with GAM boosting (preliminary neighbourhood selection);
- Build a complete DAG with unpenalized GES, adding the edge improving the sum of squared residuals (of a GAM) the most;
- Prune the DAG by looking at the p -values of the GAM terms (keep those with $p < 10^{-3}$).

A* Lasso for learning a sparse Bayesian network structure for continuous variables

J. Xiang and S. Kim

GES is a greedy algorithm to find the DAG with the best score. Exhaustive search is unreasonable: there are too many DAGs. But the score is decomposable: the search can be formulated as a shortest path problem in the subset lattice (the value of a subset is the best score attainable with the variables in that subset) which can be solved with dynamic programming. The lasso loss gives a consistent A* heuristic.

A graph autoencoder approach to causal structure learning

I. Ng et al. (2019)

NOTEARS is linear:

$$\text{Minimize}_{A, X_i} \text{Mean}_i \|X_i - AX_i\|^2 + \lambda \|A\|_1 \text{ st } \text{Tr } e^{A \odot A} = d;$$

cGAN generalizes it to nonlinear relations

$$\begin{aligned} \text{Find} & \quad A \\ \text{To minimize} & \quad \text{Mean}_i \|X_i - g_2(Ag_1(X_i))\|^2 + \lambda \|A\|_1 \\ \text{Such that} & \quad \text{Tr } e^{A \odot A} = d \end{aligned}$$

where g_1 and g_2 are pointwise.

Masked gradient-based causal structure learning

I. Ng et al. (2022)

MCSL combines NOTEARS and the Gumbel softmax approach to learn the binary adjacency matrix of a nonlinear structural model

$$X_i = g_i(A_i \odot X) + \varepsilon_1$$

Ordering-based causal discovery with reinforcement learning

X. Wang et al.

Use reinforcement learning to find, not directly the DAG, but just a topological order compatible with it (there are much fewer orders than DAGs):

- State: embedding of the latest variable selected;
- Action: variable to add;
- Reward: BIC improvement;
- Encoder: $\mathbf{R}^{n \times d} \rightarrow \mathbf{R}^{n \times d}$ (self-attention);
- Decoder: LSTM;
- Optimization: policy gradient, actor critic.

Pretrain on simulated data; fine-tune on the data of interest.

$$\text{BIC} = \sum_{jk} \log p(x_{jk} | \text{Pa}(x_{jk}); \theta_j) - \frac{|\theta_j|}{2} \log m$$

Causal discovery with reinforcement learning

S. Zhu et al.

Score-based causal discovery algorithms, such as GES, are greedy – finding the best DAG is NP-hard. Reinforcement learning is an alternative to greedy, exhaustive or random walk search:

- State: solution;
- Action: new (nearby) solution;
- Reward: score improvement.

(You may need to tweak the reward to help the system learn, and you may want to look into variants of reinforcement learning optimizing $\text{Max}_t R_t$ instead of $\sum_t \delta^t R_t$ – *risk-seeking reinforcement learning*.) Here, the approach is slightly different:

- State: bootstrap sample;
- Action: DAG;
- Reward: score + $\lambda_1 \mathbf{1}_{\text{DAG}} + \lambda_2 \text{NOTEARS}$.

Estimation of a structural vector autoregression model using non-Gaussianity
A. Hyvärinen et al.

The VAR model is

$$X_t = \sum_{k=1}^m B_k X_{t-k} + \varepsilon_t.$$

The VAR-LiNGAM model also allows for contemporaneous effects, B_0 , provided they are acyclic and the noise ε_t is non-Gaussian.

$$X_t = \sum_{k=0}^m B_k X_{t-k} + \varepsilon_t$$

The evolving causal structure of equity risk factors
G. D'Acunto et al. (2021)

VAR-LiNGAM, on a moving window, on 11 equity risk factors, with the `lingam` Python package.

Causal inference in R workshop

To estimate causation from observational data with a known causal graph (no unmeasured confounders, and $\forall x P[T = 1|X = x] \neq 0, 1$), one can:

- Adjust for confounders;
- Fit a propensity model $T \sim X$, and use inverse propensity weights (IPW), e.g.,

$$w_{\text{ATE}} = \frac{T_i}{p_i} - \frac{1 - T_i}{1 - p_i}$$

(there are other similar formulas for ATT, ATC, ATM, ATO, etc.);

- Use the propensity score to match treated and control samples (`MatchIt`).

These are estimators of the same quantity. Use the bootstrap for the confidence intervals (after reweighting or matching, the observations are no longer independent).

Correlation is sometimes causation (RCT, A/B testing), but even in these cases, you may want to adjust for the confounders or use IPW: the resulting estimators are more efficient.

To graphically assess the propensity scores:

- Histogram of the propensity scores for $T = 0$ and $T = 1$, before and after reweighting;
- “Love plot”, $i \sim \text{smd}_i$, before and after reweighting, where the standardized mean difference (smd) for variable i is

$$\text{smd} = \frac{\bar{x}_{T=1} - \bar{x}_{T=0}}{\sqrt{\frac{s_{T=1}^2 + s_{T=0}^2}{2}}}$$

- ecdf, and weighted acdf.

G-computation (G-formula),

- Fits a model $y \sim T + X$;
- Computes $\widehat{\text{ATE}} = \hat{y}|_{T=1} - \hat{y}|_{T=0}$ (using the model on copies of the data with $T := 0$, resp. $T := 1$, for all the observations)

For continuous exposures, one can:

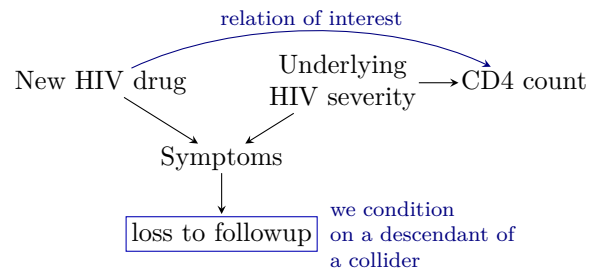

- Fit a linear model $T \sim X$ and convert the residuals into probabilities

$$p = \phi\left(\frac{T - \hat{T}}{\hat{\sigma}}\right)$$

- or bin T into quantiles and use IPW.

Tipping point sensitivity analysis (`tipr`) quantifies unmeasured confoundedness.

To address *selection bias*, fit a probability of censoring model, and use inverse probabilities as weights (multiply the probabilities, if you have several such models).

Causality-inspired models for financial time series forecasting
D.C. Oliveira et al.

Use causal discovery algorithms such as

- SeqICP (invariant causal prediction for sequential data): conditional on its parents X , the distribution of Y does not depend on the environment or period, $Y \perp\!\!\!\perp \text{time} | X$ or

$$Y_t | X_t, t \in I_i \stackrel{d}{=} Y_t | X_t, t \in I_2$$

(but it is overly conservative and tends to return $\text{Pa } Y = \emptyset$);

- Granger causality;
- VAR-LiNGAM;
- Dynotears;
- PCMCi (too slow – their small example would require two weeks of computations).

LiNGAM and Dynotears work better at forecasting monthly S&P 500 returns from macroeconomic variables (FRED-MD, a dataset of 107 macroeconomic variables, with intages, and recommended transformations to make them stationary, updated monthly).

***FRED-MD: a monthly database
for macroeconomic research***
M.W. McCracken and S. Ng (2015)

Bry-Boschan on $\text{cumsum}(\text{PC}_i)$, for $i = 1, 2, 3, 4$, to detect regime changes.

***Enhancing causal discovery in financial
networks with piecewise quantile regression***
C. Cornell et al.

VAR model, with pinball loss, to forecast the 10%, 50%, 90% quantiles, using piecewise linear transformations of the predictors, with knots at the 10% and 90% quantiles to detect tail interactions.

***semopy: a Python package
for structural equation modeling***
G. Mescheryakov and A.A. Igolkina (2019)

A **structural equation model** (SEM) is a model of the form

$$\begin{aligned}\eta &= B\eta + \varepsilon && \text{latent} \\ y &= \Lambda\eta + \delta && \text{observed}\end{aligned}$$

where the sparsity structure of B and Λ (and of $\text{Var } \varepsilon$, $\text{Var } \delta$) is known, e.g.,

It can be estimated by comparing the sample variance matrix of the observed variables, $S = \text{Var } y$, with that of the model, Σ_θ , e.g.,

$$\begin{aligned}\ell(\theta) &= \|\Sigma_\theta - S\|_F^2 \\ \ell(\theta) &= \|I - \Sigma_\theta S^{-1}\|_F^2 \\ \ell(\theta) &= \text{tr}(S\Sigma_\theta^{-1}) + \log \det \Sigma_\theta \quad (\text{Wishart}).\end{aligned}$$

***semopy 2: a structural equation modeling
package with random effects in Python***
G. Moscheryakov et al. (2021)

A **structural equation model** (SEM) is a linear model

$$x = Ax + \varepsilon$$

where some of the variables are not observed (latent) and the sparsity structure of A and $\text{Var } \varepsilon$ is known. There are special cases:

- A *path analysis* (PA) model only has observed variables

- A *confirmatory factor analysis* (CFA) model has no relations between the latent variables and between observed variables, just relations from latent to observed variables, and covariance between latent variables

Historically, SEMs distinguished between:

- Observed variables (non-leaves: x_i);
- Indicators (leaves: y_i).

Exploratory factor analysis (EFA) looks for a latent structure explaining the observed variables. A heuristic approach could be:

- Compute the correlations $(\rho_{ij})_{1 \leq i, j \leq m}$ and the corresponding distances $D_{ij} = 1 - |\rho_{ij}|$;
- Run the OPTICS clustering algorithm, with `min_cluster_size=2`, to estimate the number k of latent factors;
- Compute a sparse PCA (SPCA) and keep the first k components;
- Refine the CFA by fitting the SEM and dropping the coefficients with a large p -value.

Random forests for change point detection
M. Lonschien et al. (2023)

To find a breakpoint, compare the performance of classification models predicting, from x_t , if $t \in [t_0, \tau]$ or $t \in [\tau, t_1]$: the best performance is obtained if τ is a breakpoint. This can be generalized to several (an unknown number of) breakpoints, and efficiently approximated.

Alternatives include:

- E-divisive (ECP), which finds breakpoints minimizing the energy distance between segments; the *energy distance* between two random variables can be computed from their characteristic functions:

$$\begin{aligned}\mathcal{E}_a(X, Y) &= \int_{\mathbf{R}^d} |\phi_X(t) - \phi_Y(t)| w(t) dt \\ w(t) &\propto |t|^{-d-\alpha} \\ \alpha &= 2.\end{aligned}$$

***A kernel multiple change-point algorithm
via model selection***
S. Arlot et al. (2012)

Kernel change point methods (KCP) minimize (with dynamic programming) the kernel least squares criterion

$$R(\tau) = \frac{1}{n} \sum_{i=1}^n k(x_i, x_i) - \frac{1}{n} \sum_{\ell} \frac{1}{\tau_{\ell} - \tau_{\ell-1}} \sum_{i,j \in [\tau_{\ell-1}+1, \tau_{\ell}]} k(x_i, x_j)$$

with a penalty for the number D of segments

$$\frac{1}{n} \left[c_1 \log \binom{n-1}{D-1} + c_2 D \right].$$

The loss can also be written

$$R(\tau) = \frac{1}{n} \|\Phi(\mathbf{x}) - \Pi_{\tau} \Phi(\mathbf{x})\|^2$$

where

$$\begin{aligned} k(x, y) &= \langle \Phi(x), \Phi(y) \rangle \\ \Phi : \begin{cases} \mathcal{X} & \longrightarrow \mathcal{H} \\ x & \longmapsto k(x, \cdot) \end{cases} & \text{RKHS} \\ \mathbf{x} &= (x_1, \dots, x_n) \\ \Phi(\mathbf{x}) &= (\Phi(x_1), \dots, \Phi(x_n)) \end{aligned}$$

F_{τ} is the subset of \mathcal{H}^n of locally constant sequences with locally constant pattern (coarser than) τ ; Π_{τ} is the orthogonal projection in F_{τ} .

For the d -dimensional simplex (e.g., if x_i is a histogram – histogram features are often used for image or audio data), use the χ^2 kernel

$$k(x, y) = \exp - \frac{1}{h \cdot d} \sum_{i=1}^d \frac{(x_i - x_j)^2}{x_i + x_j}$$

(for some bandwidth $h > 0$).

Recommendation with generative models
Y. Deldjoo et al. (2024)

Classical RecSys data contains user, item, timestamp, feedback (explicit (rating) or implicit (click)).

Matrix factorization models the feedback as

$$R_{ui} = \gamma_u \cdot \gamma_i;$$

one can add offset and bias

$$R_{ui} = \alpha + \beta_u + \beta_i + \gamma_u \cdot \gamma_i$$

or include the previous item j

$$R_{uij} = \gamma_u \gamma_i + \beta_i^{\text{next}} \beta_j^{\text{previous}}.$$

User-free models only look at the similarity with items in the user's history

$$R_{ui} = \text{Mean}_{j \in u \setminus \{i\}} \gamma_i \cdot \gamma_j^{\text{history}}.$$

Generative models produce a *probabilistic forecast*: there is not a single output, but a probability distribution of outputs, from which we can sample.

A user's history is a sequence of tokens: we can use LLM-like models to forecast the next token.

RecSys can generate sets (or sequences) of items instead of isolated items: the items should be complementary or substitutable (ex: outfits).

GANs can improve traditional RecSys training by providing hard negatives (instead of uniformly sampled ones). But GANs can also be used to model normal users, and create hard-to-detect fake profiles.

Generative models also provide data augmentation.

Traditional RecSys, when followed by LLM-based reranking, can be seen as the retrieval part of a RAG system.

The data can also contain text (user profiles, item reviews) and metadata.

Conversational RecSys provide textual explanations (personalized reviews), and allow for interactive query refinement – but also personalized content and advertising.

***A contextual bandit approach to personalized
news article recommendation***
L. Li et al. (2010)

The UCB algorithm, for multi-arm bandits (MAB), chooses the arm i maximizing

$$\text{UCB}_i = \hat{\mu}_i + \sqrt{\frac{2 \log t}{n_i}}.$$

For contextual bandits, use

$$\begin{aligned} \text{LinUCB}_i &= x_i' \hat{\theta}_i + \alpha \sqrt{x_i' A_i^{-1} x_i} \\ A_i &= X_i' X_i + I \\ \hat{\theta}_i &= (X_i' X_i + I)^{-1} X_i' b_i \quad (\text{ridge}) \\ x_i &: \text{feature vector} \\ X_i &: \text{design matrix} \\ b_i &: \text{response vector} \end{aligned}$$

This can be generalized to hybrid models (some parameters are shared among the arms).

***Thompson sampling
for contextual bandits with linear payoffs***
S. Agrawal and N. Goyal (2013)

Thompson sampling can be generalized to contextual MABs:

- Compute the posterior distribution of θ_i , for each i : $N(\hat{\theta}_i, \alpha^2 A^{-1})$;
- Sample from them;
- Choose the arm i maximizing $x_i' \theta_i$.

LinTS is similar to LinUCB: the former picks the arm maximizing a random sample, the latter an arm maximizing an upper bound.

Value-difference based exploration: adaptive control between epsilon-greedy and softmax
M. Tokic and G. Palm

The *softmax* MAB algorithm is a modification of ϵ -greedy paying attention to the difference in rewards: it picks the arm i with probability $p_i \propto \exp(\hat{\mu}_i/\tau)$.

Algorithms for the multi-armed bandit problem
V. Kuleshov and D. Precup (2009)

The *pursuit* MAB algorithm is

$$p(t+1) = p(t) + \beta[e_i - p(t)]$$

where e_i is the basis vector for

$$i = \underset{i}{\operatorname{Argmax}} \hat{\mu}_i(t).$$

The *Boltzman* (softmax) algorithm uses

$$p_i(t+1) \propto \exp \hat{\mu}_i(t)/\tau.$$

The *reinforcement comparison* method uses “preferences” π instead of average rewards $\hat{\mu}$:

$$p_i(t+1) \propto \exp \pi_i(t)$$

where $\pi_i(t+1) = \pi_i(t) + \beta[r(t) - \bar{r}(t)]$ if arm i is chosen at time t and gives reward $r(t)$.

There are many variants of *UCB*:

$$j(t) = \underset{i}{\operatorname{Argmax}} \hat{\mu}_i + \sqrt{\frac{2 \log t}{n_i}}$$

$$j(t) = \underset{i}{\operatorname{Argmax}} \hat{\mu}_i + \sqrt{\frac{\log t}{n_i} \operatorname{Min}\left\{\frac{1}{4}, V_i\right\}}$$

$$V_i(t) = \hat{\sigma}_i(t) + \sqrt{\frac{2 \log t}{n_i(t)}}$$

Introduction to conformal prediction with Python
C. Molnar (2023)

6. Conformal prediction (CP) works as follows:

- Split the data into training and calibration (and test, and validation) sets;
- Train the model on the training set
- Compute a *non-conformity score* for all observations in the calibration set (any measure of how unusual y is, given x), e.g., $1 - \hat{p}(y|x)$, for a classification model;
- Compute its $1 - \alpha$ quantile \hat{q} (with a finite-sample adjustment);
- Given new data, x , return all the y ’s whose non-conformity score is below \hat{q} as *prediction set*.

(This is inductive CP; transductive CP uses the whole dataset, but needs to refit the model many times). For the splits, you can use a single split, cross-validation (CV) or leave-out-one (LOO).

7. For classification:

- The *score method* uses the probabilities of the true classes to compute the conformity scores: $s_i = 1 - \hat{p}(x_i)_{y_i}$ (where $\hat{p}(x_i)$ is the vector of predicted probabilities); it is not *adaptive*: it only guarantees *marginal coverage*, not *class-conditional coverage* – the coverage is $1 - \alpha$ only on average, but it can be much higher/lower for easier/harder classes.
- *Adaptive prediction sets* (APS) use cumulated probabilities, from the largest down to the true class; at test time, compute the cumulated sorted probabilities, and return the classes until the threshold (you can include the label just above the threshold, or not (but this can lead to empty prediction sets), or (better) decide at random);
- Top- k uses the rank of the true class; the prediction sets all have the same size;
- Regularized APS (RAPS) penalizes the inclusion of too many classes;
- Group-balanced conformal prediction applies conformal prediction separately for each group;
- Class-conditional APS uses group-balanced CP for the classes to predict: since they are not known at test time, it computes the CP for all classes, and returns the union of the forecasts.

8. For regression:

- $s(y, x) = |y - \hat{f}(x)|$ gives prediction intervals all of the same size (this is fine if the data is homoskedastic);
- Locally adaptive CP

$$s(y, x) = \frac{|y - \hat{f}(x)|}{\hat{\sigma}(x)}$$

accounts for heteroskedasticity (but can output excessively large intervals if the data is homoskedastic).

Instead of conformalizing (mean) regression, we can conformalize quantile regression

$$s(y, x) = \operatorname{Max}\{\hat{f}_{\text{low}}(x) - y, y - \hat{f}_{\text{up}}(x)\}$$

(the distance to the nearest interval boundary, with a negative sign if inside).

9. Conformal prediction can be generalized to time series (EnbPI, in spite of non-exchangeability), multi-label classification, outlier detection (CP provides accurate control of the false positive rate).

Implementation: `mapie`; also check `crepes`, `nixtla`.

Recipe for a general, powerful, scalable graph transformer
L. Rampásek et al.

GraphGPS combines (adds) MPNN layers (GIN with edge features, gated GCN, GRU in the depth direction, PNA) and global attention (transformer, performer, big bird). Input features are preprocessed by an MLP or some variable-input-size network (DeepNet, SignNet).

Design space for graph neural networks
J. You et al.

GraphGym is (was?) a descriptive Python library for GNNs, built on top of PyG, to explore the design space of GNNs:

- BatchNorm (yes/no);
- Dropout (0, 0.3, 0.6);
- Activation (ReLU, PReLU, Swish);
- Aggregation (mean, max, sum);
- Connectivity (stack, skip-sum, skip-cat);
- Pre-processing (number of MLP layers);
- Post-processing;
- Message passing (number of layers);
- Batch size;
- Learning rate;
- Optimizer (SGD, Adam);
- Training epochs.

The curse of recursion: training on generated data makes models forget
O. Shumailov et al.

Training on generated data causes model collapse:

- At each generation, since the data is finite, there is a nonzero probability that some of the data distribution will be lost; the tails will disappear, and the distribution will progressively drift;
- Since the model is only an approximation (it does not perfectly reproduce the target distribution), the generated data will follow a slightly different distribution, for instance, assigning a nonzero probability outside the support of the target distribution.

Differentiable Euler characteristic transforms for shape classification
E. Röell and B. Rieck

The Euler characteristic of a simplicial complex K is

$$\chi(K) = \sum_{n \geq 0} (-1)^n |K^n|$$

where $|K^n|$ is the number of n -simplices. If the 0-simplices $\sigma \in K^0$ have coordinates $x_\sigma \in \mathbf{R}^n$, a function $f : \mathbf{R}^n \rightarrow \mathbf{R}$ defines a function $\tilde{f} : K \rightarrow \mathbf{R}$ by

$$\begin{aligned} \tilde{f}(\sigma) &= x_\sigma & \text{for 0-simplices} \\ \tilde{f}(\sigma) &= \max_{\tau \subset \sigma} \tilde{f}(\tau) & \text{for higher-dimensional simplices} \end{aligned}$$

and a filtration $K_r = \tilde{f}^{-1}((-\infty, r])$.

The *Euler characteristic transform* (ECT) of K is the function

$$\begin{cases} \mathbf{S}^{n-1} \times \mathbf{R} & \longrightarrow \mathbf{Z} \\ (\xi, h) & \longmapsto \chi(\tilde{f}_\xi^{-1}((-\infty, h])) \end{cases}$$

where $f_\xi = \langle \cdot, \xi \rangle$.

It can be written as a sum of step functions

$$\text{ECT}(\xi, h) = \sum_k (-1)^k \sum_{\sigma_k} \mathbf{1}_{[\tilde{f}_\xi(\sigma_k), \infty)}(h).$$

To make it differentiable, replace the step functions with sigmoids.

Beyond word frequency: bursts, lulls, and scaling in the empirical distribution of words
E. G. Altmann et al.

Words have different recurrence time distributions; they can be modeled with a “stretched exponential” (aka Weibul)

$$F_\beta(\tau) = \exp(-a\tau^\beta).$$

This can be explained with a renewal process: the probability of using a word decays as a power law since the last use of that word.

Retrieve, merge, predict: augmenting tables with data lakes (experiment, analysis and benchmark paper)
R. Cappuzzo et al.

Given a table and a data lake (a large set of database tables), identify joinable tables, and join them, greedily, for best performance in some downstream task.

Neural factors: a novel factor learning approach to generative modeling of equities
A. Gopal

An autoencoder-based factor model can generate synthetic data:

- A neural network converts stock characteristics (financial statements, a few reference indices) into factor exposures β_{ijt} and the parameters of a Student distribution $\alpha_{it}, \sigma_{it}, \nu_{it}$;
- The factors follow a Gaussian distribution $z_{t+1} \sim N(0, I)$;
- The stock returns are then

$$r_{i,t+1} \sim T_{\nu_{it}}(\alpha_{it} + \beta_{i,t}^\top z_{t+1}, \sigma_{it}).$$

A new measure of risk using Fourier analysis
M. Grabinski and G. Klinkova (2024)

Use the Fourier transform (on detrended log-prices) to decompose price changes into contributions of different frequencies: if they mostly come from high frequencies, this is speculation.

Modeling arterial and venous flows in Japanese supply chain: a network-based approach to the circular economy
H. Goto

The supply chain has a bow-tie structure (the largest strongly connected component, its upstream, its downstream, the rest of the giant weakly connected component, and the rest). Take an industry classification, assume it is ordered (sic), and label flows as “arterial” or “venous”, depending on their direction. [Instead, I would take the order maximizing arterial flow.]

**Analysis of cross-shareholding network
Japanese listed companies
S. Tanabe and T. Ohnishi**

Evolution of the bow-tie structure.

**Dynamical analysis of financial stock network:
improving forecasting using network properties
I. Aчитouv**

Forecast hourly or daily returns of S&P 500 stocks from node or graph features:

- Centralities (degree, closeness, betweenness, eigenvalue);
- Clustering coefficient;
- Modularity;
- Largest component;
- Resilience (size of the largest component after removing a fraction of the nodes).

Build the graph by thresholding the correlation matrix; choose the smallest threshold that makes the degree follow a power law distribution (increase the threshold until the degree distribution becomes convex: $\rho = 0.9$).

**Regime-aware factor allocation
with optimal feature selection
T. Bosancic et al.**

The discrete jump model is

$$\text{Minimize}_{\theta_1, \dots, \theta_K \in \mathbf{R}^D, s \in \llbracket 1, K \rrbracket^T} \sum_t \ell(y_t, \theta_{s_t}) + \lambda \sum \mathbf{1}_{s_{t-1} = s_t}.$$

The continuous jump model replaces states $s \in \llbracket 1, K \rrbracket$ with probabilities $s \in \Delta_K$.

$$\text{Minimize}_{\theta_1, \dots, \theta_K \in \mathbf{R}^D, s_1, \dots, s_T \in \Delta_K} \sum_t L(y_t, \Theta, s_t) + \frac{\lambda}{4} \sum_t \|s_{t-1} - s_t\|_1^2$$

where $L(y_t, \Theta, s_t) = \sum_k s_{tk} \ell(y_t, \theta_k)$

**Graph learning
(ICML 2024 Tutorial)**

Early graph learning methods relied on node embeddings: DeepWalk, Node2Vec (a biased random walk, between depth-first search and breadth-first search). The first graph neural nets relied on message passing (MPNN), which can be written with matrix multiplications (GCN), and augmented with a gating mechanism (GAT, graph attention); if there are high-degree nodes, use sampling (GraphSAGE samples the 2-hop neighbourhoods)

Spectral graph theory studies the graph Laplacian. The first eigenvectors (“eigenfunctions”) minimize the variability of the signal. The Cheeger constant is the minimum (normalized) cut (NP hard)

$$h_G = \min_{S \subset V} \frac{|\partial S|}{\min\{\text{vol}(S), \text{vol}(\bar{S})\}}$$

(the volume is the sum of the degrees); it is related to the second eigenvalue

$$\frac{\lambda_2}{2} \leq h_G \leq \sqrt{2\lambda_2}.$$

The commute time CT (of a node u) is the expected number of steps needed for a random walk starting at u to come back to u . The effective resistance is

$$R_{uv} = \frac{\text{CT}_{uv}}{\text{vol}(G)}.$$

A *graph transformer* is a transformer (not a GNN) whose positional encoding comes from a graph:

- Laplacian eigenvectors (which generalize sines and cosines);
- Learned positional embeddings (LPE), *i.e.*, learned transformations of

$$\begin{pmatrix} \lambda_1 & \phi_{1j} \\ \vdots & \vdots \\ \lambda_m & \phi_{mj} \end{pmatrix}$$

- Centrality encoding $h_i = x_i + z_{\deg^-(v_i)}^- + z_{\deg^+(v_i)}^+$;
- Spatial encoding.

The attention matrix can be sparse: expormer uses the original graph, an expander graph, and a global sink (not unlike BigBird). GraphGPS combines MPNN layers, attention layers, and positional/structural encodings.

The expressivity of GNNs is limited by the WL isomorphism test – but 1-WL cannot distinguish d -regular graphs... To enhance expressivity, one can:

- Add features: random features, substructures, affinity measures (effective resistance, hitting time, etc.);
- Modulate message passing (e.g., with gating, in GAT);
- Modify the graph, e.g., higher-order GNNs for message passing on k -tuples of nodes instead of nodes.

The Dirichlet energy measures *oversmoothing*

$$E(H) = \text{tr}(H' L H) = \frac{1}{2} \sum_{(u,v) \in E} \left\| \frac{h_u}{\sqrt{d_u}} - \frac{h_v}{\sqrt{d_v}} \right\|^2$$

(the Rayleigh coefficient, used to define the eigenvalues, is a normalized Dirichlet energy). The rate of convergence of a random walk $x_t = P^t x_0$, resp. the heat kernel, $x_t = e^{-tL}$ to the stationary (resp. uniform) distribution is λ_2 : convergence is faster if the total effective resistance is low. To limit oversmoothing:

- Normalize the node embeddings;
- Sparsify the graph (this reduces the spectral gap);
- Regularize the weight matrix;
- Add skip connections;
- Change the GNN dynamics (GraphSAGE, GAT, PIGNN, AdaptiveGNN).

Oversquashing (the exponential growth of the perceptive field) can be measured by the Cheeger constant, the effective resistance, the curvature, the Hessian.

$$\text{sensitivity}(u \rightarrow v) = \left\| \frac{\partial h_v^{(r)}}{\partial h_u^{(0)}} \right\|$$

The symmetric Jacobian obstruction

$$\left(\frac{1}{d_v} \frac{\partial h_v^{(m)}}{\partial h_v^{(k)}} - \frac{1}{\sqrt{d_u d_v}} \frac{\partial h_v^{(m)}}{\partial h_u^{(k)}} \right) + \left(\frac{1}{d_u} \frac{\partial h_u^{(m)}}{\partial h_u^{(k)}} - \frac{1}{\sqrt{d_v d_u}} \frac{\partial h_u^{(m)}}{\partial h_v^{(k)}} \right)$$

is related to the (total) effective resistance.

Solutions include:

- Graph rewiring: spacial (SDRF, curvature) or spectral (DiffWire);
- Virtual nodes;
- Advanced architectures: AdaptiveGNN.

There is a trade-off between oversmoothing (OSM) and oversquashing (OSQ): high R , low λ_2 gives more OSQ, low R , high λ_2 gives more OSM.

Data-efficient machine learning (ICML 2024 Tutorial)

Data-efficient ML looks for a small subset of the training data, such that a model trained on that subset has a generalization error similar to that of a model trained on the whole data.

$$\text{Maximize } F(S) \text{ st } |S| \leq k \\ \text{SCV}$$

1. For supervised learning, look for a subset with similar gradients. For a single point $w \in \mathcal{W}$, take the medoids of $\{\nabla f_i(w), i \in V\}$, weighted with the cluster sizes. It is a submodular problem (diminishing returns): it can be solved (approximately) with a greedy algorithm

$$F(D^*) = \sum_{i \in V} \text{Min}_{j \in S^*} \|\nabla f_i(w) - \nabla f_j(w)\|.$$

This depends on w , but we can take the worst case:

$$F(S^*) \leq \sum_{i \in V} \text{Min}_{j \in S^*} \underbrace{\text{Max}_{w \in \mathcal{W}} \|\nabla f_i(w) - \nabla f_j(w)\|}_{d_{ij}}.$$

If f is convex,

$$d_{ij} \leq \text{const} \cdot \|x_i - x_j\|$$

where x are the feature vectors: it suffices to cluster the features. If f is not convex (e.g., a neural net), we still expect that

$$d_{ij} \leq \text{const} \cdot \left\| \nabla_{z_i^{(L)}} f_i(w) - \nabla_{z_j^{(L)}} f_j(w) \right\|.$$

(gradients wrt the last layer): for classification, we would cluster the log-probabilities; since they depend on w , we need to update the clusters from time to time.

To decide when to update the coresets, model the loss as a piecewise convex function, and change the coreset when the model moves to a different convex region: check if the current convex approximation remains valid.

$$\tilde{\ell}(\delta) = \ell(w) + g_s \delta + \frac{1}{2} \delta^\top H_s \delta \\ \frac{|\tilde{\ell}(\delta) - \ell(w + \delta)|}{\ell(w + \delta)} \leq \tau$$

To ensure SGD gets unbiased gradient estimates, select multiple random subsets of size $r \gg 1$, and form a coreset (minibatch) of size m for each of them; check the convex approximation on the union of the minibatches. As training progresses, this selects increasingly difficult examples.

There are simple heuristics, looking for difficult-to-learn examples, but they are affected by noisy labels:

- Drop unforgettable samples (a “forgetting event” occurs when a sample, which was correctly classified earlier in training, becomes incorrectly classified);
- Train several models, for only 20 epochs, and keep samples with the largest dLoss/dLastLayer;
- Cartography the dataset into:
 - High confidence, low variability: easy – discard;
 - Low confidence, low variability: potentially mislabeled – discard;
 - High variability (ambiguous), *i.e.*, the true class probability fluctuates during training – keep.

Those heuristics allow the removal of up to 30% of the data; if you want to remove more, keep the easy examples instead of the hard ones. Those heuristics do not take similarity into account; submodular optimization does, and yields a curriculum: it starts with easy examples (but not the easiest), and progressively increases the difficulty (measured by “forgettability”).

2. For self-supervised contrastive learning, this is trickier: the loss

$$\ell_{ij} = -\log \frac{\exp \text{sim}(z_i, z_j) / \tau}{\sum_{k \neq i} \exp \text{sim}(z_i, z_k) / \tau}$$

(and its gradient) for an observation depends on all the observations – it tries to

- Align augmentations of the same example (“alignment”);
- Push apart augmentations of different examples (or examples from different classes) (“divergence”).

The coreset should preserve alignment and divergence.

Define the expected alignment distance as

$$d_{ij} = \mathbb{E}_{\substack{x \in A(x_i) \\ x' \in A(x_j)}} \|x - x'\|$$

from a cheap proxy model.

To preserve alignment, ensure that, for each discarded example, there is another with similar augmentations

$$\forall u \in V_k \setminus S_k \quad \min_{j \in S_k} d_{ij} \leq \delta,$$

i.e., we select a diverse set of examples in each latent class.

The latent classes are, for instance, k -means clusters on a cheap proxy model, or a foundational model (CLIP).

To preserve divergence, find a subset preserving the centers of the latent classes (*i.e.*, select the most central examples in each latent class)

$$\underset{\substack{S \subset V \\ |S| \leq r}}{\text{Minimize}} \quad \sum_{i \in V_k \setminus S_k} \sum_{j \in S_k} d_{ij}.$$

(This is a submodular optimization problem.) Contrary to supervised learning, where we were discarding easy examples and keeping those near decision boundaries, for SLL, we train on easy examples (cluster centers).

3a. Multimodal foundational models (CLIP, contrastive language-image pretraining)

are similar: they pull together matching image-caption pairs, and push apart other pairs, but they are even more data-hungry (400 times what supervised learning requires, versus 10 times).

For diversity (alignment of modalities), find a subset preserving the cross-covariance in each latent class

$$C = \frac{1}{|V|} \sum_{i \in V} (x_{\text{vision}}^i - \mu_{\text{vision}})(x_{\text{language}}^i - \mu_{\text{language}}).$$

For centrality, preserve the latent class centers. Define the latent classes with the cross-modality similarity (from a proxy model)

$$\text{sim}(\text{caption}_1, \text{image}_2) + \text{sim}(\text{caption}_2, \text{image}_1).$$

The corresponding coresets can be

$$\begin{aligned} & \underset{S_k \subset V_k}{\text{Maximize}} \quad \sum_{i \in S_k} \text{csim}(i, i) \\ & \underset{S_k \subset V_k}{\text{Maximize}} \quad \sum_{j \in S_k} \sum_{i \in V_k} \text{csim}(i, j) \\ & \underset{S_k \subset V_k}{\text{Maximize}} \quad \sum_{\substack{i \in V_k \\ j \in S_k}} \text{csim}(i, j) + \sum_{i \in S_k} \text{csim}(i, i) \end{aligned}$$

(these are non-monotone submodular optimization problems).

Heuristics include:

- Deduplication: cluster the CLIP embeddings, discard samples when the similarity is above $1 - \varepsilon$;
- Focus on examples that are learnable but not easy to learn

$$\text{CLIP}_{\text{fully trained}}(i, i) - \text{CLIP}_{\text{partially trained}}(i, i)$$

(on a clean dataset, those heuristics do not improve on a random subset).

3b. For LLMs, we cannot match the gradients: they are too high-dimensional, even for the last layer, even for LoRA (for fine-tuning). If the curvature is small (during fine-tuning, it is), examples with similar loss trajectories (similar values for a few points – with a smaller model) have similar gradients: can sample from loss-trajectory clusters.

If you want to actually match the gradients:

- Use the V projection (from the transformer's Q , K , V matrices) at the last layer;
- Use zeroth order gradients (gradients as an expectation)
- Sparsify (keep 1000 or 2000 dimensions with the largest magnitude).

Heuristics include:

- Perplexity (prefer examples with average perplexity);
- Memorization ranking;
- Deduplication;
- Data selection with another LLM;
- Centroids of hidden states;
- Influence functions (if there is a target class);
- Data models.

Neural operator learning (ICML 2024 tutorial)

The first layer of a neural net can be written

$$b_i = \sigma \left(\frac{1}{n} \sum_j k_{ij} a_j \right)$$

$$\text{or} \quad v(y_i) = \sigma \left(\sum \kappa(y_i, x_i) a(x_j) \Delta x_j \right)$$

$$\text{i.e.,} \quad v(y) = \sigma \left(\int \kappa(y, x) a(x) dx \right);$$

it is a linear integral operator. We can add bias and skip connection

$$v(y) = \sigma \left(\int \kappa(y, x) a(x) dx + W a(y) + b(y) \right).$$

The output function can be evaluated at any point, and the input can be provided at any discretization.

The graph neural operator (GNO) implements κ as a neural net.

The Fourier neural operator uses basis functions

$$a \rightarrow \mathcal{F} \rightarrow \kappa \rightarrow \mathcal{F}^{-1} \rightarrow v$$

(on a regular grid, use the FFT).

The model can be trained on a coarse grid and evaluated on a finer one.

The integral can also be computed with:

- Gaussian quadrature;
- The multipole method (UNO: U-shaped NO, similar to UNet).

This also works for other network architectures:

- Transformers (just replace \sum with \int);
- CNNs (e.g., derivatives).

Physics-informed neural operators (PINO) use both data and a PDE (the PDE can have a higher resolution).

Mixtures of experts in the era of LLMs (ICML 2024 tutorial)

(Sparse-gated) mixtures of experts (MoE) can suffer from:

- Imbalanced routing (some experts are used too often, or too rarely);
- Redundant experts.

Many design choices are possible:

- Top-2 or fine-grained;
- Shared expert (an expert that is always used);
- Experts after each layer, with more experts in the last layers;
- Loss function.

To convert a dense LLM into a MoE, you can:

- Copy the feed-forward part to form experts (this increases the number of parameters);
- Split the feed-forward part (using k -means on the neuron activations).

Distribution-free predictive uncertainty quantification: strength and limits of conformal prediction (ICML 2024 tutorial)

Given observations $(X_1, Y_1), \dots, (X_n, Y_n)$, conformal prediction aims to find C_α such that

$$\mathbb{P}[Y_{n+1} \in C_\alpha(X_{n+1})] \geq 1 - \alpha.$$

Split conformal prediction (SCP) proceeds as follows:

- Split the data into training (75% to 90%), calibration and test (X_{n+1}) ;
- Fit a model $\hat{\mu}$ on the training set;
- Compute “conformity scores” on the calibration set

$$S_{\text{Cal}} = \{|\text{residuals}| \text{ on Cal}\} \cup \{\infty\}$$

- Use the corresponding quantiles

$$\hat{C}_\alpha(X_{n+1}) = [\hat{\mu}(X_{n+1}) \pm q_{1-\alpha}(S_{\text{Cal}})].$$

If the data is exchangeable, we have marginal validity

$$1 - \alpha \leq \mathbb{E}_{X_{n+1}} \mathbb{P}[Y_{n+1} \in \hat{C}_\alpha(X_{n+1})] \leq 1 - \alpha + \frac{1}{\#\text{Cal} + 1}$$

but SCP is not adaptive (it does not recognize heteroskedasticity).

Conformalized quantile regression (CQR) fits two quantile models, e.g., 10% and 90%, and uses the signed distance to the closest quantile (negative if inside, positive if outside).

$$\hat{C}_\alpha(X_{n+1}) = [\widehat{\text{QR}}_\ell(X_{n+1}) - q_{1-\alpha}(S_{\text{Cal}}), \widehat{\text{QR}}_u(X_{n+1}) + q_{1-\alpha}(S_{\text{Cal}})]$$

More generally, if $S = \{s(x_i, y_i), i \in \text{Cal}\} \cup \{\infty\}$,

$$\hat{C}_\alpha(X_{n+1}) = \{y : s(X_{n+1}, y) \leq_{1-\alpha}(S)\}.$$

Locally weighted SCP uses

$$s(X, Y) = \frac{|\hat{\mu}(X) - Y|}{\hat{\rho}(X)}$$

$$\hat{C}_\alpha(X) = [\hat{\mu}(X) \pm q_{1-\alpha}(S) \hat{\rho}(S)]$$

Full conformal prediction avoids data splitting it fit models \hat{A}_y on all the data plus (X_{n+1}, y) , for all possible values of y , and uses

$$S_y = \{s(X_i, Y_i, \hat{A}_y)\} \cup \{s(X_{n+1}, y, \hat{A}_y)\}$$

$$\hat{C}_\alpha(X_{n+1}) = \{y : s(X_{n+1}, y, \hat{A}_y) \leq q_{1-\alpha}(S_y)\}$$

The *jackknife* uses the leave-out-one residuals (but assumes the algorithm is “stable”).

$$S = \{|\hat{A}_{-i}(X_i) - Y_i|\} \cup \{\infty\}$$

$$\hat{C} = [\hat{A}(X_{n+1}) \pm q_{1-\alpha}(S)]$$

The *Jackknife+* does not make that assumption

$$s_i = |Y_i - \hat{\mu}_{-i}(X_i)|$$

$$u_i = \hat{\mu}_{-i}(X_i) + s_i$$

$$\ell_i = \hat{\mu}_{-i}(X_i) - s_i$$

$$U = \{u_i\} \cup \{\infty\}$$

$$L = \{\ell_i\} \cup \{\infty\}$$

$$C = [q_\alpha(L), q_{1-\alpha}(U)]$$

(the coverage is $\geq 1 - 2\alpha$, not $1 - \alpha$, unless the algorithm is stable).

Cross-Validation+ is between SCP and Jackknife+.

In a *covariate shift*, \mathcal{L}_X changes but not $\mathcal{L}_{Y|X}$. In a *label shift*, \mathcal{L}_Y changes, but not $\mathcal{L}_{X|Y}$. To deal with covariate shift, give more importance to calibration points closer to the test point.

$$(X_1, Y_1), \dots, (X_n, Y_n) \stackrel{\text{iid}}{\sim} P_X \times P_{Y|X}$$

$$(X_{n+1}, Y_{n+1}) \sim \tilde{P}_X \times P_{Y|X}$$

$$w_i \propto \frac{d\tilde{P}_X(x_i)}{dP_X(x)}$$

$$C_\alpha = \{y : s(X_{n+1}, y, \hat{A}) \leq q_{1-\alpha}(\sum w_i \delta_{s_i} + w_{n+1} \delta_\infty)\}$$

Use a similar idea for label shift.

For time series data, ACI (adaptive conformal inference) keeps track of the miscoverage ate (with an EWMA) and adjusts the quantile accordingly; AgACI uses several half-lives, combined with dynamic weights, and processes the upper and lower bounds separately.

**Convex analysis at infinity:
introduction to astral space
(ICML 2024 tutorial)**

The *astral space* is a compactification of \mathbf{R}^n for convex analysis.

We would like convex functions on \mathbf{R}^n to always have a minimum: to this end, we can add “points at infinity”. In dimension 1, we can just set $\bar{\mathbf{R}} = [-\infty, \infty]$ – the exponential function now has a minimum.

In dimension 2, we would like

$$f(x_1, x_2) = e^{-x_1} + (x_2 - x_1)^2$$

to have a minimum: we can add “points at infinity” for each direction and offset. But this is not sufficient: we also want

$$f(x_1, x_2) = e^{-x_1} + e^{-x_2+x_1/2}$$

to have a minimum, but the sequence $x_t = (t, t^2)$ does not correspond to a straight ray...

The *astral space* $\bar{\mathbf{R}}^n$ is obtained by adding to \mathbf{R}^n the sequences $(x_t)_t$ such that

$$\forall u \in \mathbf{R}^n \quad \lim(x_t \cdot u) \text{ exists (in } \bar{\mathbf{R}})$$

and identifying two sequences, $x_t \sim x'_t$ if $\forall u \quad \lim(x_t \cdot u) = \lim(x'_t \cdot u)$. This is a compact (but not metric) topological space.

For $\bar{x} \in \bar{\mathbf{R}}^n$, the *coupling function* is

$$\bar{x} \cdot u = \lim(x_t \cdot u).$$

It does not have all the properties of a scalar product, but

$$\bar{x} = \bar{x}' \text{ iff } \forall u \quad \bar{x} \cdot u = \bar{x}' \cdot u$$

$$\bar{x} \in \bar{\mathbf{R}}^n \text{ iff } \forall u \quad \bar{x} \cdot u \in \mathbf{R}$$

$$\bar{x}_t \rightarrow \bar{x} \text{ iff } \forall u \quad \bar{x}_t \cdot u \rightarrow \bar{x} \cdot u$$

An *astron* is an element of the form $x_t = tv$, for $v \in \mathbf{R}^n$ (a straight ray); it will be written $\omega v = \lim tv$. The elements of $\bar{\mathbf{R}}^2$ are of the form

$$x_t = t^2 v_1 + tv_2 + q, \quad v_1, v_2 \in \mathbf{R}^2$$

and are written $\bar{x} = \omega v_1 \star \omega v_2 \star q$ where \star is the *leftward addition*. On $\bar{\mathbf{R}}$:

$$(+\infty) \star (-\infty) = +\infty$$

$$(-\infty) \star (+\infty) = -\infty$$

$$x \star y = x + y \text{ otherwise.}$$

$$\text{On } \bar{\mathbf{R}}^n: (\bar{x} \star \bar{y}) \cdot u = (\bar{x} \cdot u) + (\bar{y} \cdot u).$$

In dimension n , every astral point can be written

$$\bar{x} = \underbrace{\omega v_1 \star \dots \star \omega v_k}_{\text{astrons}} \star \underbrace{q}_{\text{finite part}}$$

where v_1, \dots, v_k, q are orthogonal; k is the *astral rank* of \bar{x} .

A \mathcal{C}^0 function $f : \mathbf{R}^n \rightarrow \bar{\mathbf{R}}$ can be extended to $\bar{f} : \bar{\mathbf{R}}^n \rightarrow \mathbf{R}$ as

$$\bar{f}(\bar{x}) = \text{Min} \lim_{x_t \rightarrow \bar{x}} f(x_t).$$

For linear functions, $f(x) = x \cdot u$, the limit does not depend on the choice of the sequence, and $\bar{f}(\bar{x}) = \bar{x} \cdot u$, but, in general, \bar{f} is not continuous: for instance, with

$$f(x_1, x_2) = e^{-x_1} + e^{-x_2+x^2/2}$$

\bar{f} is minimized at $\bar{x} = \omega e_2 \star \omega e_1$, but \bar{f} is not continuous at \bar{x} : $x_t = (t, \frac{1}{2}t^2) \rightarrow \bar{x}$, but $f(x_t) \rightarrow 1 \neq 0$.

A convex function $f : \mathbf{R}^n \rightarrow \bar{\mathbf{R}}$ has a minimum at x iff $0 \in \partial f(x)$. This generalizes the subgradient at infinity:

$$u \in \partial \bar{f}(x) \text{ iff } \exists b \quad \forall \bar{y} \in \bar{\mathbf{R}}^n \quad \bar{f}(\bar{y}) \geq \bar{y} \cdot u + b \\ \exists x_t \rightarrow \bar{x} \quad f(x_t) - f(x_t \cdot u + b) \rightarrow 0$$

For constrained optimization

$$\text{Minimize}_{u \in \mathbf{R}^n} g(u) \quad \text{st } a \cdot u = b$$

a sufficient condition is $a \cdot u = b$, $\nabla g(u) = \lambda a$. We want to allow vertical tangents, as with

$$g(u) = \text{entropy}(u_1, u_2, 1 - u_1, -u_2)$$

(it is finite on the triangle, including its boundary, but it is not differentiable on the boundary – it is infinite outside the boundary). For $\bar{x} \in \bar{\mathbf{R}}^n$, the dual linear function is $\phi(u) = \bar{x} \cdot u$. The *dual subgradient* of a convex function $g : \mathbf{R}^n \rightarrow \bar{\mathbf{R}}$ is

$$\bar{x} \in \bar{\partial} g(u) \text{ iff } g(u) \in \mathbf{R} \\ \forall v \in \mathbf{R}^n \quad g(v) \geq \bar{x} \cdot (v - u) + g(u)$$

“Conjugacy inverts the subgradient map”: if f is closed, proper, convex,

$$u \in \partial f(x) \iff x \in \partial f^*(u).$$

More generally:

$$u \in \partial \bar{f}(\bar{x}) \iff \bar{x} \in \bar{\partial} f^*(u).$$

On \mathbf{R}^n , if f is convex, $\nabla f x = 0 \Rightarrow x$ is a minimizer. On $\bar{\mathbf{R}}^n$, if f is convex, $x_t \rightarrow \bar{x}$, and \bar{f} is continuous at

\bar{x} (this is not always the case, but most loss functions have a continuous extension), then

$$\nabla f(x_t) \rightarrow 0 \implies f(x_t) \rightarrow \inf f.$$

If f is convex and \bar{f} continuous, if the progress condition is satisfied

$$\begin{aligned} f(x_{t+1}) &\leq f(x_t) - \alpha_t h(\|u_t\|) \\ \alpha_t &\geq 0, \quad \sum \alpha_t = \infty \\ u_t &\in \partial f(x_t) \\ h &\text{ non-decreasing, } h(0) = 0, h(s) > 0 \end{aligned}$$

then $f(x_t) \rightarrow \inf f$.

Strategic ML: learning with data that behaves (ICML 2024 Tutorial)

Strategic machine learning is a generalization of adversarial learning, in which subjects can change their features, to some extent. Assuming they know the model, it is a nested min-argmax problem (adversarial learning is a minimax problem).

$$\begin{array}{ll} \text{Find} & h, x' \\ \text{To minimize} & \mathbb{E} \mathbf{1}_{y \neq h(x')} \\ \text{Where} & x' = \underset{x'}{\operatorname{Argmax}} h(x') - \underset{\text{utility}}{c(x, x')} \end{array}$$

It is a Stackelberg game: the solution is an equilibrium. Adversarial learning assumes an (exogenous) distribution shift

while strategic learning uses a strategic shift.

If the subject is close to the decision boundary, it will move to be exactly on it, but if it is too far away, it will not move.

Replace the hinge loss with a strategic hinge

which penalizes points, not where they are, but where they could be.

Strategic ML is not necessarily adversarial: for instance, in a recommendation system, both users and the system want the user to be correctly classified.

If the users do not know the model exactly, their response is smooth.

The induced distribution is also smooth.

The price of opacity, $\text{POP} = \text{err}(h, \hat{h}) - \text{err}(h, h)$ where \hat{h} is the users' approximation if h , which can be arbitrarily bad.

Previously correctly classified subjects may need to change their features because the decision boundary shifted to limit gaming – but you may want to add a penalty for this cost (“social burden”).

Data attribution at scale (ICML 2024 tutorial)

1. There are several types of data attribution:

- Corroborative attribution (evidence finding) looks for evidence (citation, copyrighted work, etc.) in a corpus (reference data, which may not be part of the training set), for a given output: for instance, information retrieval;
- Game-theoretic attribution aims to understand why the model behaved in a given way, to assign fair credit or blame (liability) to different sources for the outcome (utility): for instance, “data Shapley”;
- Predictive attribution (data modeling) predicts the model output if we change the training data, estimating

$$\theta^*(w) = \underset{\theta}{\operatorname{Argmin}} \sum_i w_i \ell_i(\theta) \quad \text{for } w \neq \mathbf{1}_n.$$

2. Leave-out-one (LOO) has a closed form solution for linear regression; for logistic regression, we can use a quadratic approximation of $L_{-j}(\theta)$ around $\theta^*(\mathbf{1}_n)$. For nonlinear, but still convex, models, we can use a linear approximation

$$\text{LOO}(j) = \theta^* - \theta_{-j}^* \approx -\frac{d\theta}{dw_j}.$$

3. The influence function

$$\hat{f}(S \setminus \{z_j\}) = f(S) - \nabla \ell(\theta)^\top H^{-1} g_j$$

is too sensitive to hyperparameter choices. Instead, learn a mapping $\hat{f} : S \mapsto \hat{f}(S)$ maximizing

$$\text{LDS} = \text{Cor}[f(S^{(i)})_{1 \leq i \leq m}, \hat{f}(S^{(i)})_{1 \leq i \leq m}],$$

e.g.,

$$\hat{f}(S') = f(S) - \sum_{i \in S \setminus S'} \text{LOO}(i)$$

or

$$f(S) = \sum_{i \in S} \beta_i = \beta^\top \mathbf{1}_S.$$

4. Do not use older attribution methods: they have $\text{LDS} \approx 0$. Better influence function and Hessian approximations exist, e.g., Gauss-Newton

$$\begin{aligned} \tilde{H} + \lambda I \\ \tilde{H} &= (\nabla_\theta h)^\top \nabla_h^2 \ell(\nabla_\theta h) \approx \nabla_\theta^2 \ell \\ \ell &= \ell(h(x, \theta), y) \end{aligned}$$

or Kronecker-based approximations (EK-FAC). One can keep track of the training dynamics, estimating the impact of observation i at epoch t . One can also compute the attribution on a surrogate model

$$\text{Differentiable model} \xrightarrow{\text{NTK}} \text{High-dimensional linear model} \xrightarrow{\text{random projection}} \text{Low-dimensional linear model} \xrightarrow{\text{IF}} \hat{f}$$

Interpretable and explainable machine learning: a methods-centric overview with concrete examples
R. Marcinkevičs and J.E. Vogt (2023)

Explainable AI refers to methods to interpret (rationalize the decisions of) already trained black-box models: feature importance, Shapley values, saliency maps, integrated gradients, global surrogate models, local surrogate models (LIME), counterfactuals, etc.

Interpretable AI refers to models interpretable by construction – interpretability is provided by their “inductive bias”:

- Falling rule lists (with monotonic output as we move along the list);
- Supersparse linear integer models (SLIM): linear regression, with integer coefficients (possibly with a sign constraint) and binary inputs – the objective function uses a 0-1 loss, an ℓ^0 penalty, and a very small ℓ^1 penalty (for the ties from the ℓ^0 penalty); it is a MIP (after big-M transformation); you can approximate it with an integer-constrained lasso regression;
- GAM, GA²M (GAM with interactions), neural GAM, [GAM boosting];
- Sparse input neural nets (group lasso penalty for the first layer weights, to select which features to use);
- Knockoff features (replace x_i with random data sampled from the distribution of $x_i|x_{\setminus i}$ (ignoring y) to see how much value it adds to the model of interest);
- Varying coefficient models, self-explaining neural networks

$$f(x) = \theta(x)^\top x \quad (\text{or } f(x) = \theta(x)^\top h(x))$$

there θ is almost constant

$$\nabla_x f(x) \approx \theta(x_0) \quad \text{if } x \text{ is close to } x_0$$

(and θ may depend on only a subset of the inputs)

– Mixture of experts

$h_j(x)$: latent representation from expert j

$c_j(x)$: output from expert j

$u_j = \sigma(W_j \cdot [h_1, c_1, \dots, h_p, c_p] + b_j)$

$a_j \propto \exp\langle u_j, \theta_j \rangle$ attention weights

$$f(x) = \sum_j a_j c_j(x)$$

with an *auxiliary loss* to minimize the discrepancy between the prediction error if we remove j and the corresponding attention weight a_j ;

– Symbolic regression;

– Interpretable representation learning.

Designing inherently interpretable machine learning models
A. Sudjianto and A. Zhang (2021)

Checklist of qualitative characteristics an interpretable model should have: additivity, sparsity, linearity, smoothness, monotonicity, visualizability, projection (sparse or near-orthogonal projections are more interpretable), segmentation (models with few “segments” are more interpretable).

GAMI-Net: an explainable neural network based on generalized additive models with structured interactions
Z. Yang et al.

GA²M,

$$y \approx \sum_i g_i(x) + \sum_{ij} g_{ij}(x_i, x_j)$$

with neural networks, sparsity penalty, and “marginal clarity” penalty ($g_i \perp\!\!\!\perp g_{ij}$).

Granger-causal attentive mixtures of experts: learning important features with neural nets
P. Schwab et al. (2019)

Define a GAM-VCM (variable coefficient model)

$$f(x) = \sum_i w_i(x) h_i(x)$$

as follows:

- Transform each input feature x_i in a nonlinear way into a forecast (“contribution”) c_i , with an MLP, with activations (latent representation) h_i

$$\begin{array}{ccccc} x_i & \longmapsto & h_i & \longmapsto & c_i \\ \text{(scalar)} & & & & \text{(scalar)} \end{array}$$

- Concatenate all the latent representations h_i and forecasts c_i into a vector h ;
- For each “expert” i , compute a context vector u_i from h , and compare it with a learned reference context u_i^{ref} , with a scalar product, $\langle u_i, u_i^{\text{ref}} \rangle$
- Compute the corresponding weights with a softmax,

$$w_i \propto \langle u_i, u_i^{\text{ref}} \rangle$$

(the paper has a different formula).

To force those “attention” weights to reflect feature importance, add a penalty, computed as follows:

- Train auxiliary predictors, using h and $h_{\setminus i}$: $p(h)$, $p_i(h_{\setminus i})$;
- Compute their error

$$\begin{aligned}\varepsilon &= \text{loss}(y, p(h)) \\ \varepsilon_i &= \text{loss}(y, p_i(h_{\setminus i})) \\ \Delta\varepsilon_i &= \varepsilon_i - \varepsilon \geq 0;\end{aligned}$$

- Compare those errors with the attention weights

$$\begin{aligned}\omega_i &= \frac{\Delta\varepsilon_i}{\sum_j \Delta\varepsilon_j} \\ \text{KL}(\omega||w) &= \sum \omega_i \log \frac{\omega_i}{w_i}\end{aligned}$$

(w_i depends on the sample, ω_i does not: average over all samples).

There is no penalty to make w slow-moving.

Self-explaining neural networks **D. Alvarez-Melis and T.S. Jaakola**

Variable coefficient models (VCM) are of the form

$$f(x) = \sum_i \theta_i(x) x_i$$

where the θ_i ’s are slow-moving functions (often, of a subset of the x_i ’s). They can be generalized to

$$f(x) = \sum_i \theta_i(x) h_i(x)$$

where h is a (low-dimensional) representation of the data (e.g., from an auto-encoder). If θ is almost constant,

$$\begin{aligned}\nabla_x f &= \theta(x)^\top \nabla_x h + \nabla_x \theta^\top h(x) \\ &\approx \theta(x)^\top \nabla_x h;\end{aligned}$$

the model can be trained by adding a penalty $\|\nabla_x f - \theta(x)^\top \nabla_x h\|$.

Towards robust interpretability with self-explaining neural networks **D. Alvarez-Melis and T.S. Jaakola**

PiML toolbox for interpretable machine learning model development and diagnostics **A. Sudjianto et al. (2023)**

Closed-source; check `imodels` instead.

Varying coefficient models **T. Hastie and R. Tibschirani (1993)**

Variable coefficient models are locally linear:

$$y \approx \sum_j \beta_j(x) x_j.$$

Often, the coefficients β_j only depend on a subset R_j of the predictors: $y \approx \sum_j \beta_j(R_j) x_j$. They can be estimated as

$$\beta_j(R_j) = \frac{\text{E} \left[X_j^2 \frac{Y - \sum_{k \neq j} \beta_k(R_k) X_k}{X_j} \middle| R_j \right]}{\text{E}[X_j^2 | R_j]}$$

with tensor product splines, minimizing

$$\left[\sum_i y_i - \sum_j x_{ij} \beta_j(r_{ij}) \right]^2 + \sum_j \lambda_j \int \beta_j''(r_j) dr_j$$

Sparse-input neural networks for high-dimensional nonparametric regression and classification **J. Feng and N. Simon (2019)**

Add a sparse group lasso penalty on the first layer weights W_1 .

$$\text{loss} = \text{error} + \lambda_0 \sum_{a \geq 2} \|W_a\|_2^2 + \lambda_{12} \|W_1\|_{12} + \lambda_1 \|W_1\|_1$$

Gradient descent (or other standard gradient-based optimizers) will not give a sparse solution: use proximal gradient.

$$\begin{aligned}W &\leftarrow w - \gamma \nabla \text{loss}_{\text{smooth}} \\ W_1 &\leftarrow S(w_1, \gamma \lambda_1) \\ W_{1:i} &\leftarrow \left(1 - \frac{\gamma \lambda_{12}}{\|W_{1:i}\|_2} \right)_+ W_{1:i}\end{aligned}$$

Supersparse linear integer models for interpretable classification **B. Ustun et al. (2014)**

For interpretable linear models, SLIM uses:

- Binary predictors,
- 0-1 loss;
- ℓ_0 penalty,
- Very small ℓ_1 penalty to avoid the ties created by the ℓ_0 penalty;
- Integer coefficients (or number with just one significant digit, possibly with a sign constraint).

This can be solved as a mixed integer linear program (with a big- M transformation), and approximated with an integer-constrained lasso regression.

Supersparse linear integer models for optimized medical scoring systems **B. Ustun and C. Rudin**

***Interpretable machine learning
based on functional Anova framework:
algorithms and comparison***
L. Hu et al. (2023)

There are many generalizations of GAM:

$$\begin{array}{ll} \text{GAM} & g(x) = g_1(x_1) + \cdots + g_n(x_n) \\ \text{AIM} & g(x) = g_1(\beta'_1 x) + \cdots + g_n(\beta'_n x) \\ \text{GA}^2\text{M} & g(x) = \sum g_i(x_i) + \sum g_{ij}(x_i, x_j) \end{array}$$

(GA²M is also known as fANOVA).

Explainable boosting machines (EBM) are similar to GA²M, but the g_i 's and g_{ij} 's are decision trees: one first fits the first order effects g_i , and only then the second order effects g_{ij} on the residuals, but only for the top k interactions, identified by comparing 4 quadrants.

GAMI-Lin-T (GAM with interactions and linear trees) are similar to EBM, but:

- The leaves contain linear functions;
- For the interactions, one variable is used only for splitting, and the other one is only used in the linear models, so we have two different terms g_{ij} and g_{ji} ;
- The top- k interactions are selected by comparing the predictive power (on the residuals) of the model trees;
- There is an additional “purifying” step, to ensure orthogonality.

$$\begin{aligned} \langle g_{ij}(x_i, x_j), g_i(x_i) \rangle &= 0 \\ \langle g_{ij}(x_i, x_j), g_j(x_j) \rangle &= 0 \end{aligned}$$

GAMINet is similar but uses neural nets for g_i and g_{ij} , with a “clarity” penalty to ensure orthogonality

$$\Omega_{jk} = \left| \frac{1}{N} \sum_{i \in \text{Observations}} g_j(x_{ij}) g_{jk}(x_{ij}, x_{ik}) \right|$$

(and a monotonicity penalty if desired).

***Using model-based trees with boosting
to fit low-order functional Anova models***
L. Hu et al.

Details of the boosting algorithm and the interaction filtering method.

***Explainable neural networks
based on additive index models***
J. Vaughan et al. (2018)

AIMs can be estimated with back-fitting or end-to-end (xNN): projection followed by univariate transformations (neural nets)

Adaptive explainable neural networks (AxNNs)
J. Chen et al. (2020)

Ensemble (boosting) of GAM and AIM, both implemented as neural nets.

$$\begin{array}{ll} \text{GAM:} & g(x) = \sum_i g_i(x_i) \\ \text{AIM:} & g(x) = \sum_i g_i(\beta'_i x) \end{array}$$

***Linear iterative feature embedding:
an ensemble framework for interpretable model***
A. Sudjianto et al.

A wide, single-layer neural net can be seen as an ensemble of narrow single-layer nets:

- Take k random neural nets

$$\begin{cases} \mathbf{R}^d & \longrightarrow \mathbf{R} \\ x & \longmapsto \hat{y} \end{cases}$$

- Use them to define samples of the data $\{i : \hat{y} > a\}$ (or $\hat{y} < a$); discard samples too large or too small;
- Train new neural nets on those samples (to learn features);
- Iterate a few times
- Combine the features thus learned (elastic net).

***An optimization approach
to learning falling rule lists***
C. Chen and C. Rudin (2018)

Monte Carlo search on frequent itemsets.

***Counterexample guided learning
of monotonic neural networks***
A. Sivaraman et al.

For each input sample x , find (with an SMT solver) the worst monotonicity counterexamples in each direction:

$$\begin{aligned} x_\ell &\geq x \quad \text{with} \quad f(x_\ell) \leq f(x) \\ x_u &\leq x \quad \text{with} \quad f(x_u) \geq f(x) \end{aligned}$$

These define the lower and upper envelopes of f .

Use them during training: (every other iteration) replace each sample (x_i, y_i) with (x_i, \hat{y}_i) , $(x_{i\ell}, \hat{y}_i)$, (x_{iu}, \hat{y}_i) , where $\hat{y}_i = \frac{1}{2}[f(x_{i\ell}) + f(x_{iu})]$.

***Interpretable machine learning
with PySR and SymbolicRegression.jl***
M. Cranmer (2023)

***Evaluating the visualization
of what a deep neural network has learned***
W. Samek et al.

Layerwise relevance propagation (LRP) gives, for each layer, a decomposition of the network output (e.g., the

log-odds, for a classification problem) into contributions of the individual neurons of that layer; in particular, the sum of the contributions is the same for all layers:

$$\sum_i R_i^{(\ell)} = \sum_j R_j^{(\ell+1)}.$$

The contributions in layer ℓ can be computed from those in layer $\ell + 1$, for instance as

$$R_i^{(\ell)} = \sum_j \left(\alpha \frac{z_{ij}^+}{\sum_{i'} z_{i'j}^+} + \beta \frac{z_{ij}^-}{\sum_{i'} z_{i'j}^-} \right) R_j^{(\ell+1)}$$

$$z_{ij} = w_{ij}^{(\ell \rightarrow \ell+1)} a_i^{(\ell)}$$

$$z_{ij} = z_{ij}^+ + z_{ij}^-$$

$$\alpha + \beta = 1.$$

Layerwise relevance propagation: an overview

in data-constrained settings***
G. Mialon (2022)

To approximate a kernel K , use

$$K(x, x') \approx \langle \psi(x), \psi(x') \rangle$$

$$\psi(x) = K(Z, Z)^{-1/2} K(Z, x)$$

where Z is a set of “anchoring points”.

***A trainable optimal transport embedding
for feature aggregation and
its relationship to attention***
G. Mialon et al. (2021)

To get a representation of (varying length) sequences x , encoded as sets of k -mers with positional embeddings, compute the optimal transport P (wrt some kernel) to a learned fixed-length sequence z , and use the optimal transport as weights: $(x_i)_i \mapsto (\sum_j P_{ij} z_j)_j$.

You could use several reference sequences. This is a pooling operation.

***GraphiT:
encoding graph structure in transformers***
G. Mialon et al. (2021)

To use transformers with graphs:

- Use a masked transformer (so that each node only attends to its k -hop neighbours) – or not;

- Use the eigenvectors of the Laplacian as positional encoding, $L = \sum \lambda_i u_i u_i'$;
- Use a graph kernel to compute the positional encoding;

$$k_r = \sum r(\lambda) u_i u_i'$$

$$r(\lambda) = e^{-\beta \lambda} \quad \text{diffusion}$$

$$r(\lambda) = (1 - \gamma \lambda)^p \quad p\text{-step random walk}$$

- Rescale the attention weights: $\exp(QQ'/\sqrt{d}) \odot k_r$.

***Screening data points
in empirical risk minimization
via ellipsoidal regions and safe loss functions***
G. Mialon et al. (2020)

$$f^*(y) = \text{Max}_t \langle t, y \rangle - f(t) \quad \text{Fenchel conjugate}$$

$$f^{**}(t) = \text{Max}_y \langle y, t \rangle - f^*(y) \quad \text{biconjugate}$$

$$f_\mu(t) = \text{Max}_y \langle y, t \rangle - f^*(y) - \mu \Omega(y)$$

$$= \text{Min}_z f(z) + \mu \Omega^* \left(\frac{t - z}{\mu} \right)$$

$$= t \square_\mu \Omega^* \quad \text{infimum convolution}$$

***safeaipackage: a Python package
for AI risk measurement***
G. Babaei

Given a (nonnegative) random variable Y :

- The Lorenz curve is `(ts, cumsum(Y[i]))`, where `ts=linspace(0,1,len(Y))`, `i=argsort(Y)`;
- The dual Lorenz curve uses `i=argsort(-Y)`;
- The concordance curve uses `i=argsort(y')` where y' is another variable.

The area under the concordance curve is

$$\frac{1}{2} \frac{\text{Cov}[Y[i'], F(Y[i])]}{\text{Cov}[Y[i], F(Y[i])]} - \frac{1}{2} \in [0, 1]$$

Different choices of (Y, Y') give different measures:

- Accuracy (“RGA”): (y, \hat{y}) (for binary data, this is the AUC);
- Robustness: (\hat{y}, \hat{y}^p) , where \hat{y}^p are forecasts after some perturbation;
- Explainability: (\hat{y}, \hat{y}^{-k}) , where \hat{y}^{-k} is the forecast of a model fitted without variable k ;
- Fairness: (\hat{y}, \hat{y}^{-k}) , where k is some protected attribute;
- Privacy: (\hat{y}, \hat{y}^{-m}) , where \hat{y}^{-k} are forecasts of a model fitted without observation m .

RGA: a unified measure of predictive accuracy
P. Giudici and E. Raffinetti (2022)

***A rank graduation accuracy measure
to mitigate artificial intelligence risks***
E. Raffinetti (2023)

Pretaining and the lasso

E. Craig et al.

Pretrain the lasso on a large dataset

$$y = C\beta'_1 + \varepsilon \quad \beta_1 \text{ sparse}$$

then, fine-tune it on the subset of interest (stratification) or on a different, smaller dataset

$$y - X\beta'_1 = X\beta'_2 + \eta \quad \beta_2 \text{ sparse}$$

where the lhs, the residuals of the first model, can be replaced by $y - (1 - \alpha)X\beta'_1$.

Estimation and inference of heterogeneous treatment effects using random forests

S. Wager and S. Athey (2017)

Under unconfoundedness $\{Y_i^{(0)}, Y_i^{(1)}\} \perp\!\!\!\perp T_i \mid X_i$, i.e., X are the only confounders

the treatment effect $\tau(X) = E[Y_i^{(1)} - Y_i^{(0)} \mid X_i = x]$ can be computed as

$$\tau(x) = E \left[Y_i \left(\frac{T_i}{e(x)} - \frac{1 - T_i}{1 - e(x)} \right) \mid X_i = x \right]$$

where $e(x) = E[T_i \mid X_i = x]$ is the propensity of receiving the treatment.

Causal forests directly estimate τ without estimating e first, by noticing that if the leaves of an (honest) tree are small enough, they look like randomized experiments and the treatment effect can be estimated with unweighted averages

$$\hat{\tau}(x) = \text{Mean}_{\substack{i \in L \\ T_i=1}} Y_i - \text{Mean}_{\substack{i \in L \\ T_i=0}} Y_i$$

where L is the leaf containing x .

There are two ways of building honest trees:

- A *propensity tree* is built without using the outcome Y , to predict the treatment T , ensuring that each leaf contains at least k observations for each treatment;
- A *double sample tree* is built using half the data, to forecast the outcome Y , but the responses are computed using the other half.

HEBO: Heteroskedastic evolutionary Bayesian optimization

A.I. Cowen-Rivers et al.

For Bayesian optimization on heteroskedastic non-stationary data:

- Use an input-warped $\Psi(x) = 1 - (1 - x^a)^{b-1}$ GP (linear + Matérn 3/2, from GPy)
- Power-transform (Box-Cox or Yeo-Johnson, in `sk-learn`) the output;
- Add noise to the posterior mean;
- Use multiple acquisition functions (NSGA-II, from `pymoo`).

Unsupervised learning of visual features by contrasting cluster assignments

M. Caron et al.

SwAV computes image features by minimizing $\ell(z_t, q_s) + \ell(z_s, q_t)$, where

- x_t and x_s are augmentations of the same image;
- $z = f_\theta(x) / \|f_\theta(x)\|$ are the corresponding features;
- c_1, \dots, c_k are (trainable) prototype vectors;
- $q = \underset{c \in \{c_1, \dots, c_k\}}{\text{Argmax}} \langle c, z \rangle$;

The three types of backtests

J. Joubert et al. (2024)

Historical, cross-validation, Monte Carlo (if you have one (or several) data generation process(es) for *all* the data used).

Gene regulatory network inference in the presence of dropouts: a causal view

H. Dai et al. (2024)

scRNAseq data contains biological zeroes (no gene expression) and technical zeroes (“dropouts”). Since $Z_i \perp\!\!\!\perp Z_j \iff X_i \perp\!\!\!\perp X_j \mid R = 0$, we can just drop the zeroes (dropouts and biological zeroes) and recover the correct conditional independence relations.

Z : True expression

D : $\mathbf{1}_{\text{dropout}}$

X : observed expression

R : observed zero

Robust agents learn causal world models

J. Richens and T. Everitt (2024)

If an RL agent is robust to distributional shifts, we can extract a causal graph from it.

Predictive auxiliary objectives in deep RL mimic learning in the brain

C. Fang and K. Stachenfeld (2024)

Auxiliary objectives in RL systems, for (long-horizon) latent state forecast (contrastive prediction), help representation learning (prevents representation collapse).

ASID: active exploration for system identification in robotic manipulation

M. Memmel et al. (2024)

Model-free RL is sample-inefficient, but model-based RL requires an accurate world simulator:

- Start with an inaccurate simulator (correct model, with approximate parameters);

- Train an exploring agent, maximizing Fisher information

$$\text{Minimize}_{\pi} \text{trace } I(p_{\theta^*}(\cdot|\pi))$$

(where p is the distribution on trajectories);

- Collect real-world data;
- Use it to refine the simulator;
- Train the (exploiting) agent.

Learning interactive real-world simulators
M. Yang et al. (2024)

UniSim is a UNet diffusion model trained on a variety of labeled video datasets, to forecast future frames from past frames and (natural language) “actions”, for reinforcement learning.

Semantic compression with large language models
H. Gilbert et al. (2024)

Ask an LLM to compress text; the result does not have to be human readable, but another GPT-4 model should be able to uncompress it.

LoftQ: LoRA-fine-tuning-aware quantization for large language models
Y. Li et al. (2023)

When fine-tuning with LoRA after quantization, do not initialize the LoRA weights with zeroes, but have them approximate the unquantized model.

LongLoRA: efficient fine-tuning of long-context large language models
Y. Chen et al.

Shifted sparse attention increases the context size of a transformer by using full attention on overlapping blocks.

Do not only use LoRA for the attention weights, also fine-tune the embeddings and the normalization.

Batched low-rank adaptation of foundation models
Y. Wen and S. Chaudhuri (2024)

Input-specific LoRA weights, for personalized, task-specific adaptation, by replacing $W + BA'$ with $W \odot (BA')$

Models tell you what to discard: adaptive KV cache compression for LLMs
S. Ge et al. (2024)

The KV cache mechanism stores previous key-value vectors to avoid recomputing them each time. Recognize the (head-specific) attention patterns:

- Local context; special tokens (punctuation, etc.);
- Column-sparse;
- Dense.

and discard unneeded tokens.

Vision transformers need registers
T. Darcet et al.

Attention maps of ViT are not informative: tokens in low-information regions (e.g., sky) appear important – they are used for internal computations. Provide additional tokens (“registers”), neither in the input nor in the output (contrary to the CLS token): the attention maps become interpretable.

Beyond Weisfeiler-Lehman: a quantitative framework for GNN expressiveness
B. Zhang et al. (2024)

Given a GNN model \mathcal{M} , computing graph representations $G \mapsto \mathcal{M}(G)$, and a substructure (a graph) F , \mathcal{M} can count F under homomorphism if

$$\forall G, H \mathcal{M}(G) = \mathcal{M}(H) \Leftrightarrow |\text{hom}(F, G)| = |\text{hom}(F, H)|.$$

The homomorphism expressivity of \mathcal{M} is the set $\mathcal{F}(\mathcal{M})$ of all substructures it can count. For instance:

$$\mathcal{F}(\text{MPNN}) = \{\text{forests}\}$$

$$\mathcal{F}(\text{subgraph GNN}) = \{F : F \text{ has an end-point-shared NED}\}$$

$$\mathcal{F}(\text{local 2-GNN}) = \{F : F \text{ has a strong NED}\}$$

$$\mathcal{F}(\text{local 2-FGNN}) = \{F : F \text{ has an almost strong NED}\}$$

$$\mathcal{F}(\text{2-FGNN}) = \{F : F \text{ has a NED}\}$$

A *nested ear decomposition* (NED) is:

A *subgraph GNN* applies a MPNN to all marked subgraphs $\{\{G^u : u \in V_G\}\}$.

GNNCert: deterministic certification of graph neural networks against adversarial perturbations
Z. Xia et al.

Divide the graph (the set of edges and/or features) into (non-overlapping) subgraphs; use a graph classifier on

each of them, and take the majority vote: this is robust to a bounded number of edge or feature perturbations.

Graph neural networks for learning equivariant representations of neural networks

M. Kofinas et al.

Neural networks are computation graphs: they can be processed with GNNs or transformers, which automatically account for their permutation symmetries.

Applications:

- Implicit neural representation (INR) classification;
- Predicting the generalization performance of a CNN classifier (example: models from the small CNN zoo – same architecture (not required), different weights);
- Improving the weights of a neural net (learning to optimize), given weights, gradients, and momentum, at several scales.

Self-RAG: learning to retrieve, generate, and critique through self-reflection

A. Asai et al.

Ask the LLM if they need RAG, if the retrieved documents are relevant, if the generated answer is consistent with these documents. Use special tokens, RETRIEVE, ISRELEVANT, SUPPORTED, etc. (ask an LLM to add those tokens to the data).

Knowledge card: filling LLM’s knowledge gaps with plugin specialized language models

S. Feng et al. (2024)

Train several small, domain-specific LLMs, and use the text they generate instead of RAG:

- Bottom-up: generate text from the query for all of them, refine those texts, and ask an LLM to use them to answer the query;
- Top-down: first, ask the LLM if it needs more data, and which specialized LLMs to use.

The documents generated by those specialized LLMs are preprocessed for relevance, brevity and factuality:

- Check relevance with the cosine similarity with the query, only keeping the top k ;
- Ensure brevity by summarizing the documents
- Check the summary is consistent with the original text;
- Check that it is factually correct using RAG.

Self-alignment with instruction back-translation

X. Li et al.

To generate instructions to fine-tune an LLM, start with the answers (good quality web pages) and ask the LLM to produce instructions that would lead to those answers; also ask the LLM to select high-quality examples.

Amortizing intractable inference in large language models

E.J. Hu et al.

Given an LLM, we may want to sample from related distributions, e.g.:

- Infilling: $q(B|A, C) \propto p_{\text{LM}}(ABC)$;
- Tempered sampling: $q(B|A) \propto p_{\text{LM}}(AB)^{1/T}$;
- Constrained generation: $q(A) \propto p_{\text{LM}}(A)c(A)$.

This can be done with *GFlowNets*, a diversity-seeking reinforcement learning algorithm, training a policy to sample tokens from an unnormalized density.

Improved techniques for training consistency models

Y. Song and P. Dhariwal (2024)

Diffusion models learn a denoising function

$$(x_{\sigma+\Delta\sigma}, \sigma + \Delta\sigma) \mapsto x_{\sigma}.$$

Consistency models directly learn

$$f_{\theta} : (x_{\sigma}, \sigma) \mapsto x_0$$

by minimizing (a weighted expectation of)

$$d[f_{\theta}(x_{\sigma_{i+1}}), f_{\theta}(\check{x}_{\sigma_i})]$$

where $\theta^- = \text{EWMA}(\theta)$, $\check{x} = x - \sigma \cdot \Delta\sigma \cdot \nabla_x \log p_{\sigma}(x)$ and the score function $\nabla_x \log p_{\sigma}(x)$ comes from a diffusion model (consistency distillation). Instead, consistency training uses $\check{x} = x + \sigma z$, $z \sim N(0, I)$.

Würstchen: an efficient architecture for large-scale text-to-image diffusion models

P. Pertinas et al. (2024)

3-stage latent diffusion model (LDM):

- A first LDM computes a very low-dimensional latent representation of the image, conditioned on the input text;
- A second LDM computes a low-dimensional latent representation of the image, conditioned on the output of the previous stage;
- Finally, a VQGAN decoder generates the full-resolution image.

Lipschitz singularities in diffusion models

Z. Yang et al.

Diffusion models are not Lipschitz at $\sigma = 0$. E-TSDM replaces $f : (x_t, t) \mapsto x_{t-\Delta t}$ with

$$\tilde{f} : (x_t, t) \mapsto \begin{cases} f(x_t, t) & \text{if } t > \tilde{t} \\ f(x_t, \tilde{t}) & \text{if } t \leq \tilde{t} \end{cases}$$

Generalization in diffusion models arises from geometry-adaptive harmonic representations
Z. Kadkhodaie et al.

Diffusion models trained on sufficiently large (10^5) non-overlapping datasets learn the same score function and generate similar images: they do not memorize their training data.

They have a GAHB bias. A (bias-free) denoiser is locally linear: $f(y) \approx \nabla f \cdot y$; its Jacobian is approximately symmetric (and psd), so it has an eigen decomposition $f(y) \approx \sum_k \lambda_k(y) \langle y, e_k(y) \rangle e_k(y)$. The denoiser performs some shrinkage in that (data-dependent) basis; this basis shows oscillating patterns.

Improving convergence and generalization using parameter symmetries
B. Zhao et al.

In the optimization problem

$$\text{Minimize}_{g \in \mathbf{R}^d} \ell(w),$$

if the loss ℓ is invariant under the action of some group G ,

$$\forall g \in G \quad \forall w \in \mathbf{R}^d \quad \ell(g \cdot w) = \ell(w),$$

symmetry teleportation is a variant of gradient descent looking for the point with the steepest gradient in the current orbit,

$$w \leftarrow g \cdot w$$

$$g = \underset{g}{\text{Argmax}} |\nabla \ell(g \cdot w)|$$

Teleporting towards larger curvatures may improve generalization.

Symmetry teleportation for accelerated optimization
B. Zhao et al.

Linear neural nets are invariant under an action of GL_{d_m} :

$$g \cdot W_m = W_m g^{-1}$$

$$g \cdot W_{m-1} = g W_{m-1}$$

$$g \cdot W_k = W_k \text{ if } k \notin \{m, m-1\}.$$

This can be generalized to neural nets with invertible nonlinearities (e.g., leaky ReLU),

$$g \cdot W_{m-1} = \sigma^{-1} [g \sigma(W_{m-1} h_{m-2})] h_{m-2}^{-1}$$

$$h_{m-1} \mapsto W_m h_{m-1} \mapsto \sigma(W_m h_{m-1})$$

(if h_{m-2} is square and invertible); note that the action depends on the data.

Symmetries, flat minima, and the conserved quantities of gradient flow
B. Zhao et al.

Given a 2-layer neural net

$$\begin{matrix} x & \longrightarrow & \boxed{V} & \longrightarrow & \boxed{\sigma} & \longrightarrow & \boxed{U} & \longrightarrow & F(x) \\ \mathbf{R}^n & & & & \mathbf{R}^h & & & & \mathbf{R}^m \end{matrix}$$

(for which $\forall z \sigma(z) \neq 0$, e.g., $\sigma = \text{sigmoid}$), there is a (data-dependent) action of GL_h on $\text{Param} \times \mathbf{R}^n$

$$g \cdot (U, V, x) = (U R_{\sigma(Vx)} R_{\sigma(gVx)}^{-1}, gV, x)$$

where

$$(R_z)_{ij} = \begin{cases} z_i \cos(\alpha_{j-1}) \left(\prod_{k < j} \sin \alpha_k \right) & \text{if } j \leq i \\ -r \sin \alpha_i & \text{if } j = i + 1 \\ 0 & \text{otherwise} \end{cases}$$

and $(r, \alpha_1, \dots, \alpha_{h-1})$ are the spherical coordinates of z

$$z_i = r \cos \alpha_i \prod_{k < i} \sin \alpha_k.$$

InfoBatch: lossless training speed up by unbiased dynamic data pruning
Z. Qin et al.

Data pruning (filtering out samples contributing little to training) leads to biased gradients. Use dynamic data pruning instead: keep track of the loss of each sample, randomly drop some proportion of the low-loss samples (anew for each epoch) and rescale the gradients of the remaining low-loss samples; for the last few epochs, use the whole dataset.

Towards a statistical theory of data selection under weak supervision
G. Kolossov et al.

To select on which data to train:

$$\pi_i = \text{Min}\{c \cdot (\text{Var } \hat{Y}_i)^\alpha; 1\}$$

$$w_i = 1 \text{ or } 1/\pi_i$$

where

- Fit a model on a small subset of the data and compute \hat{Y}_i from this surrogate model (better surrogates need not be useful);
- $\alpha < 0$ prefers easy samples (better if you want a small number of samples);
- $\alpha > 0$ prefers hard samples;
- c is chosen to have the desired number of samples;
- $w_i = 1/\pi_1$ leads to unbiased (but possibly worse) results.

Use cross-validation to choose the surrogate model, α and w – it will depend on the dimensionality of the problem, on the model, and on the proportion of the data you want to keep.

**Meta continual learning revisited:
implicitly enhancing
online Hessian approximation
via variance reduction**
Y. Wu et al.

Regularization-based continual learning uses updates of the form

$$\theta \leftarrow \theta - \alpha(H^1 + \dots + H^{k-1})^{-1} \nabla_{\theta} \mathcal{L}^k(\theta)$$

where H^i is the Hessian of the loss at the end of training for task i (e.g., the diagonal Fisher information matrix) to keep the weights that mattered for task i .

**Topological data analysis
on noisy quantum computers**
I.Y. Akhalwaya et al.

Quantum computers do linear algebra in exponentially large vector spaces. This is what TDA needs (computing the rank of an exponentially large matrix).

**Cameras as rays:
pose estimation via ray diffusion**
J.Y. Zhang et al.

A camera is typically parametrized as $(R, t, k) \in \text{SO}(3) \times \mathbf{R}^3 \times \mathbf{R}^{3 \times 3}$

$$\begin{cases} \text{World} & \longrightarrow \text{Pixels} \\ x & \longmapsto u = k[R|T]x. \end{cases}$$

Instead, model a camera as a collection of rays (r_1, \dots, r_m) associated to pixel coordinates (u_1, \dots, u_m) (patches). The ray in direction $d \in \mathbf{R}^3$ through point $p \in \mathbf{R}^3$ can be represented with Plücker coordinates

$$(d, m = p \times d) \in \mathbf{R}^3 \times \mathbf{R}^3$$

(actually $\mathbf{P}(\mathbf{R}^6)$: the Plücker embedding is $\text{Gr}_k V \hookrightarrow \mathbf{P}(\Lambda^k V)$, here with $k = 2$, $\dim V = 4$ – lines in 3-dimensional projective space are 2-dimensional linear subspaces in 4-dimensional space). To convert from cameras to rays:

$$\begin{aligned} d &= R'K^{-1}u \\ m &= (-R't) \times d \end{aligned}$$

To convert from rays to cameras: first, find the camera center, $c = \text{Argmin}_p \sum \|p \times d - m\|^2$, then the camera transformation $P = \text{Argmin}_{\|H\|=1} \sum \|Hd \times u\|$. Train a transformer (with positional encoding) to predict rays from patch features or, better if there is ambiguity because the data is too sparse, a diffusion model.

**Accelerating distributed stochastic
optimization via self-repellent random walks**
J. Hu et al.

Given a time-reversible Markov chain with transition kernel P and stationary distribution μ , the *self-repellent random walk* (SRRW)

$$K_{ij}(x) \propto P_{ij} \left(\frac{x_i}{\mu_j} \right)^{-\alpha},$$

where x_j is the number of visits to state j , has a smaller asymptotic variance and converges faster.

The *token algorithm* is a decentralized SGD, implemented using a random walk (e.g., SRRW) on a graph, each node updating θ using its local gradient and sending the new value to one of its neighbours.

**Self-repellent random walks on general graphs:
achieving minimal sampling variance
via nonlinear Markov chains**
V. Doshi et al. (2023)

Stochastic heavy ball
S. Gadat et al. (2016)

To find the minimum of a function f , the (deterministic) *heavy ball* method (HBF, heavy ball with friction) considers a ball, moving on the graph of f , subject to both damping γ and acceleration

$$\ddot{x}_t + \gamma_t \dot{x}_t + \nabla f(x_t) = 0.$$

It converges towards a minimum of f if

$$\begin{aligned} \int_0^\infty \gamma_s ds &= \infty \\ \int_0^\infty \exp\left(-\int_0^t \gamma_s ds\right) dt &< \infty, \end{aligned}$$

e.g., if $\gamma_t = r/t$ ($r > 1$) or $\gamma_t = \gamma > 0$.

It can be discretized

$$\begin{aligned} y_{t+1} &= (1 - \gamma_t)y_t - \nabla f(x_t) \\ x_{t+1} &= x_t + y_{t+1} \end{aligned}$$

and one can replace the gradient $\nabla f(x_t)$ with an approximation (computed on a different minibatch each time).

**Understanding in-context learning
in transformers and LLMs
by learning to learn discrete functions**
S. Bhattamishra et al.

In-context learning (ICL) is the task of forecasting y from x after seeing a handful of examples.

$$(x_1, y_1, x_2, y_2, \dots, x_n, y_n, x_{n+1}) \mapsto y_{n+1}$$

**ReLU strikes back: exploiting activation
sparsity in large language models**
I. Mirazadeh et al.

ReLU (contrary to the trendier GELU or SiLU) activation functions lead to sparse activations, and a significant reduction of CPU-GPU data transfers, with a negligible impact on convergence and performance. For pretrained models, replace their activation functions with ReLU and fine-tune them.

**Unprocessing seven years
of algorithmic fairness**
A.F. Cruz and M. Hardt

Experimental evidence suggests that processing a model to equalize the error rates in different demographic groups is Pareto-optimal: varying the group-specific acceptance threshold yields the fairness-accuracy frontier.

**On the joint interaction
of models, data and features**
Y. Jiang et al. (2024)

According to the GDE (generalization disagreement equality), the (expected) agreement in a deep ensemble (an ensemble of randomly initialized networks, on unlabeled data) equals its (expected) test accuracy – but this only holds for *calibrated* ensembles.

The agreement can be modeled by a tensor

$$\Omega \in \{0, 1\}^{\#models \times \#samples \times \#features}$$

built as follows:

- Fit M classification models;
- For each of them, define “features” as the principal components of its penultimate layer;
- Cluster the features (greedy algorithm for k -partite matching) attempting to put in the same cluster principal components whose correlation is above some threshold;
- Match features to observations.

Experiments suggest that the agreement, computed from that tensor, is very close to the test accuracy, even for non-calibrated ensembles.

Assessing generalization via disagreement
Y. Jiang et al.

Given a well-calibrated ensemble of classification models (same model, trained with a stochastic algorithm and different random seeds), the disagreement rate (on unseen, unlabeled data) equals the test error (in expectation).

**Statistically optimal k -means clustering
via nonnegative low-rank
semidefinite programming**
Y. Zhuang et al.

The k -means problem

$$\text{Minimize}_{\beta_1, \dots, \beta_k \in \mathbb{R}^p} \sum_{i=1}^n \text{Min}_{k \in [1, k]} \|X_i - \beta_k\|_2^2$$

is NP-complete and often solved with heuristics or relaxations: Lloyd’s algorithm, spectral clustering, NMF, SDP. The problem can be reformulated as

$$\text{Maximize}_{G_1 \sqcup \dots \sqcup G_k = [1, n]} \sum_k \frac{1}{|G_k|} \sum_{i, j \in G_k} \langle X_i, X_j \rangle$$

or

$$\text{Minimize}_{\substack{H \in \{0, 1\}^{n \times k} \\ H\mathbf{1}_k = \mathbf{1}_n}} \langle A, HBH^\top \rangle$$

where

$$A = -X'X$$

$$B = \text{diag}(|G_1|^{-1}, \dots, |G_k|^{-1})$$

The SDP relaxation looks for $Z = HBH^\top$ instead:

$$\text{Minimize}_{Z \succeq 0} \langle A, Z \rangle \quad \text{st} \quad \text{tr } Z = k, \quad Z\mathbf{1}_n = \mathbf{1}_n, \quad Z \succeq 0.$$

Further relax it by assuming Z is low-rank, $Z = UU'$ (and replacing $UU^\top \succeq 0$ with the stronger $U \succeq 0$)

$$\text{Minimize}_{U \in \mathbb{R}^{n \times r}} \langle A, UU^\top \rangle \quad \text{st} \quad \|U\|_F^2 = k, \quad UU^\top \mathbf{1}_n = \mathbf{1}_n, \quad U \succeq 0$$

(this keeps most of the theoretical properties of the SDP relaxation). The NMF relaxation did not have those equality constraints:

$$\text{Minimize}_{U \in \mathbb{R}^{n \times r}} \|A + UU^\top\|_F^2 \quad \text{st} \quad U \succeq 0.$$

**Mixed-type tabular data synthesis
with score-based diffusion in latent space**
H. Zhang et al.

**On the humanity of conversational AI:
evaluating the psychological portrayal of LLMs**
J.T. Huang et al.

Comparison of the results of psychological tests for humans and LLMs: LLMs lie more, and are more self-confident.

**What data benefits my classifier?
Enhancing model performance and
interpretability through influence-based
data selection**
A. Chhabra et al.

The *influence* of a sample (x_j, y_j) on some quantity of interest f (loss, fairness, robustness, etc.) is

$$I(x_j) = \nabla_\theta f(\hat{\theta})^\top H_\theta^{-1} \nabla_\theta \ell(x_j, y_j; \hat{\theta})$$

where

$$H_\theta = \frac{1}{n} \sum_i \nabla_\theta^2 \ell(x_i, y_i; \hat{\theta})$$

$$\hat{\theta} = \text{Argmin}_\theta \frac{1}{n} \sum_i \ell(x_i, y_i; \theta).$$

To interpret it, train a decision tree

$$(x_j, y_j) \mapsto I(x_j).$$

Use *hierarchical shrinkage* on the resulting tree.

***Hierarchical shrinkage:
improving the accuracy and
interpretability of tree-based methods***
A. Agarwal et al. (2022)

Consider a decision tree h :

q : input
 t_0 : root
 t_n : leaf containing q
 $t_n \subset t_{n-1} \subset \dots \subset t_0$: leaf-to-root path
 $\phi(t)$: number of sampled in node t
 $\xi(q, t)$: output for q in node t .

Its output

$$h(q) = \xi(q, t_0) + \sum_{j \geq 1} \xi(q, t_j) - \xi(q, t_{j-1})$$

can be shrunk to

$$\hat{h}(q) = \xi(q, t_0) + \sum_{j \geq 1} \frac{\xi(q, t_j) - \xi(q, t_{j-1})}{1 + \lambda / \phi(t_{j-1})}.$$

This alternative to pruning also applies to random forests: it often improves accuracy and simplifies the decision boundaries.

Code in `imodels`.

***Never train from scratch: fair comparison
of long-sequence models
requires data-driven priors***
I. Amos et al.

Do not train your models from a random initialization: pretrain them, on the downstream data (*self-pretraining*), with some denoising objective.

Flow matching on general geometries
R.T.Q. Chen and Y. Lipman

***Stochastic interpolants:
a unifying framework for flows and diffusions***
M.S. Albergo et al.

Given two probability distributions p_0 and p_1 , we want to progressively transform samples from p_0 into samples from p_1 (or the opposite).

Score-based diffusion models consider an OU process transforming p_0 into an (approximate) Gaussian p_0 , we sample x_1 from p_1 (a Gaussian) and use the backward SDE (its drift involves the score function $\nabla_{!x} \log p_t(x)$, which has to be learned) to get a corresponding x_0 . The path $(x_t)_t$ is stochastic, but one can use an ODE instead, and get a deterministic path.

Many paths give rise to the same intermediate distribution p_t : deterministic, with straight lines (optimal transport) or not (normalizing flows, in discrete “time”, or neural ODE, in continuous time), or stochastic.

A *stochastic interpolant* between p_0 and p_1 is a stochastic process x of the form

$$x_t = I(t, x_0, x_1) + \gamma(t)z, \quad t \in [0, 1]$$

where

$$\begin{aligned} I(0, x_0, x_1) &= x_0 \\ I(1, x_0, x_1) &= x_1 \\ \gamma(0) &= \gamma(1) = 1 \\ \gamma &\geq 0 \\ (x_0, x_1) &\sim \nu \\ \text{pr}_{1\#}\nu &= p_0, \text{ pr}_{2\#}\nu = p_1 \\ z &\sim N(0, I). \end{aligned}$$

For instance,

$$x_t = (1-t)x_0 + tx_1 + \sqrt{1t(1-t)}z$$

or (pure noise for $t = \frac{1}{2}$)

$$x_t = \cos^2(\pi t) \left(\mathbf{1}_{t < \frac{1}{2}} x_0 + \mathbf{1}_{t > \frac{1}{2}} x_1 \right) + \sqrt{2t(1-t)}z.$$

The density $(p_t)_t$ satisfies the *transport equation*

$$\partial_t p + \nabla \cdot (bp) = 0$$

where the *velocity* is

$$\begin{aligned} b(t, x) &= \mathbb{E}[\dot{x}_t | x_t = x] \\ b &= \underset{b}{\text{Argmin}} \mathbb{E}_{\substack{(x_0, x_1) \sim \nu \\ z \sim N(0, I) \\ t \sim \text{Unif}(0, 1)}} \left[\frac{1}{2} |b(t, x_t)|^2 = \dot{x}_t \cdot b(t, x_t) \right] \\ b &= v - \dot{\gamma} s \end{aligned}$$

Its *score* is

$$\begin{aligned} s &= \nabla_x \log p_t(x) = \gamma^{-1} \mathbb{E}[z | x_t = x] \\ &= \underset{x_0, x_1, z, t}{\text{Argmin}} \mathbb{E} \left[\frac{1}{2} |s(t, x_t)|^2 + \gamma(t)^{-1} z \cdot s(t, x_t) \right] \\ &= \underset{s}{\text{Argmin}} \mathbb{E}[|s|^2 + e \nabla \cdot s]. \end{aligned}$$

The *denoiser* is

$$\begin{aligned} \eta(t, x) &= \mathbb{E}[z | x_t = x] \\ \eta &= \underset{x_0, x_1, z, t}{\text{Argmin}} \mathbb{E} \left[\frac{1}{2} |\eta(t, x_t)|^2 = z \cdot \eta(t, x_t) \right] \end{aligned}$$

The *velocity field* is

$$\begin{aligned} v(t, x) &= \mathbb{E}[\partial_t I(t, x_0, x_1) | x_t = x] \\ v &= \underset{v}{\text{Argmin}} \mathbb{E} \left[\frac{1}{2} |v|^2 - \nabla_t Y \cdot v \right]. \end{aligned}$$

The forward and backward *Fokker-Plank equations* are

$$\begin{aligned} \partial_t p + \nabla \cdot (b_F p) &= \varepsilon \Delta p & p(0) &= p_0 \\ \partial_t p + \nabla \cdot (b_B p) &= -\varepsilon \Delta p & p(1) &= p_1 \end{aligned}$$

where ε is a non-negative (or positive semi-definite) function, and the forward and backward drifts are

$$\begin{aligned} b_F(t, x) &= b(t, x) + \varepsilon(t)s(t, x) \\ b_B(t, x) &= b(t, x) - \varepsilon(t)s(t, x). \end{aligned}$$

They are more robust than the transport equation to errors in the velocity and scores.

The following processes have the same law as the stochastic interpolant x_t .

$$\begin{aligned} \frac{d}{dt}X_t &= b(t, X_t) & X_0 &\sim p_0 \\ dX_t^F &= b_F(t, X_t^F)dt + \sqrt{2\varepsilon(t)}dW_t & X_0^F &\sim p_0 \\ dX_t^B &= b_B(t, X_t^B)dt + \sqrt{2\varepsilon(t)}dW_t^B & X_1^B &\sim p_1 \\ & & W_t^B &= W_{1-t} \end{aligned}$$

The density p_t can be computed from solutions of the ODE

$$\begin{aligned} p_t(x) &= \exp\left(-\int_0^t \nabla \cdot b(\tau, X_{t,\tau}(x))d\tau\right) p_0(X_{t,0}(x)) \\ &= \exp\left(\int_t^1 \nabla \cdot b(\tau, X_{t,\tau}(x))d\tau\right) p_1(X_{t,1}(x)) \end{aligned}$$

where

$$\begin{aligned} \frac{d}{dt}X_{st}(x) &= b(t, X_{st}(x)) \\ X_{ss}(s) &= x. \end{aligned}$$

For the SDEs:

$$\begin{aligned} p_1^F(x) &= \mathbb{E}\left[\exp\left(-\int_0^1 \nabla \cdot b_F(t, Y_t^B)dt\right) p_0(Y_0^B) \middle| Y_1^B = x\right] \\ p_1^B(x) &= \mathbb{E}\left[\exp\left(-\int_0^1 \nabla \cdot b_B(t, Y_t^F)dt\right) p_1(Y_1^F) \middle| Y_0^F = x\right] \end{aligned}$$

Other interpolants include:

– Diffusive interpolant

$$\begin{aligned} x_t &= I(t, x_0, x_1) + \sqrt{2a(t)}B_t \\ B: &\text{Brownian bridge} \end{aligned}$$

– One-sided interpolant

$$\begin{aligned} x_t &= \alpha(t)x_0 + J(t, x_1) \\ \alpha: &0 \rightsquigarrow 1 \\ J: &0 \rightsquigarrow x_1 \end{aligned}$$

– Mirror interpolant (cf denoisers)

$$\begin{aligned} x_t &= k(t, x_1) + \gamma(t)z \\ k: &x_1 \rightsquigarrow x_1 \end{aligned}$$

– Linear interpolant

$$\begin{aligned} x_t &= \alpha(t)x_0 + \beta(t)x_1 + \gamma(t)z \\ \alpha(0) &= \beta(1) = 1 \\ \alpha(1) &= \beta(0) = \gamma(0) = \gamma(1) = 0 \\ \forall t \quad &\alpha^2 + \beta^2 + \gamma^2 = 1 \end{aligned}$$

The *Schrödinger bridge* problem is

$$\begin{aligned} &\text{Find} && u, p \\ &\text{To minimize} && \int \int_{\substack{t \in [0,1] \\ x \in \mathbf{R}^n}} |u|^2 p \\ &\text{Such that} && \partial_t p + \nabla \cdot (up) = \varepsilon \Delta p \\ &&& p(0) = p_0, p(1) = p_1 \end{aligned}$$

Its solution is $p, \nabla \lambda$, where

$$\begin{aligned} \partial_t p + \nabla \cdot (\nabla \lambda p) &= \varepsilon \Delta p \\ \partial_t \lambda + \frac{1}{2} |\nabla \lambda|^2 &= \varepsilon \Delta \lambda. \end{aligned}$$

***How to avoid machine learning pitfalls:
a guide for academic researchers***
M.A. Jones

Flow matching for generative modeling
Y. Lipman et al.

A time-dependent vector field $v : [0, 1] \times \mathbf{R}^d \rightarrow \mathbf{R}^d$ defines a flow $\phi : [0, 1] \times \mathbf{R}^d \rightarrow \mathbf{R}^d$

$$\begin{aligned} \dot{\phi}_t(x) &= v_t(\phi_t(x)) \\ \phi_0(x) &= x \end{aligned}$$

and a probability density path

$$p_t = (\phi_t)_*(p_0)$$

or, equivalently (*continuity equation*)

$$\dot{p} + \text{div}(pv) = 0.$$

For each observation $x_1 \in \text{Data}$, the optimal transport from $N(0, I)$ to $N(x_1, \sigma_{\min}^2)$ defines the *conditional probability path*

$$x_t \sim N(tx_1, [1 - \sigma_{\min}]^2) = p_t(\cdot | x_1)$$

and the corresponding conditional vector field

$$u_t = \frac{x_1 - (1 - \sigma_{\min})x}{1 - (1 - \sigma_{\min})t}$$

(the deterministic probability flow of denoising diffusion models is more complex and can overshoot).

Find a vector field v_t (a deep neural network) v_t minimizing the *conditional flow matching* (CFM) objective

$$\mathbb{E}_{\substack{t \sim \text{Unif}(0,1) \\ x_1 \sim \text{Data} \\ x \sim p_t(\cdot | x_1)}} \|v_t(x) - u_t(x | x_1)\|^2$$

(easier to train than score matching).

**Improving and generalizing
flow-based generative models
with minibatch optimal transport**
A. Tong et al.

The flow-matching objective

$$\mathcal{L}(\theta) = \mathbb{E}_{\substack{t \sim \text{Unif}(0,1) \\ x_1 \sim \text{Data} \\ x \sim p_t(\cdot|x_0)}} \|v_\theta(t, x) - u_t(x|x_1)\|^2$$

where

$$p_t = N(tx_1, (t\sigma - t + 1)^2)$$

$$u_t(x|x_1) = \frac{x_1 - (1 - \sigma)x}{1 - (1 - \sigma)t}$$

can be generalized to

$$\mathbb{E}_{\substack{t \sim \text{Unif}(0,1) \\ x_0, x_1 \sim q \\ x \sim p_t(x_0, x_1)}} \|v_\theta(t, x) - u_t(x|x_0, x_1)\|^2$$

where

$$q(x_0, x_1) = q(x_0)q(x_1) \text{ (independent coupling)}$$

$$u_t(x|x_0, x_1) = x_1 - x_0$$

$$p_t(\cdot|x_0, x_1) = N(tx_1 + (1 - t)x_0, \sigma^2)$$

or q = optimal transport from q_0 to q_1 , or the entropy-regularized optimal transport.

$$q = \underset{\substack{(\text{pr}_0)_{\#} \pi = q_0 \\ (\text{pr}_1)_{\#} \pi = q_1}}{\text{Argmin}} \text{KL}(\pi \| \pi_{\text{ref}})$$

$$p_t = N(tx_1 + (1 - t)x_0, t(1 - t)\sigma^2)$$

$$u_t = \frac{1 - 2t}{2t(1 - t)} [x - (tx_1 + (1 - t)x_0)] + (x_1 - x_0)$$

Implementation in `torchcfm`.

**Minibatch optimal transport distances;
analysis and applications**
K. Fatras et al.

Computing the optimal distance on minibatches and averaging is efficient and biased (and it is no longer a distance); it can be debiased.

Poisson flow generative models
Y. Xu et al.

Given a probability distribution on \mathbf{R}^n , put electric charges in $[z = 0] \subset \mathbf{R}^n \times \mathbf{R}$ according to it, and consider the motion of a particle (of the same charge) starting at $(x, \varepsilon) \in \mathbf{R}^n \times \mathbf{R}$, $\varepsilon > 0$: after a while, those particles will be uniformly distributed on a hemisphere.

To generate data from this distribution, start with uniform data on a large hemisphere, and let it evolve along the reverse process.

Learn the Poisson field from data.

$\Delta\phi = -\rho$	Poisson equation
$\rho : \mathbf{R}^{n+1} \rightarrow \mathbf{R}$	Source function
$\phi : \mathbf{R}^{n+1} \rightarrow \mathbf{R}$	Potential function
$E = -\nabla\phi$	Poisson field
$\frac{\partial p}{\partial t} = -\nabla \cdot (pE)$	Gradient flow
$\phi(x) = \int G(x, y)\rho(y)dy$	
$G(x, y) \propto \ x - y\ ^{(n+1)-2}$	

**PFGM++: unlocking the potential
of physics-inspired generative models**
Y. Xu et al.

PFGM adds one dimension; instead, add D dimensions. The limit $D \rightarrow \infty$ corresponds to diffusion models, but smaller values give more robust models.

**Elucidating the design space
of diffusion-based generative models**
T. Karras et al.

Diffusion models consider a process in which we progressively add noise to a sample from the data distribution

$$x_0 \sim p_0 \text{ (data)}$$

$$x_{k+1} = x_k + \varepsilon_{k+1}, \quad \varepsilon_{k+1} \sim N(0, \sigma_{k+1}^2 I).$$

For $k \gg 1$, x_k is approximately Gaussian

$$x_k \sim p_k \approx N(0, \sigma^2 I).$$

Diffusion models try to reverse that process, starting with $x_k \sim N(0, \sigma^2 I)$, and trying to find $x_0 \sim p_0$.

Instead of looking at samples x_k , we can look at the corresponding distributions

$$p_{k+1} = p_k * N(0, \sigma_{k+1}^2 I).$$

In the continuous limit, we have a probability flow

$$x(0) \sim p_0$$

$$\dot{x} = -\dot{\sigma} \nabla_x \log p_t.$$

Deterministic diffusion models sample from p_0 as follows:

- Learn the score function $s = \nabla_x \log p_t$ from data;
- Sample from $x(1) \sim N(0, \sigma^2 I) \approx p_1$;
- Solve the ODE using $x(1)$ as final condition;
- x_0 is then distributed as p_0 .

The ODE $\dot{y} = f(t, y)$ can be solved with Euler's method

$$y_{i+1} = y_i + hf(t_i, y_i)$$

or *Heun's method* (aka improved Euler, trapezoidal)

$$\tilde{y}_{i+1} = y_i + hf(t_i, y_i)$$

$$y_{i+1} = y_1 + h \frac{f(t_i, y_1) + f(t_{i+1}, \tilde{y}_{i+1})}{2}.$$

If we keep the stochasticity, the ODE becomes an SDE

$$dx_{\pm} = -\dot{\sigma}\sigma s dt \pm \beta\sigma^2 s dt + \sqrt{2\beta}\sigma dW$$

where $\beta = \dot{\sigma}/\sigma$ (other choices are possible), *i.e.*

$$\begin{aligned} dx_+ &= \sqrt{2\beta}\sigma dW && \text{adding noise} \\ dx_- &= -2\dot{\sigma}\sigma s dt + \sqrt{2\beta}\sigma d\bar{W} && \text{denoising.} \end{aligned}$$

This is Anderson's *time reversal* formula

$$\begin{aligned} dX &= \mu dt + \sigma dW \\ d\bar{X} &= (\mu - \sigma^2 s) dt + \sigma d\bar{W} \\ s &= \nabla_x \log p \end{aligned}$$

(valid if $\sigma = \sigma_t$ does not depend on t). As in the deterministic case, *stochastic diffusion* models sample from p_0 :

- Learn the score function from data;
- Sample $x(1) \sim N(0, \sigma^2 I) \approx p_1$;
- Solve (*i.e.*, sample from) the backward SDE;
- $x(0)$ is then distributed as p_0 .

To solve (*i.e.*, sample from) an SDE $dX = \mu dt + \sigma dW$, Euler-Maruyama performs an ODE step and then adds noise;

$$\begin{aligned} \text{Euler} \quad \Delta X &= \mu \Delta t + \sigma \Delta W \\ \text{Milstein} \quad \Delta X &= \mu \Delta y + \sigma \Delta W + \frac{1}{2} \sigma \sigma' [(\Delta W)^2 - \Delta y] \\ \text{RK} \quad \hat{y}_n &= y_n + \mu(y_n) \Delta t + \sigma(y_n) (\Delta t)^{1/2} \\ y_{n+1} &= y_n + \mu(y_n) \Delta t + \sigma(y_n) \Delta W + \\ &\quad \frac{\sigma(\hat{y}_n) - \sigma(y_n)}{2} \frac{(\Delta W)^2 - \Delta t}{\sqrt{\Delta t}} \end{aligned}$$

reversing those operations (pay attention to the step size: it has to remain the same SDE).

$$\begin{aligned} \tilde{x}_{i+1} &= x_1 + \mu(x_i, t_i) h \\ x_{i+1} &= \tilde{x}_{i+1} + \sigma(x_i, t_i) (W_{i+1} - W_i) \end{aligned}$$

The score can be computed from a *denoiser*

$$\begin{aligned} D(\cdot, \sigma) &= \underset{D}{\text{Argmin}} \mathbb{E}_{y \sim \text{Data}} \mathbb{E}_{\varepsilon \sim N(0, \sigma^2 I)} \|D(y + \varepsilon, \sigma) - y\|^2 \\ \nabla_x \log p(x, \sigma) &= \frac{D(x, \sigma) - x}{\sigma^2} \end{aligned}$$

Do not learn D directly (the magnitudes of the inputs and outputs depend on σ) but F

$$D(x, \sigma) = x - \sigma F(x)$$

or, better

$$D(x, \sigma) = c_1(\sigma) + c_2(\sigma) F\left(\frac{\sigma \cdot \sigma_{\text{data}}}{\sqrt{\sigma^2 + \sigma_{\text{data}}^2}} c_3(\sigma) x, \frac{1}{\sqrt{\sigma^2 + \sigma_{\text{data}}^2}} c_4(\sigma) \log \sigma\right)$$

In the loss, use $1/c_2^2$ as weights.

Use data augmentation but, to prevent the augmentations from leaking into the generated images, use the augmentation parameters as conditioning inputs for F , and set them to zero during inference.

The unreasonable effectiveness of deep features as a perceptual metric R. Zhang et al.

The average distance between latent representations is more consistent with human evaluations than traditional metrics. Add a linear layer after the latent representation, or fine-tune the whole network, if you have data (LPIPS, learned perceptual image patch similarity).

Tackling decision processes with non-cummulative objectives using reinforcement learning M. Nägele et al.

Non-cummulative MDPs (NCMDP) maximize an arbitrary function of the rewards, rather than their discounted sum: Sharpe ratio, weakest link (maximize the minimum reward), optimization (find the state with the maximum reward). To apply classical RL algorithms, turn the NCMDP into an MDP:

- Replace the rewards with $f(r_{\leq t}) - f(r_{< t})$;
- Augment the state space to make the decision process Markov (sufficient statistics).

Text embeddings reveal (almost) as much as text J.X. Morris et al.

To invert vector embeddings of text, one could learn a mapping

$$\begin{cases} \text{embeddings} \longrightarrow \text{distributions on text} \\ e \longmapsto p(t|e). \end{cases}$$

Instead, train an error-correcting model $(e, \varepsilon) \longmapsto p(t|e, \varepsilon)$ and apply it iteratively

$$e \longmapsto t \longmapsto (e, \text{emb}(t) - e) \longmapsto t \longmapsto \dots$$

(4 times is enough).

Lag-Llama: towards foundation models for probabilistic time series forecasting K. Rasul et al.

Pretrain a transformer on 8000 time series (with stratified sampling), using lag features and time features, and Freq-Mix, Freq-Mask data augmentation, for univariate probabilistic forecasts (output the parameters of a Student T distribution). Also check: AutoArima, AutoETS, CrostonSBA, DynOptTheta, NPTS; AutoGluon (DeepAR, PatchTST, TFT); N-BEATS, Informer, Autoformer, ETSFormer; OneFitsAll.

MOMENT: A family of open time-series foundation models
M. Goswami et al.

The *time series pile* is a large collection of time series from various domains. Train a simple transformer (3 sizes) for masked prediction (divide the time series into patches, mask some of them, project to a d -dimensional embedding, apply a transformer, and reconstruct the patches); use for forecasting, prediction, anomaly detection, imputation.

Non-transformer approaches may work better: ARIMA (short-horizon forecasting), N-BEATS (long-horizon), k -NN (anomaly detection). Also check: Time-LLM, GPT4TS (OneFitsAll), TimesNet, PatchTST, FedFormer, DLinear, Stationary, LightTS, SeasonalNaive, AnomalyTransformer

One Fits All: power general time series analysis by pretrained LM
T. Zhou et al.

LLMs are of the form

input → encoder → transformers → decoder → output.

Freeze the transformers (the “intelligence” of the model) and retrain just the encoder (patch embedding) and decoder, for time series tasks (imputation, classification, anomaly detection, long-term/short-term/few-shot/zero-shot forecasting).

A time series is worth 64 words: long-term forecasting with transformers
Y. Nie et al.

PatchTST (time series transformer):

- Does not use pointwise attention, but segments the time series into patches;
- Independently processes the components of a multivariate time series, with shared weights for the embedding and transformers.

Informer: beyond efficient transformer for long sequence time series forecasting
H. Zhou et al.

The sparsity of a query q_i is

$$\text{KL}(\text{Unif} \| p(k_j | q_i));$$

up to a constant

$$\log \sum_j \exp \frac{q_i k_j^\top}{\sqrt{d}} - \text{Mean}_j \frac{q_i k_j^\top}{\sqrt{d}}.$$

ProbSparse attention is

$$(Q, K, V) \mapsto \text{Softmax} \left(\frac{\bar{Q} K^\top}{\sqrt{d}} \right) V$$

where \bar{Q} only contains the top- u entries of Q (the others are uninformative).

Self-attention distillation reduces the time dimension (1-dimensional convolution, width=3, maxpooling, stride=2).

Autoformer: decomposition transformers with autocorrelation for long-term series forecasting
H. Wu et al.

Autocorrelation self-attention uses a convolution between keys and values instead of a product.

FEDFormer: frequency enhanced decomposed transformer for long-term series forecasting
T. Zhou et al.

Use a seasonal-trend decomposition, and apply the transformer in the frequency domain.

ITransformer: inverted transformers are effective for time series forecasting
Y. Liu et al.

(For multivariate time series), instead of attention between timestamps, use attention between time series.

Anomaly transformer: time series anomaly detection with association discrepancy
J. Xu et al.

Anomalies, in a time series, may be similar to their immediate neighbourhood, but not the whole series. The *anomaly transformer* measures this by the discrepancy (symmetrized KL divergence) between the “prior association”

$$P_i = \phi \left(-\frac{|j-i|}{\sigma_i} \right)_{1 \leq j \leq N}$$

and the “series association”

$$S_i = \text{Softmax} \left(\frac{Q_i K^\top}{\sqrt{d}} \right).$$

The prior association is trained to minimize discrepancy. The series association is trained to maximize discrepancy and reconstruct the input.

Mamba: linear time sequence modeling with selective state spaces
A. Gu and T. Dao

The S4 model is a continuous model

$$\begin{aligned} \dot{h} &= Ah + Bx \\ y &= Ch, \end{aligned}$$

discretized

$$\begin{aligned} h_t &= \bar{A}h_{t-1} + \bar{B}x_t \\ y_t &= Ch_t \end{aligned} \quad \begin{array}{c} y_t \\ \uparrow C \\ h_t \\ \xleftarrow{B} h_{t-1} \\ \uparrow A \\ x_t \end{array}$$

The discretization can be naive

$$\begin{aligned} \bar{A} &= I + hA \\ \bar{B} &= hB \end{aligned}$$

or not

$$\begin{aligned} \bar{A} &= \exp(\Delta A) \\ \bar{B} &= (\Delta A)^{-1}(\bar{A} - I)(\Delta B). \end{aligned}$$

The matrix A is structured, e.g., diagonal. The state space model (SSM) is applied independently to each channel. Since the model's dynamics are constant over time (linear time invariant (LTI) model), it can be computed efficiently.

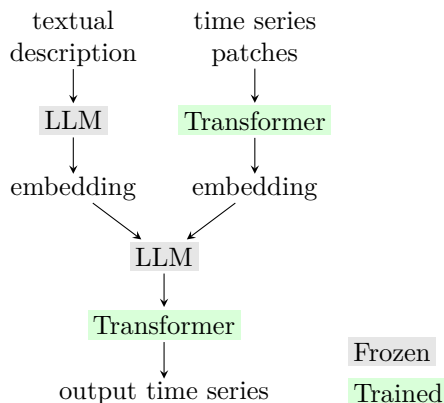

In the S6 model, B , C , Δ depend on the input x (linearly, with a softplus for Δ). It can still be implemented efficiently.

A decoder-only foundation model for time series forecasting **A. Das et al.**

Yet another time series foundational model, which breaks down the time series into patches (with larger patches in the output than in the input, for long-term forecasts).

Time-LLM: time series forecasting by reprogramming large language models **M. Jin et al.**

Use a pretrained LLM for time series forecasting: as inputs, provide an embedding (pre-trained, frozen) of a textual description of the time series (metadata in the prompt) and a sequence of patch embeddings (trained transformer); process with a pretrained, frozen LLM; and decode the output into a time series (trained transformer).

Learning programs by learning from failures **A. Cropper and R. Morel**

Popper is an inductive logic programming (ILP) system (learning from failures, LFF):

- Start with a set of hypotheses;
- Pick one of them, check if it fits the data;
- Prune the set of hypotheses if it does not (remove its generalizations if the hypothesis entails a negative example (too general), remove its specializations if it does not entail all the positive examples (too specific)).

Also check: Aleph, Metagol (Prolog), ILASP3 (answer set programming), ∂ ILP (neural nets).

Direct least squares fitting of ellipses **A. Fitzgibbon et al. (1999)**

To fit an ellipse (not an arbitrary conic) to a cloud of points

$$\begin{aligned} \text{Find} \quad & \underline{a} = (a \ b \ c \ d \ e \ f)' \\ \text{To minimize} \quad & \sum_i F(\underline{a} \cdot \underline{x}_i)^2 \\ \text{Subject to} \quad & b^2 - 4ac = -1 \\ \text{Where} \quad & \underline{x} = (x^2 \ xy \ y^2 \ x \ y \ 1)' \end{aligned}$$

(the constraint can be written $a'Ca = 1$).

Using Lagrange multipliers, this reduces to a generalized eigenvalue problem

$$\begin{aligned} D'Da &= \lambda CA \\ a'Ca &= 1 \end{aligned}$$

where the design matrix is $D = [\underline{x}_1, \dots, \underline{x}_n]'$. The solution is given by the unique positive eigenvalue.

Topological time series analysis **J.A. Perea**

The *maximum persistence* (length of the longest interval in the 1-dimensional barcode) is a useful feature, e.g., for periodicity quantification (gene expression, video) and regime (change point) detection.

Sliding windows and persistence: an application of topological methods to signal analysis **J.A. Perea and J. Harer (2013)**

Maximum persistence can be used to quantify periodicity (deciding whether a time series is periodic). Also check: `jtk_cycle`, Lomb-Scargle.

Jtk_cycle: an efficient non-parametric algorithm for detecting rhythmic components in genome-scale datasets **M.E. Hughes et al. (2010)**

To test if a signal is periodic:

$$\underset{\phi, T}{\text{Argmax}} \tau(x[i], s_{\phi, T}[i])$$

where x is the data, $i = \text{argsort}(x)$, τ is Kendall's tau, and $s_{\phi,T}$ is a signal with phase ϕ and period T – but the objective function oscillates a lot. R implementation in `MetaCycle`.

MetaCycle: an integrated R package to evaluate periodicity in large scale data
G. Wu et al.

Universal differential equations for scientific machine learning
C. Rackaukas et al. (2021)

UDEs model physical systems as $x'' = f_{\theta}(x) + \varepsilon(x)$, where

- f_{θ} is a known function corresponding to a known approximation of the phenomenon (or 0);
- θ are unknown parameters (mass of an object, charge of a particle, etc.);
- ε is a free-form unknown function (e.g., a neural net);
- The ODE can be replaced with a PDE.

Down with determinants
S. Axler (1995)

Most of linear algebra (eigenvalues, minimal polynomial, characteristic polynomial, Jordan form, etc.) can be done without determinants – they are still needed for the change-of-variable formula in multiple integrals, but they can be defined as the product of the eigenvalues, with multiplicity. More details in his book, *Linear algebra done right*.

A survey of the Schrödinger problem and some of its connections with optimal transport
C. Léonard (2014)

The *dynamic Schrödinger problem* (Schrödinger bridge) is

$$\text{Minimize}_P \text{KL}(P\|R) \text{ such that } P_0 = \mu_0, P_1 = \mu_1$$

where

- P is a probability measure on $\mathcal{C}^0([0, 1], \mathbf{R}^n)$;
- R is the law of Brownian motion on \mathbf{R}^n (unbounded measure);
- μ_0, μ_1 are probability measures on \mathbf{R}^n (prescribed marginals).

The *static Schrödinger problem* is

$$\text{Minimize}_{\pi} \text{KL}(\pi\|R_{01}) \text{ such that } \pi_0 = \mu_0, \pi_1 = \mu_1$$

where

- R_{01} is the joint law of the initial and final positions of R ;
- π is a probability measure on $(\mathbf{R}^n)^2$.

The two are linked by

$$P(\cdot) = \int_{(\mathbf{R}^n)^2} R^{xy}(\cdot) \pi(dx dy)$$

where R^{xy} is the Brownian bridge from x to y

$$R^{xy}(\cdot) = R(\cdot | X_0 = x, X_1 = y)$$

(the Schrödinger bridge is a mixture of Brownian bridges, governed by π).

These are eerily similar to the (Monge-Kantorovich) dynamical and static optimal transport problems.

An introduction to Otto's calculus
L. Ambrosio et al. (2021)

The Wasserstein distance on $\mathcal{P}_2^a(\mathbf{R}^2)$, the space of absolutely continuous measures $\mu = \rho dx$, comes from the scalar product on $T_{\rho}\mathcal{P}_2^a(\mathbf{R}^n)$

$$\langle s, s' \rangle = \int \langle \nabla \phi, \nabla \phi' \rangle \rho dx$$

where

- $s, s' \in T_{\rho}\mathcal{P}_2^a(\mathbf{R}^n)$, i.e., they are functions with zero mean, $\int s \rho dx = 0$;
- $-\text{div}[(\nabla \phi)\rho] = s$;
- $-\text{div}[(\nabla \phi')\rho] = s'$.

The gradient flow ρ_t for the vector field $\nabla \phi_t$ is the solution of the continuity equation

$$\frac{d}{dt}\rho_t + \text{div}[(\nabla \phi_t)\rho_t] = 0.$$

Comment: causal inference competitions: where should we aim?
E. Karavani et al.

Because of the “fundamental problem of causal inference” (we cannot observe counterfactuals), we have to limit ourselves to simulation studies. But they rely on strong/arbitrary assumptions, which may not hold in real setups: vary the parameters of the DGP, and score them separately (only aggregate the scores if you need to select a single winner). It is possible to use real observational data, when there is a soon-to-be published experimental trial.

Adjustment identification distance: a gadjid for causal structure learning
L. Henckel et al.

To define a causal distance between two DAGs, g_{true} and g_{guess}

- For each pair of nodes (TmY), compute a valid adjustment set in g_{guess} ;
- Check if it is a valid adjustment set in g_{true} ;
- Count the discrepancies.

There are many possible choices for the valid adjustment set:

- The parents of T (this gives the SID, structural intervention “distance” – note that $d(g_{\text{true}}, g_{\text{guess}}) = 0$ iff $g_{\text{true}} \subset g_{\text{guess}}$);
- All the nodes before T in a topological order;
- The “optimal adjustment set”.

This can be generalized to other (non-adjustment-based) identification strategies, provided you can check if it is valid.

Implementation (Rust/Python) for DAGs and CPDAGs in `gadjid`.

**Graphical criteria
for efficient total effect estimation
via adjustment in causal linear models
L. Henkel et al. (2020)**

Parent adjustment is not optimal, in terms of asymptotic variance. Instead, use $\text{pa}(\text{cn}) \setminus \text{forb}$, where

- cn are the “causal nodes” of $X \rightarrow Y$, *i.e.*, nodes on a directed path $X \rightarrow \dots \rightarrow Y$, excluding X but including Y (mediators);
- pa are the parents;
- $\text{forb} = \text{de}(\text{cn}) \cup \{X\}$: forbidden nodes;
- $\text{dec}(\text{cn})$ are the descendants of cn , including cn .

The adjustment set prefers variables explaining less of X and more of Y . For instance, if the DAG is

do not condition on A , but on B .

**Measuring causality with the
variability of the largest eigenvalue
A.R. Dominguez and O.H. Yadav (2024)**

$\lambda_1/(\lambda_1 + \lambda_2)$ where $\{\lambda_1, \lambda_2\}$ is the spectrum of $\text{Var}[Y_t, X_{t-k}]$.

**Efficient causal graph discovery
using large language models
T. Jiralerspong et al.**

To learn causality from metadata, using an LLM, do not feed the pairs of variables one by one (“which is more likely? 1. $A \rightarrow B$ 2. $B \rightarrow A$ 3. $A \leftarrow \cdot \rightarrow B$ 4. $A \perp\!\!\!\perp B$) but progressively

- Which are the variables not caused by any other?
- Which are the variables caused directly by X ? (Give all the conclusions so far to the LLM; you can also provide more information, *e.g.*, $\text{Cor}(X, \cdot)$.)
- Continue, depth-first, until you have exhausted all the variables.

**A survey on causal discovery:
theory and practice
A. Zanga and F. Stella (2023)**

Conditional independence relations cannot distinguish between all DAGs: they can only recover the *Markov equivalence class* (MEC) of the causal model, which can be described by its CPDAG (completed partial directed acyclic graph), a PDAG where

- All undirected edges are reversible (you can choose either direction, that will not change the MEC);

- All directed edges are compelled (if you flip them, the graph moves to another MEC).

If we want to account for missing confounders, things get more complicated, and the graphs (partial ancestral graphs, PAG) have 4 types of edges:

- $X \rightarrow Y$ cause
- $X \leftrightarrow Y$ unobserved confounder
- $X \circ \rightarrow Y$ cause or missing confounder
- $X \circ \dashrightarrow Y$ any of the above

Allowing for cycles (feedback) complicates things further (σ -separation and directed mixed graphs).

Here are some causal discovery algorithms.

- The *PC algorithm* starts with a complete graph, uses conditional independence tests to remove edges and identify colliders, and finally orients some of the remaining edges, assuming we have found all the colliders.
- The *FCI algorithm* generalizes this to account for unobserved confounders.
- The *GES algorithm* (greedy equivalence search) adds the edges one by one, to increase a score (BIC, AIC, BDeu, BDs).
- *FGES* is an efficient implementation of GES, avoiding recomputations.
- Greedy FCI (*GFCI*), is FCI on the GES skeleton.
- *LinGAM* assumes the SCM is linear with non-Gaussian independent noise $x = Ax + \varepsilon$ (with A triangular), *i.e.*, $\varepsilon = (I - A)x$, and uses ICA to find the linear transformation of x whose coordinates maximize non-Gaussianity.
- *NOTEARS* looks for a matrix A such that $x \approx Ax$, with the constraint that it be acyclic – this can be formulated as $\text{tr} \exp |A| = n$, where A is the elementwise absolute value and n the number of variables.
- Interventional algorithms include GIES, IGSP, FCI-JCI, Ψ -FCI, DCDI, etc.

**Methods and tools
for causal discovery and causal inference
A.R. Nogueira et al. (2022)**

Another causal discovery review paper.

**Stochastic causal programming
for bounding treatment effects
K. Padh et al.**

In presence of unobserved confounders, auxiliary variables can help identify causal effects.

Stochastic causal programming (SCP) does not model the distribution of the unobserved confounders but, for each variable V

the distribution over function $f_{z,V}$

$$V = f_{z,V}(\text{Pa } V)$$

with basis functions, and constraints (smoothness, maximum number of inflection points, etc.). We can then compute the maximum and minimum of $E[Y \mid \text{do}(X = x)]$ over all plausible models.

A versatile causal discovery framework to allow causally related hidden variables
X. Dong et al.

D-separation can be inferred by conditional independence tests. *T-separation* can be inferred by the rank of the (cross)covariance matrix

$$\text{rank } \Sigma_{A,B} = \text{Min}\{|C_A| + |C_B| : A \perp\!\!\!\perp_t B \mid C_A, C_B\}.$$

It subsumes d-separation, and is more informative in presence of latent variables.

$$A \perp\!\!\!\perp_d B \mid C \text{ iff } \text{rank } \Sigma_{A \cup C, B \cup C} = |C|$$

A *trek* $X \xrightarrow{(P_1, P_2)} Y$ is a pair of paths with the same source, and X and Y as respective sinks. A and B are *t-separated* given (C_A, C_B) if, for every trek (P_1, P_2) from a node in A to a node in B , either $P_1 \cap C_A \neq \emptyset$ or $P_2 \cap C_B \neq \emptyset$.

Causal inference for time series analysis: problems, methods and evaluation
R. Moraffah et al.

Causal discovery for time series often relies on (generalizations of) Granger causality, the PC algorithm (PCMCI) or structural equation models (LiNGAM on VAR residuals).

Review of causal discovery methods based on graphical models
C. Glymour et al.

Clear explanation of the PC, FCI and LiNGAM algorithms.

Introduction to the foundations of causal discovery
F. Eberhardt (2016)

Use a MaxSAT solver to combine background knowledge with the output of a causal discovery algorithm.

A random variable (X_1, \dots, X_n) is *Markov* wrt a graph G if $\forall X \ X \perp\!\!\!\perp \text{NonDesc}(X) \mid \text{Pa}(X)$; this implies

$$X \perp\!\!\!\perp_d Y \mid C \implies X \perp\!\!\!\perp Y \mid C.$$

It is *faithful* to the graph if the converse holds:

$$X \perp\!\!\!\perp Y \mid C \implies X \perp\!\!\!\perp_d Y \mid C$$

(i.e., the graph has no extra edges, and there are no cancellations).

Causal discovery on high-dimensional data
Z. Hao et al. (2014)

To find a causal graph in high dimension:

- For each variable y , find its potential neighbours by using the max relevance min redundancy criterion

$$\text{Maximize}_S \sum_{x \in S} I(y; x) - \frac{1}{|X|} \sum_{x, x' \in S} I(x; x');$$

greedily:

$$x_{k+1} = \text{Argmax}_{x \in X \setminus S_k} I(y; x) - \frac{1}{k} \sum_{x' \in S_k} I(x; x')$$

$$S_{k+1} = S_k \cup \{x_{k+1}\}.$$

- Use conditional independence tests (χ^2 , G or kernel-based) to prune S and only keep direct causes and consequences of y ;
- Orient the edges with entropy-based IGCI: if x is more random than y , i.e., if $H(x) > H(y)$, then choose the direction $x \rightarrow y$.

A causal feature selection algorithm for stock prediction modeling
Z. Zhang et al. (2013)

Replace feature selection (lasso, etc.) with *causal feature selection*:

- Greedily add variables x with large $I(x; y)$, unless they are independent of x conditionally on the variables already selected;
- Identify the causes of y by noticing that y is a collider for them.

CausalTime: realistically generated time series for benchmarking of causal discovery
Y. Cgeng et al.

- Fit a non-linear VAR (NAR) (with noise modeled with a normalizing flow);
- Define the parents of a variable X_i as the variables with the largest feature importance (DeepShap);
- Split the NAR into 3 terms: causal (from the identified parents), residual and noise

$$x_i = f_i(x \odot H) + [f_i(x) - f_i(x \odot H)] + \varepsilon_i$$

where H is the adjacency matrix of the discovered parents;

- Use the model to generate new data, of dimension $2N$, keeping (separately) both the causal and residual terms, with adjacency matrix

$$\begin{bmatrix} H & \mathbf{1} \\ I & 0 \end{bmatrix}.$$

Beware of the simulated DAG! Causal discovery benchmarks may be easy to game
A.G. Reisach et al.

Sorting the variables by increasing variance can recover a topological order of the causal graphs; use the lasso (regressing each variable on its potential parents) to recover the graph.

If the data has been normalized, correlations tend to increase (decrease) in the causal (anti-causal) direction:

$$i \rightarrow j \rightarrow k \quad \text{Cor}(X_i, X_j) \leq \text{Cor}(X_j, X_k).$$

Approximate kernel-based conditional independence tests for fast nonparametric causal discovery
E.V. Strobl et al.

The *kernel conditional independence test* (KCIT) can be approximated with random features (randomized conditional independence test, RCIT):

$$\begin{aligned} H_0 : X \perp\!\!\!\perp Y \mid Z \\ \ddot{X} &= (X, Z) \\ \ddot{A} &= [f_1(\ddot{X}), \dots, f_m(\ddot{X})] \\ \ddot{B} &= [h_1(Y), \dots, h_q(Y)] \\ \ddot{C} &= [g_1(Z), \dots, g_d(Z)] \\ g_1(Z) &= \sqrt{2} \cos(W^\top Z + B) \\ W &\sim N(0, I) \\ B &\sim \text{Unif}(0, 2\pi) \\ \text{idem for the } f_i\text{'s and } h_i\text{'s} \\ \hat{\Sigma}_{\ddot{A}B \cdot C} &= \hat{\Sigma}_{\ddot{A}B} - \hat{\Sigma}_{AC}(\hat{\Sigma}_{CC} + \gamma I)^{-1} \hat{\Sigma}_{CB} \\ &= \text{Cov}[\text{res}(\ddot{A} \sim C), \text{res}(B \sim C)] \end{aligned}$$

(using ridge regression).

The *randomized conditional correlation test* (RCoT) uses X instead of \ddot{X} .

$$\text{test statistic} = n \left\| \hat{\Sigma}_{\ddot{A}B \cdot C} \right\|_F^2$$

(the distribution of the test statistic under H_0 is complicated: linear combination of χ^2 variables, with weights given by the eigenvalues of some covariance matrix).

Conditional independence testing based on a nearest neighbour estimator of conditional mutual information
J. Runge

Conditional mutual information

$$I(X; Y \mid Z) = H(X, Z) + H(Y, Z) - H(Z) - H(X, Y, Z)$$

can be estimated with the KL (Kozachenko-Leonenko) entropy estimator. To estimate its (finite-sample) distribution under

$$H_0 : X \perp\!\!\!\perp Y \mid Z$$

use random permutations, taking care to only destroy the relation between X and Y , while preserving that between X and Z .

Python implementation in `tigramite`.

Better simulations for validating causal discovery with the DAG-adaptation of the onion method
B. Andrews and E. Kummerfeld

The onion method samples from the space of correlation matrices by building correlation matrices one dimension at a time.

$$R_{i+1} = \begin{pmatrix} R_1 & r_{i+1} \\ r'_{i+1} & 1 \end{pmatrix} \quad 1 - r'_{i+1} R_i^{-1} r_{i+1} < 1$$

It can be modified to sample from correlation matrices compatible with a given DAG.

Causal discovery from heterogeneous/nonstationary data
B. Huang et al.

CD-NOD is a PC-like causal discovery algorithm, which deals with heterogeneous and/or nonstationary data by adding a “domain” and/or “time” variable; variables connected to them have changing causal mechanisms. Assuming that the distribution shifts are due to a small number of variables also helps identify some edge directions: in the situation

if we see changes in $P(X|Y)$ and $P(Y)$ and $(P(X) \text{ xor } P(Y|X))$, we conclude that $X \rightarrow Y$.

Amortized causal discovery: learning to infer causal graphs from time series data
S. Löwe et al.

Neurons (in different patients s) have the same dynamics, but different connectivity (causal graphs) G_s

$$\underline{x}_s^{t+1} = g(\underline{x}_s^{\leq t}, G_s).$$

Model them, jointly, as

$$\begin{aligned} \hat{G}_s &= f_\phi(\underline{x}_s) \\ \underline{x}_s^{t+1} &\approx f_\theta(\underline{x}_s^{\leq t}, \hat{G}_s). \end{aligned}$$

Baselines:

- Linear Granger causality;
- Neural Granger causality, with MLP, LSTM, or eSRU (economy statistical recurrent unit);
- MPIR (minimum predictive information regularization);
- Transfer entropy;
- Mutual information.

Data: particles; phase-coupled oscillators; simulated fMRI (netsim).

Neural Granger causality

A. Tank et al.

Nonlinear Granger causality, with a sparse-input MLP or an LSTM.

Economy statistical recurrent units for inferring nonlinear Granger causality

S. Khanna and V.Y.F. Tan

The statistical recurrent unit (SRU) is yet another RNN/GRU/LSTM variant, with feedback. Use it, componentwise, for nonlinear Granger causality testing: the causal relations can be extracted from the model parameters. Reduce the number of parameters by reducing the dimension of (some of) the latent space(s) with sketching (fixed random projections), and add sparsifying penalties.

Discovering nonlinear relations with minimum predictive information regularization

T. Wu et al.

To test for Granger causality with neural nets, there is no need to try the variables one by one: allow each $X_{j,t-1}$ to have learnable corruption $\tilde{X}_{j,t-1}$, as much as possible (measure it with the mutual information between $\tilde{X}_{j,t-1}$ and $X_{j,t-1}$) while maintaining good prediction of X_{it} .

Causal structure learning supervised by large language model

T. Ban et al.

Use some (data-based) causal learning algorithm; then ask an LLM if the edges are correct, and add a constraint to remove the incorrect edges; iterate until convergence.

The DeCAMFounder: nonlinear causal discovery in the presence of hidden variables

R. Agrawal et al.

To estimate a causal graph in presence of *pervasive confounding* (unobserved confounders affecting many observed variables), use PCA to recover (sufficient statistics) of the unobserved variables.

ABIDES-Economist: agent-based simulation of economic systems with learning agents

K. Dwarakanath et al.

Multi-agent system, with households (labour, consumption, saving), firms (wages, prices, production, inventory), central bank (interest rate) and government (tax rate, tax credits).

RiskMiner: discovering formulaic alphas via risk-seeking Monte Carlo tree search

T. Ren et al.

Alpha mining, not with a genetic algorithm (gplearn), but with reinforcement learning (MCTS), with

- $\text{Cor}(\alpha, \text{returns}) - \text{Mean}_{\alpha'} \text{Cor}(\alpha, \alpha')$ as intermediate rewards, to ensure diversity;
- $\text{Cor}(\alpha, \text{returns}) = \text{IC}$ as final reward.

Do not optimize the expected cumulated reward, but some quantile of it.

DiffFormer: a diffusion transformer on stock factor augmentation

Y. Gao et al.

Diffusion models (DDPM) progressively add noise to their input

$$x_t = \sqrt{1 - \beta_t} x_{t-1} + \sqrt{\beta_t} \varepsilon_t, \quad \varepsilon_t \sim N(0, I),$$

equivalently,

$$x_t = \sqrt{\bar{\alpha}_t} x_0 + \sqrt{1 - \bar{\alpha}_t} \varepsilon, \quad \varepsilon \sim (, I),$$

and try to reverse the process

$$\text{Minimize}_{\theta} \mathbb{E}_{\substack{x_0 \sim \text{data} \\ \varepsilon \sim N(0, I) \\ t \sim \text{Uniform}}} \|\varepsilon - \varepsilon_{\theta}(x_t, t)\|^2.$$

Do not denoise pure noise, but noisy inputs (diffusion-based augmentation).

ABCs (and Ds) of understanding VARs

J. Fernández-Villaverde et al.

In a state space model

$$x_{t+1} = Ax_t + Bw_{t+1}$$

$$y_{t+1} = Cx_t + Dw_{t+1}$$

where x is hidden and w are stocks, when can we recover the shocks w_{t+1} by comparing y_{t+1} and $\mathbb{E}_t[y_t]$?

$$\text{DSGE} \rightarrow \text{SSM} \rightarrow \text{VAR}$$

DSGE models

A. Mikusheva (2007)

A DSGE model considers agents (firms, households, banks, state, etc.), each maximizing its utility, subject to a few balance equations. Writing the first order equations and linearizing everything gives a linear SSM, amenable to the Kalman filter (or a particle filter, if you do not linearize).

Properties of the entropic risk measure EVaR in relation to selected distributions

Y. Mishura et al.

Explicit computation of the entropic value at risk

$$\text{EVaR}_{\alpha} X = \inf_{t > 0} \frac{1}{t} \log \frac{m_X(t)}{1 - \alpha}$$
$$m_X(t) = \mathbb{E}[e^{tX}] \quad \text{moment generating function}$$

for a few distributions (using the Lambert W function, $W(x)e^{W(x)} = x$).

Plutos: towards interpretable stock movement prediction with financial large language model
H. Tong et al.

Have several models (technical analysis, sentiment, financial ratios, etc.) output their forecasts as text, with an explanation, and use another LLM to aggregate them, with an explanation.

Optimal text-based time series indices
D. Ardia and K. Bluteau (2024)

To convert text (news) into macroeconomic time series, one typically uses some (trained) sentiment indicator, computed from heuristically selected documents (based on the presence of keywords) – instead, the selection process should be part of the optimization process.

Application to EPU (economic policy uncertainty).

Modeling financial time series with generative adversarial networks
S. Takahashi et al. (2019)

Stylized facts of financial time series include:

- Linear unpredictability (no correlation);
- Fat tails, $3 < \alpha < 5$;
- Volatility clustering $\text{Cor}(|r_t|, |r_{t+k}|) \propto k^{-\beta}$;
- Leverage: $\text{Cor}(r_t, \sigma_{t+k}) < 0$;
- Coarse-fine volatility correlation

$$\begin{aligned} \text{coarse}_t &= \left| \sum_{1 \leq i \leq \tau} r_{t-i} \right| \\ \text{fine}_t &= \sum |r_{t-i}| \\ \rho(k) &= \text{Cor}(\text{coarse}_{t+k}, \text{fine}_t) \\ \Delta\rho(k) &= \rho(k) - \rho(-k) < 0 \end{aligned}$$

- Gain-loss asymmetry: the waiting time for a +10% price change is larger than that for a -10% change (prices drop faster than they rise).

Macroeconomic regimes
L. Baele et al. (2014)

Model inflation, output and interest rate as

$$\begin{aligned} \pi_t &= \delta \hat{\pi}_t + (1 - \delta)\pi_{t-1} + \lambda y_t + \text{noise} \\ y_t &= \mu \hat{y}_t + (1 - \mu)y_{t-1} - \phi(i_t - \hat{\pi}_t) + \text{noise} \\ i_t &= p \hat{i}_t + (1 - \rho)(\beta \hat{\pi}_t + \gamma y_t) + \text{noise} \end{aligned}$$

with regime switching for (β, γ) , $\text{Var } \varepsilon_\pi$, $\text{Var } \varepsilon_y$, $\text{Var } \varepsilon_i$.

Modeling the term structure of interest rates: an introduction
M. Fisher (2003)

Pricing the term structure with linear regressions
T. Adrian et al. (2013)

Alternative risk premia timing: a point-in-time macro, sentiment, valuation analysis
O. Blin et al. (2018)

List of (multi-asset) long-short strategies.

Probabilistic machine learning
K.P. Murphy (2022)

1. A machine learning problem combines a task, training data, and a performance measure. *Epistemic* uncertainty (model uncertainty) reflects our ignorance of the model. *Aleatoric* uncertainty (data uncertainty) reflects the noise in the model.

Unsupervised learning can be seen as (interpretable) data compression.

2. Summary statistics have limitations (Anscombe quartet, datasaurus dozen).

In medicine, to compute $P[\text{infected}|\text{test}]$ with Bayes's rule, we need sensitivity, specificity and prevalence.

$$\frac{\text{sensitivity} \times \text{prevalence}}{\text{sensitivity} \times \text{prevalence} + (1 - \text{specificity}) \times (1 - \text{prevalence})}$$

$$y \sim \text{Bernoulli}(\sigma(w'x + b)) \quad \text{logistic regression}$$

$$y \sim \text{Cat}(\text{softmax}(Wx + b)) \quad \text{multinomial logistic regression}$$

The *log-sum-exp trick* is

$$\log \sum e^{a_i} = m + \log \sum e^{a_i - m};$$

with $m = \text{Max } a_i$, the $a_i - m$ are negative, and the exponential does not overflow.

Common distributions include Gaussian, Student, Laplace, Cauchy, beta, gamma, exponential, chi squared, inverse gamma.

$$\text{Exp}(\lambda) = \text{Gamma}(1, \lambda)$$

$$\chi^2(\nu) = \text{Gamma}\left(\frac{\nu}{2}, \frac{1}{2}\right)$$

If $X \sim p_X$ and $Y = f(X)$, then $Y \sim p_Y$, where the change-of-variable formula is

$$p_Y(y) = p_X(f^{-1}(y)) \left| \det \frac{df^{-1}(y)}{dy} \right|.$$

If $X \perp\!\!\!\perp Y$, then $p_{X+Y} = p_X * p_Y$.

3. *Simpson's paradox* says that a statistical trend that appears in different groups can disappear or reverse sign when those groups are combined.

The *conditional Gaussian distribution* is

$$\begin{aligned} \begin{pmatrix} Y_1 \\ Y_2 \end{pmatrix} &\sim N\left(\begin{pmatrix} \mu_1 \\ \mu_2 \end{pmatrix}, \begin{pmatrix} \Sigma_{11} & \Sigma_{12} \\ \Sigma_{21} & \Sigma_{22} \end{pmatrix}\right) \\ Y_1 | Y_2 = y_2 &\sim N(\mu_{1|2}, \Sigma_{1|2}) \\ \mu_{1|2} &= \mu_1 + \Sigma_{12}\Sigma_{22}^{-1}(y_2 - \mu_2) \\ \Sigma_{1|2} &= \Sigma_{11} - \Sigma_{12}\Sigma_{22}^{-1}\Sigma_{21} = \Lambda_{11}^{-1} \\ \Lambda &= \Sigma^{-1} = \begin{pmatrix} \Lambda_{11} & \Lambda_{12} \\ \Lambda_{21} & \Lambda_{22} \end{pmatrix}. \end{aligned}$$

The *Bayes rule for Gaussians* is: if

$$\begin{aligned} z &\sim N(\mu_z, \Sigma_z) \\ y|z &\sim N(Wz + b, \Sigma_y) \end{aligned}$$

then $z|y \sim N(\mu_{z|y}, \Sigma_{z|y})$, where

$$\begin{aligned} \mu_{z|y} &= \Sigma_{z|y}[W'\Sigma_y^{-1}(y - b) + \Sigma_z^{-1}\mu_z] \\ \Sigma_{z|y}^{-1} &= \Sigma_z^{-1} + W'\Sigma_y^{-1}W \end{aligned}$$

(the Gaussian distribution is conjugate prior for the Gaussian likelihood).

The “completing the square” trick is not limited to scalars:

$$\begin{aligned} f(x) &= x'Ax + x'b + c \\ &= (x - h)'A(x - h) + k \\ h &= -\frac{1}{2}A^{-1}b \\ k &= c - \frac{1}{4}b'A^{-1}b \end{aligned}$$

The *exponential family density* is

$$\begin{aligned} p(y) &= h(y) \cdot \exp[\eta'T(y) - A(\eta)] \\ h: &\text{scale, e.g., } 1 \\ \eta: &\text{natural parameters, } t \\ T: &\text{sufficient statistic, e.g., id} \\ A: &\text{log-partition function (convex).} \end{aligned}$$

These are maximum entropy distributions, solutions of

$$\begin{aligned} \text{Find } & p \\ \text{To maximize } & H(p) \text{ (or } -\text{KL}(p||h)) \\ \text{Such that } & \mathbb{E}_{y \sim p}[T(y)] = t. \end{aligned}$$

The log-partition function A is the cumulant generating function

$$\begin{aligned} K(t) &= \log \mathbb{E}[e^{tX}] \\ \kappa_n &= K^{(n)}(0). \end{aligned}$$

In particular,

$$\begin{aligned} \nabla A(\eta) &= \mathbb{E}[T(y)] \\ \nabla^2 A(\eta) &= \text{Cov}[T(y)] \succcurlyeq 0 \end{aligned}$$

and A is convex.

4. The *maximum likelihood estimator* (MLE) is

$$\begin{aligned} \hat{\theta}_{\text{MLE}} &= \text{Argmax}_{\theta} \text{KL}(\text{data}||p_{\theta}) \\ &= \text{Argmax}_{\theta} H(\text{data}, p_{\theta}) \quad (\text{cross-entropy}) \\ &= \text{Argmin}_{\theta} \text{NNL}(\theta) \quad (\text{negative log-likelihood}). \end{aligned}$$

For binary classification, use a *surrogate loss function* (convex, decreasing, and above $\mathbf{1}_{[z \leq 0]}$) such as

$$\begin{aligned} \text{hinge} &: \text{ReLU}(1 - m) \\ \text{log} &: \log(1 + e^{-m}) \\ \text{exp} &: \exp(-m) \end{aligned}$$

where $m = \hat{y}y$, $y \in \{\pm 1\}$, $\hat{y} \in \mathbf{R}$.

The *method of moments* is an alternative to MLE; it may give invalid results.

Regularization with \log_{prior} is an equivalent to MAP (maximum a posteriori). Estimate the strength of the regularization with cross-validation.

The “one standard error rule” suggests to take the simplest model whose risk is no more than one standard deviation above that of the best model.

The *Bayesian* approach views probability in terms of *information*, rather than *repeated trials*.

Mixtures of conjugate distributions are still conjugate.

“Uninformative” priors are informative: call them “diffuse” instead.

To estimate the parameters and hyperparameters, one can use MLE, MAP, or a Bayesian approach – there is a hierarchy of increasingly Bayesian approaches:

Method	Parameters	Hyper-parameters
ML	ML	none
MAP	MAP	fixed
ML-II (empirical Bayes)	Bayes	ML
MAP-II	Bayes	MAP
Full Bayes	Bayes	Bayes

To summarize the posterior distribution, provide a (centered) *credible interval* or the *highest posterior density* (HPD) region (highest density interval, HDI).

If exact posterior inference is not possible, use approximations such as

– Laplace approximation

$$\begin{aligned} \int f(\theta) d\theta &\approx \frac{(2\pi)^{n/2}}{\sqrt{\det H}} f(\theta_{\text{Max}}) \\ \theta_{\text{Max}} &= \text{Argmax}_{\theta} f \\ H &= -\nabla^2 \log f|_{\theta=\theta_{\text{Max}}} \end{aligned}$$

obtained by approximating f with a Gaussian, *i.e.*, using a Taylor expansion of f at its mode; use a change of variable to make f more symmetric and closer to a Gaussian;

– Variational inference;
– MCMC (HMC).

In frequentist statistics (the data is a random variable, the parameters are fixed), the MLE is asymptotically Gaussian

$$\hat{\theta}_{\text{MLE}} \xrightarrow{d} N(\theta^*, (NF(\theta^*))^{-1})$$

where the *Fisher information matrix* is

$$\begin{aligned} F(\theta) &= \mathbb{E}_{X \in p_\theta} [(\nabla \log p_\theta(X))(\nabla \log p_\theta(X))^\top] \\ &= - \mathbb{E}_{X \sim p_\theta} [\nabla^2 \log p_\theta(X)] \\ &= \text{Hessian of the NNL.} \end{aligned}$$

There is a trade-off between bias and variance.

$$\begin{aligned} \text{bias} &= \mathbb{E}[\hat{\theta}] - \theta^* \\ V[\hat{\theta}] &= \mathbb{E}[\hat{\theta}^2] - \mathbb{E}[\hat{\theta}]^2 \\ \mathbb{E}[\cdot] &= \mathbb{E}_{\mathcal{D} \sim p_{\mathcal{D}}} [\cdot] \end{aligned}$$

5. The loss function we minimize should include the cost of incorrect output (and the reward of correct ones). For instance, classification problems could have a *reject option* (the algorithm is allowed to output “I do not know”).

$$\begin{aligned} (p_1, \dots, p_n) &\sim \text{Dirichlet}(1, \dots, 1) \\ j &\sim \text{Cat}([1, \dots, n], [p_1, \dots, p_n]) \\ i &= \underset{i}{\text{Argmax}} p_i \\ i &= p_i > \lambda ? i : 0 \\ \text{cost} &= \begin{cases} 0 & \text{if } i = j \\ \lambda_{\text{reject}} & \text{if } i = 0 \\ \lambda_{\text{error}} & \text{otherwise} \end{cases} \end{aligned}$$

The threshold λ minimizing $\mathbb{E}[\text{cost}]$ is

$$1 - \frac{\lambda_{\text{reject}}}{\lambda_{\text{error}}}.$$

In case of class imbalance, prefer the precision-recall curve to the ROC curve.

The *interpolated precision* for a given recall level α is the maximim precision of a recall level at least α (the precision is not necessarily decreassing with α). The *average precision* is the average of the interpolated precisions.

The F_β score is the weighted harmonic mean of precision and recall, with weights 1 and β^2 ; if recall (resp. precision) is more important, try $\beta = 2$ (resp. $\beta = 1/2$).

To choose between two models, in a Bayesian way, one can look at the *Bayesian factor* (for Bayesian hypothesis testing):

$$\begin{aligned} \frac{P(M_1|D)}{P(M_2|D)} &= \frac{P(M_1, D)/P(D)}{P(M_2, D)/P(D)} \\ &= \frac{P(D|M_1)P(M_1)}{P(D|M_2)P(M_2)} \\ B &= \frac{P(D|M_1)}{P(D|M_2)} \text{ if } P(M_1) = P(M_2) = \frac{1}{2}. \end{aligned}$$

These are *marginal likkelihoods* (or “evidence”): the parameters have been integrated out,

$$p(D|M) = \int p(D|M, \theta)p(\theta|M)d\theta.$$

The marginal likelihood can be difficult to compute: by approximating the posterior with a Gaussian (Laplace approximation)

$$\begin{aligned} \log p(D|M) &\approx \log p(D|\hat{\theta}) + \log p(\hat{\theta}) - \frac{1}{2} \log |H| \\ H &= -\nabla^2 \log p(D, \theta)|_{\theta=\hat{\theta}}, \end{aligned}$$

choosing a uniform prior $p(\theta) \propto 1$, and approximating the Occam factor

$$\begin{aligned} H &= \sum_i \nabla^2 \log p(D_i|\theta) \\ &= \sum_i H_i \\ &\approx N \cdot \hat{H} \\ \log |H| &\approx \log |N \hat{H}| \\ &= D \log N + \log |\hat{H}| \\ &\approx D \log N \end{aligned}$$

(because $\log |\hat{H}|$ is constant and becomes negligible when $D \log N \rightarrow \infty$), we get the Bayesian information criterion (BIC)

$$\log p(d|m) \approx \log p(D, \hat{\theta}, m) - \frac{D_m}{2} \log N$$

(it is sometimes multiplied by -2 to get a loss). Alternatives to the BIC include:

$$\begin{aligned} \text{AIC} &= -2 \log p(D|\hat{\theta}, m) + 2D \\ \text{MDL} &= -\log p(D|\hat{\theta}, m) = \log p(m) \end{aligned}$$

where $p(m)$ is the number of bits needed to specify which model m it is.

Point null hypotheses, $H_0 : \mu = 0$, are irrelevant: eeplace 0 with a *region of practical equivalence* (ROPE) $H_0 : \mu \in [-\varepsilon, \varepsilon]$; we can then compute $P(H_0|\text{Data})$ (Bayesian T test).

The (frequentist) risk of an estimator $\hat{\theta}$ is

$$\text{Risk}(\theta, \hat{\theta}) = \mathbb{E}_{X \sim p_\theta} [\ell(\theta, \hat{\theta}(X))].$$

The *Bayesian risk* integrates out the (unknown) true parameter θ with a prior.

In supervised learning, the population risk is

$$\text{Risk}(f, p^*) = \mathbb{E}_{x, y \sim p^*} [\ell(y, f(x))]$$

where (x, y) are sampled from the true (unknown) joint distribution p^* . The empirical risk replaces p^* with the empirical distribution of the observed data

$$\text{Risk}(f, \text{Data}) = \mathbb{E}_{x, y \sim \text{Data}} [\ell(y, f(x))].$$

The empirical risk can be decomposed into

- The approximation error (risk of the best model in the class considered);
- The estimation error (generalization gap), stemming from the difference between the population distribution and the empirical distribution.

Add a regularization to the risk

$$\text{Risk}(f, \text{Data}) + \lambda C(f)$$

and choose λ to minimize the LOO-CV risk.

Frequentist hypothesis testing is based on a fallacy:

If H_0 were true, this statistic would probably not occur.

This statistic did occur.

Therefore, H_0 is probably false.

If a person is American, he is probably not a member of congress.

This person is a member of congress.

Therefore, he is probably not American.

6. Joint entropy, mutual information, conditional entropy behave like set union, intersection and difference.

$$H(p) = \mathbb{E}_{X \sim p} -\log_2 p(x) \quad \text{entropy}$$

$$H_{ce}(p, q) = \mathbb{E}_{X \sim p} -\log_2 q(x) \quad \text{cross-entropy}$$

$$H(X, Y) = -\sum_{x, y} p(x, y) \log_2 p(x, y) \quad \text{joint entropy}$$

$$H(Y|X) = \mathbb{E}_{x \sim p_X} H(Y|X = x) \quad \text{conditional entropy}$$

$$= H(X, Y) - H(X)$$

$$H(X_1, \dots, X_n) = \sum H(X_i | X_1, \dots, X_{i-1}) \quad \text{chain rule}$$

$$\text{perplexity}(p) = 2^{H(p)} \quad \text{average branching factor}$$

$$\text{KL}(p||q) = \mathbb{E}_{X \sim p} \left[\log \frac{p(x)}{q(x)} \right] \quad \text{relative entropy}$$

$$= -H(p) + H_{ce}(p, q)$$

$$I(X; Y) = \text{KL}(p(x, y) || p(x)p(y)) \quad \text{mutual information}$$

$$= H(X) - H(X|Y)$$

$$= H(X, Y) - H(X|Y) - H(Y|X)$$

$$= H(X) + H(Y) - H(X, Y)$$

$$I(X; Y|Z) = \mathbb{E}_{z \sim p_Z} [I(X; Y)|Z = z]$$

$$= I(Y; X, Z) - I(Y; Z)$$

$$I(Z_1, \dots, Z_n | X) = \sum I(Z_i; X | Z_1, \dots, Z_{i-1})$$

$$\text{NMI}(X, Y) = \frac{I(X; Y)}{\text{Min}(H(X), H(Y))} \leq 1$$

$$X \rightarrow Y \rightarrow Z \text{ Markov} \implies X \perp\!\!\!\perp Z | Y$$

$$\implies I(X; Y) \geq I(X; Z)$$

7. The *induced norm* of a matrix $A \in \mathbf{R}^{m \times n}$ is

$$\|A\|_p = \text{Max}_{\|x\|=1} \|Ax\|_p;$$

in particular,

$$\|A\|_2 = \sqrt{\lambda_{\max}(A^T A)} = \text{Max}_i \sigma_i$$

is the largest singular value.

The *nuclear norm* (or trace norm) is

$$\|A\|_* = \text{tr} \sqrt{A^T A} = \sum_i \sigma_i = \sum_i |\sigma_i| = \|\sigma\|_1;$$

as an L^1 norm, it has a sparsifying effect on the singular values: it encourages low-rank matrices. The *Shatten p norm* generalizes it:

$$\|A\|_p = (\sum_i \sigma_i^p)^{1/p}.$$

The *Frobenius norm* is the L^2 norm of the entries of a matrix,

$$\|A\|_F^2 = \|\text{vec } A\|_2^2 = \text{tr}(A^T A) = \mathbb{E}_{v \sim N(0, I)} \|Av\|_2^2.$$

To invert (or compute the determinant) of a partitioned matrix $\begin{pmatrix} * & * \\ * & * \end{pmatrix}$, pre-multiply it by $\begin{pmatrix} I & * \\ 0 & I \end{pmatrix}$ to get $\begin{pmatrix} * & 0 \\ * & * \end{pmatrix}$, and post-multiply the result with $\begin{pmatrix} I & 0 \\ * & I \end{pmatrix}$ to get to get $\begin{pmatrix} * & 0 \\ 0 & * \end{pmatrix}$, which is easier to invert; the result contains *Schur complements* $E - FH^{-1}G$.

$$\begin{bmatrix} I & -FH^{-1} \\ 0 & I \end{bmatrix} \begin{bmatrix} E & F \\ G & H \end{bmatrix} \begin{bmatrix} I & 0 \\ -H^{-1}G & I \end{bmatrix} = \begin{bmatrix} E - FH^{-1}G & 0 \\ 0 & H \end{bmatrix}$$

Using instead $\begin{pmatrix} I & 0 \\ * & I \end{pmatrix}$ and $\begin{pmatrix} I & * \\ 0 & I \end{pmatrix}$ and equating the resulting formulas gives the *Woodbury formula* (inverse of a Schur complement)

$$(E - FH^{-1}G)^{-1} = E^{-1} + E^{-1}F(H - GE^{-1}F)^{-1}GE^{-1}$$

(the matrix to invert on the rhs can have a different, smaller dimension).

Applications include

$$(\Sigma + \underset{N \times N}{XX'})^{-1} = \Sigma^{-1} - \Sigma^{-1}X(\underset{D \times D}{I + X'\Sigma^{-1}X})^{-1}X'\Sigma^{-1},$$

the rank-1 update

$$(A + uv')^{-1} = A^{-1} - \frac{A^{-1}uv'A^{-1}}{1 + v'A'u}$$

and the distribution of a conditional Gaussian

$$\begin{aligned} X_1|X_2 &\sim N(\bar{\mu}, \bar{\Sigma}) \\ \bar{\mu} &= \mu_1 + \Sigma_{12}\Sigma_{22}^{-1}(x_2 - \mu_2) \\ \bar{\Sigma} &= \Sigma_{11} - \Sigma_{12}\Sigma_{22}^{-1}\Sigma_{21}. \end{aligned}$$

PCA whitening

$$\begin{aligned} \Sigma &= \frac{1}{N}X'X = EDE' \quad (\text{eigendecomposition}) \\ X &= USV' \quad (\text{SVD}) \\ W_{\text{pca}} &= D^{-1/2}E' \\ Y &= \frac{X}{N \times D} \frac{W_{\text{pca}}}{D \times D} \end{aligned}$$

ensures $\text{Cov } Y = I$, but we can add any rotation matrix; *Mahalanobis whitening* keeps the transformed data as close as possible to the original

$$W_{\text{zca}} = ED^{-1/2}E' = \Sigma^{-1/2} = VS^{-1}V'.$$

The Schur complement of E in $\begin{bmatrix} E & F \\ G & H \end{bmatrix}$ is

$$\begin{aligned} \overline{E} &= \overline{H} - \overline{G} \overline{E}^{-1} \overline{F} \\ \bar{E} &= H - GE^{-1}F. \end{aligned}$$

Similarly,

$$\begin{aligned} \overline{H} &= \overline{E} - \overline{F} \overline{H}^{-1} \overline{G} \\ \bar{H} &= E - FH^{-1}G. \end{aligned}$$

8. Gradient descent, with learning rate $\eta < 2/L$, where L is the Lipschitz constant of the gradient, is guaranteed to converge,

$$\theta_{t+1} = \theta_t - \eta \nabla \mathcal{L}(\theta_t).$$

The *Armijo-Goldstein condition*, for the stepsize ensure sufficient reduction of the objective function without performing an exact line search,

$$\ell(\theta_t + \eta d_t) \leq \mathcal{L}(\theta_t) + c\eta d_t^\top \nabla \mathcal{L}(\theta_t),$$

where d_t is the descent direction, e.g., $-\nabla \mathcal{L}(\theta_t)$, and $c = 10^{-4}$.

Momentum methods (heavy ball, Nesterov) modify the descent direction using past (or extrapolated) gradients.

Second order methods approximate Newton's method

$$\theta_{t+1} = \theta_t - \eta (\nabla^2 \mathcal{L}(\theta_t))^{-1} \nabla \mathcal{L}(\theta_t)$$

by using approximations of the Hessian (BFGS) or adding constraints (trust region, if the Hessian is not positive semi-definite, if the objective function is not convex).

To choose the learning rate, check the loss after a few epochs, for several learning rates (e.g., in $[10^{-5}, 10^1]$). Common learning rate schedules include

- Exponential decay;
- Polynomial decay;
- One cycle (linear warm-up, followed by cosine cool-down);
- Cyclical learning rate.

Stochastic variance reduced gradient (*SVRG*) uses a control variate: a baseline value of the gradient, computed on the whole dataset, updated once in a while.

$$g_t = \nabla \mathcal{L}(\theta_t) - \nabla \mathcal{L}_t(\tilde{\theta}) + \nabla \mathcal{L}(\tilde{\theta})$$

SAGA is similar, but keeps track of the latest gradient of each minibatch to progressively update the gradient.

Preconditioned SGD

$$\theta_{t+1} = \theta_t - \eta M_t^{-1} g_t$$

includes AdaGrad, RMSProp, AdaDelta, Adam; non-diagonal preconditioners include full-matrix AdaGrad

$$\begin{aligned} M_t &= [(G_t G_t^\top)^{1/2} + \varepsilon T]^{-1} \\ G_t &= [g_1, \dots, g_1] \end{aligned}$$

and *Shampoo* (a block-diagonal, Kronecker approximation).

The constrained optimization problem

$$\text{Maximize}_{\theta} \mathcal{L}(\theta) \text{ such that } g(\theta) \leq 0, h(\theta) = 0$$

can be written

$$\text{Minimize}_{\theta} \text{Max}_{\mu \geq 0, \lambda} \underbrace{\mathcal{L}(\theta) + \mu^\top g(\theta) + \lambda^\top h(\theta)}_{L(\theta, \mu, \nu): \text{generalized Lagrangian}}$$

If \mathcal{L} and g are convex, the critical points satisfy the Karush-Kuhn-Tucker (KKT) conditions

$$\begin{aligned} g(\theta) &\leq 0, \quad h(\theta) = 0 && \text{feasibility} \\ \nabla \mathcal{L}(\theta) + \sum \mu_i \nabla g_i(\theta) + \sum \lambda_j \nabla h_j(\theta) &= 0 \\ \mu &\geq 0 && \text{dual feasibility} \\ \mu \odot g &= 0 \end{aligned}$$

To optimize objective functions of the form

$$\mathcal{L}(\theta) = \mathcal{L}_{\text{smooth}}(\theta) + \mathcal{L}_{\text{rough}}(\theta),$$

the *proximal gradient* method uses

$$\theta_{t+1} = \text{prox}_{\eta \mathcal{L}_{\text{rough}}} [\theta_t - \eta \nabla \mathcal{L}_{\text{smooth}}(\theta_t)]$$

where the proximal operator is

$$\begin{aligned} \text{prox}_{\eta \mathcal{L}}(\theta) &= \underset{z}{\text{Argmin}} \left(\mathcal{L}(z) + \frac{1}{2\eta} \|z - \theta\|_2^2 \right) \\ &= \underset{z}{\text{Argmin}} \mathcal{L}(z) \text{ such that } \|z - \theta\|_2 \leq \rho \end{aligned}$$

(where ρ depends on η). Examples include

- Projected gradient (hard constraint $\theta \in C$, *i.e.*, $\mathcal{L}_{\text{rough}} = I_C$);
- L^1 regularization (soft thresholding)

$$\begin{aligned} \text{prox}_{\lambda \|\cdot\|_1}(\theta) &= \underset{x}{\text{Argmin}} \|x\| + \frac{1}{2\lambda} (x - \theta)^2 \\ &= \begin{cases} \theta - \lambda & \text{if } \theta \geq \lambda \\ 0 & \text{if } |\theta| \leq \lambda \\ \theta + \lambda & \text{if } \theta \leq -\lambda \end{cases} \end{aligned}$$

- Quantization

$$\mathcal{L}_{\text{rough}}(\theta) = \inf_{\theta_0 \in C} \|\theta - \theta_0\|_1,$$

where $C = \{\pm 1\}^D$ (the proximal operator is a generalization of soft-thresholding: ProxQuant).

The *MM algorithm* (minorize-maximize) maximizes a function $\ell(\cdot)$ by using a surrogate function $G(\cdot, \cdot)$ such that

$$\begin{aligned} Q(\theta, \theta') &\leq \ell(\theta) \\ Q(\theta, \theta) &= \ell(\theta) \end{aligned}$$

by iterating $\theta_{t+1} = \underset{\theta}{\text{Argmax}} Q(\theta, \theta_t)$.

The *EM algorithm* maximizes the likelihood of the observed data y by marginalizing the unobserved (latent, missing) data z

$$\ell(\theta) = \sum_n \log p(y_n | \theta) = \sum_n \log \sum_z p(y_n, z | \theta)$$

by using Jensen's inequality

$$\begin{aligned} \ell(\theta) &= \sum_n \log \sum_z q_n(z) \frac{p(y_n, z | \theta)}{q_n(z)} \\ &\geq \sum_n \sum_z q_n(z) \log \frac{p(y_n, z | \theta)}{q_n(z)} \\ &= \text{ELBO}(\theta, q_{1:N}) \end{aligned}$$

$$Q(\theta, \theta') = \text{ELBO}(\theta, p(z_n | y_n, \theta)_{n \in [1, N]})$$

It can be used to compute the MLE or MAP estimator of a Gaussian mixture model.

9. A generative classifier is a model of the form

$$p(y|x) \propto p(x|y)p(y)$$

(as opposed to a discriminative classifier, which models $p(y|x)$ directly). For instance, Gaussian discriminant analysis uses

$$X | Y = y \sim N(\mu_y, \Sigma_y);$$

if the covariance matrices Σ_y do not depend on y , this is *linear discriminant analysis* (LDA); if not, this is quadratic discriminant analysis (QDA).

Fisher linear discriminant analysis (FLDA) first reduces the dimension, choosing the projection giving the best classification possible.

The naive Bayes classifier assumes that the features are independent when conditioned on the class label

$$p(\mathbf{x}|y) = \prod_d p(x_d|y).$$

10. (Binary) logistic regression is a discriminative classification model

$$Y | X = x \sim \text{Bernoulli}(\sigma(w'x + b)).$$

The gradient and the Hessian of the log-likelihood can be computed explicitly; Newton's method can be formulated as an iteratively-reweighted least squares (IRLS) problem; *Fisher scoring* replaces the Hessian with its expectation, the Fisher information matrix.

(Multinomial) logistic regression can be fitted with *bound optimization* (aka the MM algorithm)

$$\begin{aligned} \ell(\theta) &= Q(\theta, \theta') \\ Q(\theta, \theta') &= \ell(\theta') + (\theta - \theta')^\top \nabla \ell(\theta') + \frac{1}{2} (\theta - \theta')^\top B (\theta - \theta') \\ \theta_{t+1} &= \theta_t - B^{-1} \nabla \ell(\theta_t) \end{aligned}$$

where $\forall \theta \ H(\theta) \succcurlyeq B$. For binary logistic regression, $B = -\frac{1}{4} X^\top X$ works.

Multinomial logistic regression $p(y|x) \propto \exp(w_y^\top x)$ can be generalized to *maximum entropy classifiers*

$$p(y|x) \propto \exp[w^\top \phi_y(x)]$$

(they are often used in NLP).

For consistent hierarchical classification (taxonomy), add mutual exclusion constraints between sibling label nodes.

If there is a large number of classes, try a hierarchical softmax, *i.e.*, a tree of binary classifiers structured, e.g., with Huffman coding.

To deal with class imbalance, try:

- Logit adjustment;
- Resampling, to make the data more balanced;

$$p_y \propto N_y^q \quad q \in [0, 1]$$

- Nearest mean classifier

$$f(x) = \underset{y}{\text{Argmin}} \left\| \phi(x) - \underset{i: y_i = y}{\text{Mean}} \phi(x_i) \right\|_2^2$$

where ϕ are learned features, from a DNN, trained on the original, unbalanced data.

To make logistic regression robust, *bitempered logistic regression*

- Uses *tempered cross-entropy* as loss function, to reduce the influence of mislabeled points far away from the decision boundary;
- Uses a *tempered softmax* to reduce the influence of mislabeled points close to the decision boundary.

For Bayesian logistic regression, use a Laplace approximation

11. Least squares regression can be fitted with:

- $\hat{w} = (X'X)^{-1}X'y$;
- SVD (more numerically stable);
- QR (faster if X is tall);
- Conjugate gradient (if $X \succcurlyeq 0$);
- GMRES (if X is sparse);

The gradient and Hessian of the residual sum of squares are

$$\begin{aligned}\nabla_w \text{RSS}(w) &= X'Xw - X'y \\ \nabla_w^2 \text{RSS}(w) &= X'X.\end{aligned}$$

Modeling (X, Y) as a joint Gaussian and conditioning on X is equivalent to linear regression (only for Gaussian models).

Ridge regression linear regression MAP) can be fitted with standard OLS regression by adding virtual data to account for the prior; use empirical Bayes

$$\lambda = \underset{\lambda}{\text{Argmax}} \log p(D|\lambda)$$

to choose the regularization parameter λ .

The *lasso* is a MAP estimator with a Laplace prior; it can lead to unstable results if some predictors are highly correlated (sometimes including one, sometimes the other) – the *elasticnet* addresses that problem (if there is a group of highly correlated predictors, it tends to include either none or all of them, with comparable weights: *soft grouping*).

The lasso can be solved with:

- Coordinate descent (soft-thresholding, one coordinate at a time);
- Projected gradient descent (after writing the lasso loss as a quadratic program, by splitting $w = w_+ - w_-$;
- Proximal gradient descent (ISTA);
- LARS (a continuation method, aka homotopy method) to get the whole regularization path: start with a large value of λ , so that the model only uses one predictor, progressively decrease λ (it is possible to find, analytically, the value of λ when the set of predictors used changes);
- LAR (a greedy simplification of LARS: it only adds predictors, but never removes them).

For *spline* regression, check **patsy.bs**. B-splines use a fixed number of knots. Smoothing splines use N knots if there are N data points and add an ℓ^2 regularization.

Generalized additive models (GAM) can be estimated with backfitting.

A Student (SGD, EM) or Laplace (LP) likelihood leads to robust regression. The Huber loss is faster.

RANSAC makes regression robust by fitting a model to a small subset of points, using it to remove outliers, and refitting the model on the inliers (with multiple restarts).

Bayesian linear regression generalizes ridge regression (which is just a MAP estimator).

MAP with an empirical Bayes prior on the regression coefficients results in a sparse estimate \hat{w} (automatic relevancy determination, ARD, sparse Bayesian learning).

12. A GLM is a conditional exponential family

$$\begin{aligned}p(y|x, w, \sigma) &\propto h(y, \sigma^2) \exp \frac{\langle y, w'x \rangle}{\sigma^2} \\ &= h(y, \sigma^2) \exp \frac{\langle y, \eta \rangle - A(\eta)}{\sigma^2} \\ \eta &= w'x \text{ (natural parameter)}\end{aligned}$$

$$E[y|x, w, \sigma^2] = A'(\eta) = \ell^{-1}(\eta)$$

$$\text{Var}[y|x, w, \sigma^2] = A''(\eta)\sigma^2$$

ℓ : link function

13. The perceptron used a (non-differentiable) Heaviside activation function.

MLPs can be used for

- Heteroskedastic regression;

- Classification (tabular/image/text data);
- etc.

Activation functions include: ReLU, leaky ReLU, ELU, SELU, Swish (aka SiLU), GELU, etc.

Initialization schemes include Xavier (logistic), He (ReLU), LeCun, LSUV (layer sequential unit variance: start with orthogonal weight matrices, and rescale them so that the activations have unit variance on the first minibatch).

Regularization includes early stopping, weight decay, sparsity (but prefer block-sparse matrices: GPUs are optimized for dense matrix operations), dropout, Bayesian neural nets, (stochastic) gradient descent (implicit regularization).

Other feed-forward networks include:

- RBF networks:

$$\begin{aligned}y|x &\sim N(w'\phi_\mu(x), \sigma_y^2) \\ \phi_\mu(x) &= [k(x, \mu_1), \dots, k(x, \mu_m)] \\ k(x, \mu) &= \exp -\frac{1}{2\sigma_x^2} \|x - \mu\|^2\end{aligned}$$

(if the μ_i 's are fixed, this is a linear regression);

- Mixtures of experts (for multi-modal output distributions, one-to-many functions)

$$z \sim \text{Cat}(\text{Softmax } f(x))$$

$$y \sim N(\mu_z(x), \sigma_z^2(x))$$

16. Distance-based methods, such as *k-nearest neighbours*, suffer from the curse of dimensionality: in high dimension, the nearest point is far away, and all pairwise distances tend to be the same. Efficient implementations can use k-d trees or LSH (in Python, check `faiss`).

Metric learning searches for a Mahalanobis matrix M such that the distance

$$d(x, x') = \sqrt{(x - x')^\top M (x - x')}$$

works well when used for *k*-nn classification (or such that samples in the same class are close and samples in different classes are far apart).

This can be solved with semidefinite programming. Alternatively, parametrize M as $M = w'w$.

The probability that j is the nearest neighbour of i is

$$p_{ij} \propto \exp - \|Wx_i - Wx_j\|_2^2.$$

We can choose W such that it maximizes the expected number of samples correctly classified with 1-nn (neighbourhood component analysis, NCA). Latent coincidence analysis (LCA) estimates the model

$$Z \sim N(Wx, \sigma^2 I)$$

$$Z' \sim N(Wx', \sigma^2 I)$$

$$P[y = y'] = \exp - \|z - z'\|^2$$

Deep metric learning (DML) also learns an embedding and computes the distances in embedding space (you can then remove M).

Losses for DML include

- Pairwise contrastive loss (hinge loss);
- Triplet loss (may require hard negative mining);
- *n*-pairs loss (InfoNCE).

The word “kernel” has several (sometimes overlapping) meanings in statistics:

- A *density kernel* is a function $\mathbf{R}^n \times \mathbf{R}^n \rightarrow \mathbf{R}$ with non-negative values, used for smoothing (kernel density estimation (KDE), kernel regression)
- A *positive definite kernel* is a function $\kappa : \mathbf{R}^n \times \mathbf{R}^n \rightarrow \mathbf{R}$, such that

$$\forall l \forall x_1, \dots, x_m \in \mathbf{R}^n \quad (\kappa(x_i, x_j))_{i \leq l, j \leq m} \succcurlyeq 0$$

is positive definite; it is used for the “kernel trick”;

- The transition kernel of a Markov chain;
- A convolution kernel;
- etc.

17. Positive definite kernels (aka *Mercer kernels*) correspond to feature maps: for structured objects

(graphs, text, etc.), it may be easier to define kernels than features (string kernel, random walk kernel).

Random features can approximate the RBF kernel.

18. Classification and regression trees (CART) are fitted greedily, splitting the nodes by looking at:

- The Gini index (a generalized entropy – the Herfindahl index);
- The entropy (aka deviance).

Bagging uses random subsets of the data. *Random forests* also use random subsets of the variables. *Boosting* successively fits models on data weighted by the errors made by the best linear combination of the models so far. Bagging and random forests reduce the variance; boosting reduces the bias.

19. Empirical risk minimization (ERM) minimizes the expected loss wrt the empirical distribution – but a sum of Dirac masses is unlikely to be a good approximation of the population distribution. Data augmentation attempts to address this problem (vicinal risk minimization).

Transfer learning adapts a pretrained model

- By fine-tuning it;
- By replacing its last layers;
- By adding adjustment layers (“adapters”) inside.

Self-supervised learning (SSL) often uses

- Imputation tasks (fill-in-the-blank);
- Proxy tasks, in particular *contrastive tasks*: attempting to tell if two samples are related (e.g., augmentations of the same sample, or in the same class) or not (SimCLR).

In *transfer learning*, the input is similar, but the output is different. In *domain adaptation*, the inputs are different, but the output labels are the same. For instance, domain adversarial learning trains a classifier whose latent representation is unable to distinguish between the source and target domains.

Self-training with *pseudo-labels* (using predictions as labels for unlabeled data) suffers from *confirmation bias*: only keep pseudo-labels the model is confident in. Co-training and tri-training estimate that confidence by training several models, either on (independent) sets of features, or on subsets of the data.

Entropy minimization is another for of semi-supervised learning, which implements the *cluster assumption*: the decision boundary should be in a low-density region of the data manifold.

Label propagation is another semi-supervised learning technique: build a similarity graph of samples, and propagate the labels from the labeled samples.

Data augmentation can also be applied to unlabeled data; perturbations of a data point should not cause a large change in the output (*consistency regularization*).

Deep generative models, such as VAEs, can also be

leveraged for semi-supervised learning.

You can also train the discriminant of a GAN to output “fake” or the class label (instead of “fake”/“real”).

20. To select the number of principal components to retain, some suggest to look at the maximum of the *profile likelihood*: the likelihood of a Gaussian $N(\mu_1, \sigma^2)$ on $\lambda_1 \geq \dots \geq \lambda_L$ and $N(\mu_2, \sigma^2)$ on $\lambda_{L+1} \geq \dots \geq \lambda_n$ (the two Gaussian have the same variance).

Factor analysis (FA)

$$\begin{aligned} z &\sim N(\mu_0, \Sigma_0) \\ x &= Wz + \mu + \varepsilon \\ \varepsilon &\sim N(0, \Psi) \end{aligned}$$

can be computed with the EM algorithm.

Probabilistic PCA (PPCA) is the special case $\Psi = \sigma^2 I$. FA can be generalized: non-linear FA, mixture FA, exponential family FA, etc.

For paired data, check

– Supervised PCA

$$\begin{aligned} z &\sim N(0, I) \\ x &= W_1 z + \varepsilon & \varepsilon &\sim N(0, \sigma_1^2 I) \\ y &= W_2 z + \varepsilon & \eta &\sim N(0, \sigma_2^2 I) \end{aligned}$$

– Partial least squares

$$\begin{aligned} z_0 &\sim N(0, I) \\ z_1 &\sim N(0, I) \\ x &= W_1 z_0 + B z_1 + \varepsilon & \varepsilon &\sim N(0, \sigma_1^2 I) \\ y &= W_2 z_0 + \varepsilon & \eta &\sim N(0, \sigma_2^2 I) \end{aligned}$$

– Canonical correlation analysis

$$\begin{aligned} z_0 &\sim N(0, I) \\ z_1 &\sim N(0, I) \\ z_2 &\sim N(0, I) \\ x &= W_1 z_0 + B_1 z_1 + \varepsilon & \varepsilon &\sim N(0, \sigma_1^2 I) \\ y &= W_2 z_0 + B_2 z_2 + \varepsilon & \eta &\sim N(0, \sigma_2^2 I) \end{aligned}$$

Auto-encoders are non-linear generalizations of PCA; the latent representation is usually a narrow bottleneck layer

but one could use a larger layer, if it is regularized (noise, sparsity, etc.)

There are many *manifold learning* algorithms:

– Multidimensional scaling (MDS – actually PCA)

$$\text{Minimize}_z \sum (\langle \tilde{x}_i, \tilde{x}_j \rangle - \langle \tilde{z}_i, \tilde{z}_j \rangle)^2$$

where the \tilde{x}_i 's are the centered data points;

– Metric MDS

$$\text{Minimize}_z \sum (\|x_i - x_j\| - \|z_i - z_j\|)^2$$

– Non-metric MDS

$$\text{Minimize}_{f \text{ monotonic}, z} \frac{\sum [f(\|x_i - x_j\|) - \|z_i - z_j\|]^2}{\sum \|z_i - z_j\|^2}$$

– Sammon (metric MDS with more weight on shorter distances)

$$\text{Minimize}_z \sum \frac{(\|x_i - x_j\| - \|z_i - z_j\|)^2}{\|x_i - x_j\|}$$

– Isomap is MDS on the k -nearest neighbour graph of the datapoints

– Kernel PCA (kPCA) is PCA on the Gram matrix for some kernel

– Maximum variance unfolding (MVU)

$$\begin{aligned} \text{Find } z \\ \text{To maximize } & \sum \|z_i - z_j\|^2 \\ \text{Such that } & \forall (i, j) \in G \quad \|z_i - z_j\| = \|x_i - x_j\| \end{aligned}$$

where G is the k -NN graph (this can be formulated as a semidefinite program)

– Local linear embedding (LLE)

$$\text{Minimize}_z \sum_i \left\| z_i - \sum_j w_{ij} z_j \right\|^2$$

where the w_{ij} are the barycentric coordinates of x_i in the k -nn graph (W is sparse)

$$W = \underset{w}{\text{Argmin}} \sum \left\| x_i - \sum_{i \sim j} w_{ij} x_j \right\|^2 \text{ st } \forall i \sum w_{ij} = 1$$

– Laplacian eigenmaps

$$\text{Minimize}_z \sum W_{ij} \|z_i - z_j\|^2 \text{ st } W^\top D Z = I$$

where

$$W_{ij} = \exp - \frac{\|x_i - x_j\|^2}{2\sigma^2}$$

if $i \sim j$ is in the k -nn graph (this is equivalent to the generalized eigenvalue problem $Lz_i = \lambda_i D z_i$, where $L = D - W$, and D is the degree matrix $D_{ii} = \sum_{ij} W_{ij}$).

Stochastic neighbour embedding (SNE) replaces distances with probability distributions

$$p_{j|i} \propto \exp - \frac{\|x_i - x_j\|^2}{2\sigma_i^2}$$

(the probability that j is a neighbour of i) and looks for points z_i with similar probability distributions

$$q_{j|i} \propto \exp - \|z_i - z_j\|^2$$

(the variance is fixed) as measured by the KL divergence

$$\text{Minimize}_z \sum_i \text{KL}(p_i \| p_j) = \sum_{ij} p_{j|i} \log \frac{p_{j|i}}{q_{j|i}}.$$

Symmetric SNE uses

$$\text{Minimize}_z \text{KL}(p \| q)$$

where

$$p_{ij} \propto \exp - \frac{\|x_i - x_j\|^2}{\sigma^2}.$$

T-distributed SNE (t-SNE) uses a Cauchy distribution (Student T with 1 degree of freedom) instead of a Gaussian to limit over-crowding

$$q_{ij} \propto \frac{1}{1 + \|z_i - z_j\|^2}.$$

The scales σ_i are chosen so that the p_i 's have a user-specified perplexity (*i.e.*, entropy), which can be interpreted as the effective number of neighbours.

UMAP is faster than t-SNE and tends to preserve the global structure better.

Latent semantic indexing (LSI) is a low-rank factorization of the term-document (or tf-idf) matrix.

Latent semantic analysis (LSA) is the SVD of the word co-occurrence matrix, or the PMI (pointwise mutual information) matrix

$$\text{PMI}_{ij} = \log \frac{p(i, j)}{p(i)p(j)} \quad \text{or} \quad \text{Max}(\text{PMI}_{ij}, 0).$$

GloVe is a simplified, faster alternative to word2vec's skipgram.

21. There is no satisfactory way of assessing the quality of a clustering:

- Purity = $\sum_i \frac{N_i}{N} p_i$, where N_i is the size of cluster i and p_i its purity, *i.e.*, the proportion of items belonging to the majority class (but this does not penalize the number of clusters);
- Rand index: accuracy of the classifier of pairs, using “are in the same cluster” as a predictor of “are in the same class”;
- Adjusted Rand index, which compares the Rand index with its expected value;
- Mutual information (but this does not penalize the number of clusters);

– Normalized mutual information

$$\text{NMI}(U, V) = \frac{I(U; V)}{\frac{1}{2}[H(U) + H(V)]}.$$

To estimate the number of clusters, one could look at the distortion, the silhouette, or (better) the BIC (from the log marginal likelihood) of a probabilistic model, *e.g.*, a GMM (Gaussian mixture model).

The eigenspace, for the eigenvalue 0, of the (weighted) Laplacian of a graph is spanned by the indicator vectors of its connected component. *Spectral clustering* is k -means in the span of the eigenvectors of the Laplacian of the similarity matrix with the smallest eigenvalues (prefer the normalized Laplacian, $L_{\text{sym}} = D^{-1/2} L D^{-1/2}$). It is a relaxation of the normalized cut problem.

22. Recommender systems can use:

- Matrix factorization (fitted with alternating least squares, ALS, or SGD, which handles missing values);
- Auto-encoders $\hat{Y} = W^\top \phi(VY)$;
- Factorization machines

$$x = [\text{one-hot}(u), \text{one-hot}(i)]$$

$$f(x) = \mu + \sum w_i x_i + \sum_{i < j} (v_i^\top v_j) x_i x_j$$

– Neural matrix factorization

$P_{u\cdot}, U_{u\cdot}$: user embeddings

$Q_{i\cdot}, V_{i\cdot}$: item embeddings

$$z_{ui}^1 = P_{u\cdot} \odot Q_{i\cdot}$$

$$z_{ui}^2 = \text{MLP}([U_{u\cdot}, V_{i\cdot}])$$

$$\hat{Y}_{ui} = \sigma(w^\top [z_{ui}^1, z_{ui}^2])$$

They can also leverage implicit feedback (if a user did not rate an item, they were not really interested in it).

23. To compute node embeddings, try to reconstruct the graph, using:

- A dot-product decoder, $\hat{w} = zz^\top$;
- A distance decoder, $\hat{w}_{ij} = d(z_i, z_j)$, possibly with a Poincaré (hyperbolic) distance,

$$d(z_i, z_j) = \text{arccosh} \left[1 + \frac{2 \|z_i - z_j\|^2}{(1 - \|z_i\|^2)(1 - \|z_j\|^2)} \right].$$

For directed graphs, learn two embeddings per node: a source and a target embedding.

DeepWalk, Node2Vec use a skipgram method on random walks to compute node embeddings.

**Getting more for less:
better A/B testing via causal regularization
K. Webster (2022)**

Price changes can be decomposed into market impact (caused by your trade) and alpha (everything else).

You cannot estimate trade impact from actual trades: they have alpha. You can estimate them from random (alpha-less) trades but, since they are costly, you have very few of them. Instead, estimate trade impact on actual trades, but with a regularized model (e.g., ridge regression), and use random trades to select the regularization parameter

***Investment decisions
under almost complete causal ignorance***
J. Simonian (2022)

The *probability distance* between two DAGs is the number of conditional independencies entailed by one and not by the other (normalized by the number of possible independencies). The *counterfactual distance* is the number of causes (pairs of nodes (X, Y) , such that there exists a causal path $X \rightarrow \dots \rightarrow Y$) present in one but not in the other (normalized by the number of possible causes). Take the sum of those two distances.

If you hesitate between several causal graphs, you could pick that minimizing $\lambda_i = \sum_{j \neq i} d(G_i, G_j)$. Alternatively, you could build a strategy for each of them, investing w_{ik} in asset k , and build a portfolio, with weights $\sum_i w_{ik} x_k$, maximizing $\sum_{ik} \lambda_i w_{ik} x_k$ (and subject to constraints of your choice).

***Addendum on how many times
cointelated pairs cross paths***
B. Mahdavi-Damghani and S. Roberts (2020)

The cointelation (sic) model allows for arbitrary short-term correlation (even $\rho = -1$) and mean reversion ($\rho = 1$) in the long term.

$$\begin{aligned} \frac{dX}{X} &= \mu dt + \sigma dW_1 && \text{leading} \\ dY &= \theta(X - Y)dy + \sigma Y dW_2 && \text{lagging} \\ d\langle W_1, W_2 \rangle &= \rho dt \end{aligned}$$

***Performance analysis
of matrix completion optimization
with applications to block causal inference***
A. Capponi and M. Stojnic (2023)

Low-rank matrix completion (nuclear norm minimization) assumes the data is missing completely at random. If the missing data shows a block pattern (e.g., corresponding to a counterfactual treatment), recovery is still possible if

$$\frac{k}{n} < 1 - 2\sqrt{\eta - \eta^2}, \quad \eta = \ell_1/n.$$

***A new entropic measure
for the causality of the financial time series***

Granger causality assumes numeric (univariate) time series. For more complex data, such as ETF transaction imbalance,

- Convert the data to images (2-dimensional fingerprints, transaction rate vs imbalance dollar value);
- Train a (convolutional) GAN to generate similar data;
- Measure if the data was easy to reproduce.

$$\text{Mean log}_2 \frac{\cos(\text{train, fake})}{\cos(\text{test, fake})} \quad \text{or} \quad \frac{\text{KL}(\text{test} \parallel \text{fake})}{\text{KL}(\text{train} \parallel \text{fake})}$$

Forking paths in financial economics
G. Coqueret (2023)

Replace bootstrap samples by “forking paths”, *i.e.*, (hundreds of) samples, obtained by varying the pre-processing options and the hyperparameters. To check for p -hacking, look at the histogram of p -values (on a linear scale): it should be (approximately) decreasing and convex. There are several forms of p -hacking:

- Simple p -hacking looks for a “path” (preprocessing pipeline) with a good p -value;
- Robust p -hacking looks for a path whose neighbourhood has good p -values, to provide robustness checks;
- Vicious p -hacking is a variant also requiring robustness to p -hacking tests.

***Estimating categorical counterfactuals
via deep twin networks***
A. Vlontzos et al. (2021)

Causal inference is not limited to the study of *interventions*

$$\mathbb{E}[Y \mid \text{do}(T = 1)];$$

we can also look at *counterfactuals*

$$\mathbb{E}[Y \mid Y = 0, \text{do}(T = 1)].$$

They can be estimated with Bayesian inference on the *twin network*: duplicate T and Y ; observe T_1 and Y_1 ; intervene on T_2 ; compute the effect on Y_2 .

Unfortunately, the counterfactual is not always identifiable, e.g.,

U : unobserved, 4-valued

T : binary

$Y = X, 0, 1$ or $\neg X$, depending on U

where U has distribution $(\frac{1}{2}, \frac{1}{6}, \frac{1}{6}, \frac{1}{6})$ or $(\frac{1}{3}, \frac{1}{3}, \frac{1}{3}, 0)$. However, if $T \rightarrow Y$ is monotonic, counterfactuals are identifiable.

Train a neural network, whose architecture mimicks the twin network, with a monotonicity constraint (penalty, counter-example-guided learning, lattice network), using domain-knowledge (or average treatment effect, ATE) to order the values of T .

Metastable financial markets
D. Marcondes and A. Simonis

The market can be modeled as a hidden Markov model (HMM), e.g., with state space

$\{\text{momentum up, momentum down}\} \times \{\text{low vol, high vol}\}$.

It is *metastable*: there are clusters of states in which the market remains a very long time (there are low-probability connections between those clusters).

A changing stock-bond correlation: explaining short-term fluctuations
G. Flannery

Forecast the short-term (3-month) correlation between stocks and bonds using:

- Whether individual investors' forecasts of stock and bond markets have the same sign;
- Prospective inflation volatility;
- Whether the signs of the 21-day changes in the 2-year and 10-year government yield have been the same in the past 3 months.

Linear and non-linear causality in financial markets
H. Ma et al.

Nonlinear generalizations of Granger causality include:

- *Transfer entropy*

$$\text{TE}_{X \rightarrow Y} = H(Y_{t+1}, Y_t) + H(Y_t, X_t) - H(Y_{t+1}, Y_t, X_t) - H(Y_t)$$

(divide by $\sqrt{H(Y_{t+1}, Y_t)H(X_{t+1}, X_t)}$ to normalize to $[0, 1]$);

- Convergent cross-mapping

To separate linear and nonlinear dependence, use *Fourier transform surrogates*: start with a univariate series x , compute its Fourier transform randomize the phases, and compute the inverse Fourier transform \tilde{x} – this destroys the nonlinearities:

$$\rho_{\text{linear}}(x, y) = \rho(\tilde{x}, \tilde{y})$$

(average over several surrogates).

Some systems exhibit spans of positive and negative correlations, e.g.,

$$x_{t+1} = x_t \cdot (r_x - r_x x_t - \beta_{y \rightarrow x} y_t)$$

$$y_{t+1} = y_t \cdot (r_y - r_y y_t - \beta_{x \rightarrow y} x_t)$$

with $r_x = 3.8$, $r_y = 3.5$, $\beta_{y \rightarrow x} = 0.02$, $\beta_{x \rightarrow y} = 0.1$.

Modeling systemic risk: a time-varying nonparametric causal inference framework
J. Etesami et al.

To measure the causal relations between financial institutions, from time series data, try the “directed information graph”, which generalizes Granger causality

by looking at the regret (difference between a model with X and one without),

$$\text{DI}_{X \rightarrow Y} = \mathbb{E}_t \log \frac{P[Y_t = y_t | X_{<t}, Y_{<t}, Z_t]}{P[Y_t = y_t | Y_{<t}, Z_t]}$$

where Z are all the other variables. It is the conditional mutual information

$$E_t I(Y_t; X_{<t} | Z_{<t}, Y_{<t})$$

(use a k -nn estimator).

Analyzing stock-bond correlation: a dynamic causal system perspective
S. Du and Z. Zhang (2023)

The *convergent cross mapping* method generalizes Granger causality $X \rightarrow Y$ as $\text{cot}(Y, \hat{Y})$, where \hat{Y} is the forecast from a k -nn model (with Gaussian weights) on a delay embedding. Use $\text{CCM}_{\text{Bonds} \rightarrow \text{Equities}}$ and $\text{CCM}_{\text{Equities} \rightarrow \text{Bonds}}$ to forecast $\text{Cor}(\text{Equities}, \text{Bonds})$.

Causal network representations in factor investing
C. Howard et al. (2024)

Use DyNoTears on the constituents of the S&P 500. Applications include:

- Clustering (Node2Vec + k -means), for peer group neutralization;
- Long-short low centrality strategy;
- Market timing with the network density average eccentricity): lower eccentricity heralds left skewed and leptokurtic returns (and sometimes market crashes).

Towards automating causal discovery in financial markets and beyond
A. Sokolov et al. (2023)

Finance is not a closed, stationary system: the causal graph changes over time. LLMs can help – they only need a textual description of the variables, no actual data – the domain knowledge provided by LLMs can be used as prior for (score-based) causal discovery algorithms, but they do not scale beyond 30 nodes.

To remedy this, ask an LLM to:

- Cluster the features;
- Provide a label and a textual description for each cluster;
- Provide a causal DAG between the clusters;
- Provide a causal DAG (separately) within each cluster;
- Review those DAGs and fix any mistake made.

Then, one can take the product of the between-cluster DAG and the within-cluster DAGs.

Use do-calculus to assess the strength of each edge:

- Separately inside each cluster

- For the between-cluster DAG, replace the features inside each cluster with their first principal component.

***On the three demons in causality in finance:
time resolution, nonstationarity
and latent factors***

X. Dong et al.

Financial data pose a few problems for causal discovery:

- The observed data has a lower frequency than the causal data, and is often aggregated

- The data is not stationary – adding a new variable, time, can help;
- There are unobserved confounders; algorithms like FCI tend to output the most general graph (a clique for each latent variable), even when rank deficiency suggests a simpler structure.

gCastle: a Python toolbox for causal discovery

N. Zhang et al. (2021)

***Causal discovery in financial markets:
a framework for nonstationary time series data***

A. Sadeghi et al. (2024)

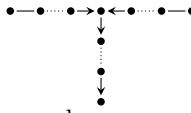

Adapt the PC algorithm, for causal discovery with non-stationary time series by:

- Adding a “time” variable;
- Considering several lags;
- Computing conditional independence tests: KCIT, RCoT, CMikm, ParCorr
- Orienting edges with known directions ($\text{Time}_t \rightarrow X_t$, $X_{t-k} \rightarrow Y_t$);
- Orienting the other edges, whenever possible (as in the original PC algorithm).

***Discovering causal models with optimization:
confounders, cycles and instrument validity***

F. Eberhardt et al.

Build a causal graph from causal independence relations by reducing the problem to a MIP (mixed integer program).

Find $x \in \{0, 1\}^{\tilde{E}}$
 $y \in \{0, 1\}^{P(\tilde{E}, \zeta)}$
 z
 Where \tilde{E} is a set of candidate edges
 $P(\tilde{E}, \zeta)$ is the set of simple paths
 $\bullet - \bullet \dots - \bullet - \bullet$ or extended paths

 Such that x and y are consistent
 y recognizes d-separation:
 $i \perp\!\!\!\perp j | C$ with error z_{ijC}
 y recognizes d-connection:
 $i \not\perp\!\!\!\perp j | C$ with error z_{ijC}
 To minimize $\sum_{ijC} z_{ijC}$

The set of candidate edges \tilde{E} is grown progressively, by adding the smallest number of edges to account for all potential colliders ($\bullet \rightarrow \bullet \leftarrow \bullet$) and non-colliders ($\bullet \rightarrow \bullet \rightarrow \bullet$ or $\bullet \leftarrow \bullet \leftarrow \bullet$) not yet explained; only include one edge for each such triple.

***Structural intervention distance (SID)
for evaluating causal graphs***

J. Peters and P. Bühlmann

Given a ground-truth causal graph g , and an estimated graph \hat{g} , the SID is the number of pairs of nodes (X, Y) for which the parents of X in \hat{g} are not a sufficient conditioning set for $X \rightarrow Y$ in g .

This is not a distance: it is not symmetric, and $\text{SID}(g, \hat{g}) = 0 \not\Rightarrow g = \hat{g}$.

The *structural Hamming distance* (SHD) between DAGs is the L^1 distance between their adjacency matrices.

***Canonical portfolios:
optimal asset and signal combination***

N. Firoozye et al. (2022)

Look for an easy-to-forecast portfolio, with CCA (canonical correlation analysis)

$$\text{Maximize}_{a,b} \text{Cor}(a'X, b'R)$$

where

X_{it} : signal
 R_{it} : return
 i : asset
 t : time.

Disciplined saddle programming
P. Schiele et al. (2023)

A convex-concave *saddle function* $f : \mathcal{X} \times \mathcal{Y} \rightarrow \mathbf{R}$ is convex in x (for y fixed) and concave in y (for x fixed). A *saddle point* (x^*, y^*) satisfies

$$\forall x \forall y \quad f(x^*, y) \leq f(x^*, y^*) \leq f(x, y^*),$$

i.e.,

$$x^* = \underset{x}{\operatorname{Argmin}} f(x, y^*)$$

$$y^* = \underset{y}{\operatorname{Argmax}} f(x^*, y).$$

The *saddle extremum functions* are

$$G(x) = \sup_{y \in \mathcal{Y}} f(x, y)$$

$$H(y) = \inf_{x \in \mathcal{X}} f(x, y).$$

Problems with saddle point extremum constraints

$$\underset{x}{\operatorname{Minimize}} \phi(x) \text{ st } G(x) \leq 0$$

are “semi-infinite constraint” problems: there is an infinite number of constraints

$$\underset{x}{\operatorname{Minimize}} \phi(x) \text{ st } \forall y \quad f(x, y) \leq 0.$$

Robust optimization problems are saddlepoint problems.

To solve the minimax problem

$$\underset{x}{\operatorname{Minimize}} \underset{y}{\operatorname{Max}} f(x, y)$$

replace $\underset{y}{\operatorname{Max}} f(x, y)$ with its dual to have a minimin (convex optimization) problem. This can be automated for “conically representable saddle functions”; Python implementation in `dsp`.

$$f(x, y) = x'y$$

$$f(x, y) = \operatorname{convex}(x)' \operatorname{concave}(y)$$

$$f(x, y) = \left(\sum y_i x_i^2 \right)^{1/2}$$

$$f(x, y) = \log \sum y_i \exp x_i$$

$$f(x, y) = \begin{pmatrix} x \\ y \end{pmatrix}' \begin{pmatrix} P & * \\ * & -Q \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} \quad P, Q \text{ psd}$$

$$f(x, Y) = x'Yx \quad Y \text{ psd}$$

Synthetic data applications in finance
V.K. Potluru et al.

To generate synthetic tabular datasets, try SDV; also look at the t-SNE scatterplot of the synthetic and real data.

Synthetic data generation is often unsupervised (agnostic to the downstream task), but it can be supervised:

- Bayesian optimization to select the model hyperparameters;

- Weights of a mixture of several data generation processes.

For event data, try Hawkes processes and their generalizations (Cox processes), and automated planning (agents have a state (accounts, balance, rent, taxes, utility bills) and a (random) goal).

For time series, try parametric models (SDE), non-parametric models (TimeGAN, QuantGAN, TimeVAE, neural SDE, implicit neural representations (hypernetworks) and agent-based models (ABIDES))

***Architectures of topological deep learning:
a survey on topological neural networks***
M. Papillon et al.

Introduction to topological deep learning (generalizations of GNNs to sets, graphs, simplicial complexes, cellular complexes, hypergraphs, combinatorial complexes), with nice diagrams.

***giotto-tda: a topological data analysis toolkit
for machine learning and data exploration***
G. Tauzin et al.

Persistent homology, Mapper algorithm, to generate features for sklearn models (with plots). Also check `scikit-tda` (easy to use), `gudhi` (rather complete), `dionysus`.

***Topological tail dependence:
evidence from forecasting realized volatility***
H.G. Souto (2023)

Compute the (birth-death) persistence diagram (PD) for one month of daily log-returns for stocks in a given basket (e.g., sector) (T days for n stocks gives T points in \mathbf{R}^n); then use the Wasserstein distance between consecutive PDs as a predictor of realized volatility.

It is an alternative to the change in average absolute correlation.

Path problems in networks
J.S. Baras and G. Theodorakopoulos (2010)

The *algebraic path problem* aggregates edges along a path, and then aggregates the results across paths:

- For the shortest path problem, we sum the edge weights along a path, and then take the path with the minimum weight;
- For the maximum reliability problem, we multiply the edge weights (probability of non-failure) along a path, and then take the path with the largest weight.

The shortest path can be computed with:

- Dijkstra (for non-negative weights);
- Bellman-Ford (if there are no negative cycles): iterate

$$d_v \leftarrow \min_u d_u + w(u, v)$$

until convergence (the updates can be asynchronous);

- Floyd-Warshall (dynamic programming, to compute the all-pairs shortest paths, by progressively increasing the set of vertices used)

$$D^0 \leftarrow A$$

$$D_{ij}^k \leftarrow \text{Min}\{D_{ij}^{k-1}, D_{ik}^{k-1} + D_{kj}^{k-1}\}.$$

The algebraic path problem on a semiring $(S, \oplus, \otimes, 0, 1)$, e.g., $(R \cup \{\infty\}, \min, +, \infty, 0)$ or $([0, 1], \max, \times, 0, 1)$, computes

$$d_{st} = \bigoplus_{p \in P_{st}} w(p)$$

$$w(p) = w(v_1, v_2) \otimes \cdots \otimes w(v_{k-1}, v_k).$$

If S is a semiring, then so are

- $S^{n \times n}$ (matrices);
- $S[[x]]$ (formal power series);
- $S[[x]]/(x^2) \simeq S \times S$;
- End S ;
- S_f (fixed points of $f : S \rightarrow S$, if f is a “reduction”).

In matrix form, the problem is $d' = d'A \oplus 1'_s$, where

d' : row vector
 A : weighted adjacency matrix
 1_s : vector of 0's, except for a 1 in position s .

Bellman-Ford iterates $d' \leftarrow d'A \oplus 1'_s$. The all-pairs shortest path problem solves $D = DA \oplus I$ (and Floyd-Warshall iterates $D \leftarrow DA \oplus I$). Under reasonable assumptions, the limit $A^* = I \oplus A \oplus A^2 \oplus \cdots$ exists; the solution is not unique but (under further reasonable assumptions) A^* is the smallest.

Applications include

- Path enumeration: algebraic path problem on S_f , where

$$S = \mathcal{P}(V \cup V^2 \cup \cdots \cup V^n)$$

\oplus : union
 \otimes : path concatenation

$$f(W) = \{w \in W : w \text{ elementary}\}$$

- Expectations, from a Markov chain (expected number of visits of a given node, expected value of a path $s \rightarrow t$);
- Minimum spanning tree;
- Shortest path;
- Widest path;
- Most reliable path;
- k shortest paths;
- etc.

Non-semiring path problems (aka non-Markovian path problems), e.g., the sortest path with discounting, can often be converted to semiring problems, by enlarging the carrier set S and selecting an appropriate reduction function f .

Neural Bellman-Ford networks: a general graph neural network framework for link prediction Z. Zhu et al. (2021)

Compute the representation of a pair of nodes (a potential edge) $g(s, t)$ from the representation of the edges on the path from s to t , with the generalized Bellman-Ford algorithm

$$f(s, t) = \bigoplus_{\substack{p: s \rightarrow t \\ p=(s=v_0, v_1, \dots, v_k=t)}} f(v_0, v_1) \otimes \cdots \otimes f(v_{k-1}, v_k)$$

where $\oplus, \otimes, 0$ are learned. Distance, Katz index, personalized page rank, etc., are special cases.

Direct preference optimization: your language model is secretly a reward model R. Rafailov et al. (2023)

RLHF (reinforcement learning with human feedback) can be reformulated without reinforcement learning.

RLHF first learns a reward function, with a Bradley-Terry model

$$P(y_1 > y_2) = \frac{e^{r(x, y_1)}}{e^{r(x, y_1)} + e^{r(x, y_2)}}$$

$$\text{loss}(\phi) = - \mathbb{E}_{x, y_1, y_2 \sim \text{Data}} \log \sigma(r_\phi(x, y_1) - r_\phi(x, y_2))$$

and uses it for RL

$$\text{Maximize}_{\pi} \mathbb{E}_{\substack{x \sim \text{Data} \\ y \sim \pi}} [r_\phi(x, y)] - \beta \cdot \text{KL}(\pi \| \pi_{\text{ref}})$$

$$\pi(y|x) = \frac{\pi_{\text{ref}}(y|x) e^{r_\phi(x, y)/\beta}}{Z(x)}.$$

But the reward can be expressed with the policy

$$r_\phi(x, y) = \beta \cdot \log \frac{\pi(y|x)}{\pi_{\text{ref}}(y|x)} + \beta \log Z(x)$$

and the Bradley-Terry model only uses the difference between the rewards: the partition function disappears,

$$P(y_1 > y_2|x) = \sigma \left[\beta \log \frac{\pi(y_1|x)}{\pi_{\text{ref}}(y_1|x)} - \beta \log \frac{\pi(y_2|x)}{\pi_{\text{ref}}(y_2|x)} \right]$$

The DPO loss is

$$\text{loss}(\pi) = - \mathbb{E}_{x, y_1, y_2} \log \sigma \left[\beta \log \frac{\pi(y_1|x)}{\pi_{\text{ref}}(y_1|x)} - \beta \log \frac{\pi(y_2|x)}{\pi_{\text{ref}}(y_2|x)} \right].$$

BERTopic: neural topic modeling with a class-based TF-IDF procedure M. Grootendorst (2022)

BERTopic is a topic modeling pipeline:

- Document embedding (sentence transformer, SBERT);
- Dimension reduction (UMAP);

- Clustering (HDBScan);
- Keyword extraction (cTF-IDF);
- Topic representation fine-tuning (either None (just use the list of keywords) or an LLM to which you provide the keywords and the documents).

For visualization, check DataMapPlot.

PreTraining is a hot topic: contextualized document embeddings improve topic coherence
F. Bianchi et al. (2020)

ProdLDA is a VAE-based topic model.

CTM (Combined Topic Model) adds contextualized word embeddings to the input.

Fine-grained human feedback gives better rewards for language model training
Z. Wu et al.

In RLHF, do not ask for a single reward for the whole answer, but one after each sentence, and decompose it into relevance, factuality and (only at the end), completeness.

Extending context window of large language models via position interpolation
S. Chen et al.

To extend the context size, do not extrapolate

but interpolate the positional embedding

Textbooks are all you need
S. Gunasekar et al.

Data quality matters and impacts the scaling laws (textbook quality web data, GPT-generated textbooks about Python coding).

Emergence of autopoietic vesicles able to grow, repair and reproduce in a minimalist particle system
T. Cabaret

Life-like particle system, with 4 types of particles: precursor, catalyst, intermediary, surfactant.

Portfolio construction when regimes are ambiguous
M. Kritzman et al.

Do not define all-or-nothing regimes

$$r_t = \mathbf{1}_{x_t \geq \text{threshold}}$$

but

$$r_t = - \underbrace{\left(\frac{x_t - x_0}{\sigma} \right)^2}_{\text{similarity}} + \underbrace{\left(\frac{x_t - \bar{x}}{\sigma} \right)^2 + \left(\frac{x_0 - \bar{x}}{\sigma} \right)^2}_{\text{informativeness}}$$

(use the Mahalanobis distance, $(x-y)'\Sigma^{-1}(x-y)$, if the indicator x is multivariate). Use the relevance r_t (truncated, to discard less relevant observations) as weights to compute regime-specific expected returns and asset covariances.

Robust statistics for portfolio construction and analysis
R.D. Martin et al.

Replace winsorization with *adaptive winsorization*: clip observations $k \cdot \text{MAD}$ away from the median; upper and lower MAD for skewed data.

M -estimators minimize

$$\sum_i \rho \left(\frac{\varepsilon_i(\theta)}{\hat{s}} \right)$$

where

- ρ is a replacement for the square loss;
- $\varepsilon_i(\theta)$ are the model residuals;
- \hat{s} is a robust scale, computed before the optimization.

Rho functions include:

- Huber (quadratic for small values, linear for large values);
- mOpt (constant for large values).

For linear regression, $\varepsilon_i(\theta) = y_i - x_i^\top \theta$ and the first order condition is

$$x_i \rho' \left(\frac{\varepsilon_i(\theta)}{\hat{s}} \right) = 0.$$

For mOpt, ρ' is

$$\psi(x) = \begin{cases} x & \text{if } |x| \leq 1 \\ \frac{\phi(1)}{\phi(1) - a} \left(x - \text{sign}(x) \frac{a}{\phi(x)} \right) & \text{if } 1 \leq |x| \leq c \\ 0 & \text{if } |x| \geq c, \end{cases}$$

with $a = 0.0132$, $c = 3.00$. It can be implemented with IRLS, with weights $w(x) = \psi(x)/x$.

The *MM estimator* computes a robust covariance by iterating

$$\begin{aligned} \sum w_i(x_i - \mu) &= 0 && \text{weighted mean} \\ \frac{1}{N} \sum w_i(x_i - \mu)(x_i - \mu)' &= C && \text{weighted covariance} \end{aligned}$$

and

$$\begin{aligned} d &= (x_i - \mu)T^\top C^{-1}(x_i - \mu) = \left\| C^{-1/2}(x_i - \mu) \right\|^2 \\ w_i &= W(d_i/cs) \end{aligned}$$

where

$$\begin{aligned} W(x) &= \begin{cases} 1 & \text{if } x \leq 4 \\ q(x) & \text{if } 4 \leq x \leq 9 \\ 0 & \text{if } x > 9 \end{cases} \\ q(x) &= \text{polynomial of degree 3} \\ s &: \text{robust scale} \\ c &: \text{tuning parameter.} \end{aligned}$$

In R, check **RobStatTM**, **PCRA** (risk analysis) and **facmodCS** (cross-sectional factor models).

Monotone operator equilibrium network **E. Winston and J.Z. Kolter**

An *operator* is a subset $F \subset \mathbf{R}^n \times \mathbf{R}^n$, seen as a multi-valued function. *Operator splitting* refers to ways of finding zeroes of a sum of operators, *i.e.*, solving $0 \in (F + G)(x)$. For a maximal monotone sum, use *forward-backward splitting*

$$x_{k+1} = R_G[x_k - \alpha F(x_k)]$$

or *Peaceman-Rachford splitting*

$$\begin{aligned} u_{k+1} &= C_F C_G(u_k) \\ x_k &= R_G(u_k). \end{aligned}$$

The *resolvent* and *Cayley* operators are

$$\begin{aligned} R_F &= (I + \alpha F)^{-1} \\ C_F &= 2R_F - I. \end{aligned}$$

If $F(x) = Gx + h$ is linear, then

$$R_F(x) = (I + \alpha G)^{-1}(x - \alpha h).$$

If $F = \partial f$ (with f convex, closed, proper (CCP)), then

$$R_F(x) = \text{prox}_f^\alpha(x) = \underset{z}{\text{Argmin}} \frac{1}{2} \|x - z\|_2^2 + \alpha f(z).$$

A *deep equilibrium network* (DEQ) model is a weight-tied, input-injected network

$$z_{i+1} = g(z_i, x).$$

A fixed point $z^* = \sigma(Wz^* + Ux + b)$ is a zero of the operator splitting problem $0 \in (F + G)(z^*)$

$$\begin{aligned} F(z) &= (I - W)z - (Ux + b) \\ G &= \partial f \\ \sigma &= \text{prox}_f^1 \\ f &\text{ CCP.} \end{aligned}$$

If $I - W \succcurlyeq mI$ for some $m > 0$, *i.e.*, if

$$W = (1 - m)I - A'A + B - B'$$

then, there is a unique solution.

Common non-linearities (ReLU, sigmoid, tanh, soft-plus) are proximal operators.

The DEQ iteration $z \leftarrow \sigma(Wz + Ux + b)$ may not converge, but the forward-backward (for small α) and the Peaceman-Rachford updates (for all α – it is also faster) do.

Monotone deep Boltzmann machines **Z. Feng et al. (2023)**

A (non-restricted) Boltzmann machine defines a joint probability distribution

$$p(x) \propto \exp \left(\sum_{ij} x'_i \Phi_{ij} x_j + \sum_i b'_i x_i \right).$$

Parametrize Φ as a block-hollow matrix

$$\begin{aligned} \Phi_{ij} &= \begin{cases} -\hat{A}'_i \hat{A}_j & \text{if } i \neq j \\ 0 & \text{if } i = j \end{cases} \\ \hat{A}_i &= A_i \cdot \text{Min} \left\{ \frac{\sqrt{1 - m}}{\|A_i\|_2}, 1 \right\}; \end{aligned}$$

this ensures $I - \Phi \succcurlyeq mI$. Then, the mean-field fixed point

$$q_h = \text{softmax}(\Phi_{hh}q_h + \Phi_{ho}x_o + b_h)$$

is the fixed point of a monotone deep equilibrium (mon-DEQ) model.

A non-parametric k-nearest neighbour entropy estimator **D. Lombardi and S. Pant (2015)**

To estimate the entropy from samples,

$$\hat{H} - \frac{1}{N} \sum_i \log \frac{1}{\hat{p}(x_i)},$$

the KL estimator assumes that \hat{p} is constant in $B(x_i, \varepsilon_i)$, where ε_i is the distance to the nearest neighbour

$$\hat{H} = \psi(N) - \psi(k) + \log c_d + \frac{d}{N} \sum_{i=1}^N \log \varepsilon_i$$

ψ : digamma function

$$c_d = \begin{cases} 2^d & \text{for } \|\cdot\|_\infty \\ \frac{\pi^{d/2}}{\Gamma(1 + d/2)} & \text{for } \|\cdot\|_2 \end{cases}$$

In particular, this assumes the distribution is isotropic in the ball $B(x_i, \varepsilon_i)$. Instead, the KpN estimator assumes it is a (truncated) Gaussian $N(\mu_i, \Sigma_i)$, where μ_i, Σ_i are the sample mean and variance of the $p \geq k$ nearest neighbours of x_i :

$$g_i(x) = \exp -\frac{1}{2}(x - \mu_i)' \Sigma_i^{-1} (x - \mu_i)$$

$$G_i = \int_{B(x_i, \varepsilon_i)} g_i(x) dx$$

$$\hat{H} = \psi(N) - \psi(k) - \frac{1}{N} \sum \log \frac{g_i(x_i)}{G_i}.$$

Computing the Gaussian integral G_i is tricky, but can be done, for the L^∞ ball, with expectation propagation multivariate Gaussian probability.

***Gaussian probabilities
and expectation propagation***
J.P. Cunningham et al. (2011)

How to compute a Gaussian integral

$$\mathbb{P}_{X \sim N(\mu, \Sigma)} \left[X \in \prod_i [\ell_i, u_i] \right]$$

approximately, with expectation propagation.

Flow annealed importance sampling bootstrap
L.I. Midgley et al.

Importance sampling (IS) samples from a distribution p_0 and reweights the samples to match a distribution p_1 .

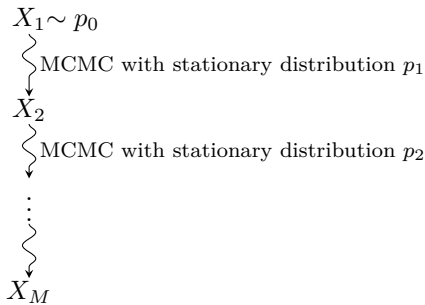

$$x \sim p_0$$

$$w(x) = \frac{p_1(x)}{p_0(x)}$$

Annealed importance sampling (AIS) uses a chain of distributions,

$$\log p_i = \beta_i \log p_0 + (1 - \beta_i) \log p_M,$$

progressively moving from p_0 to p_M ,

$$w(x_M) = \frac{p_1(x_1) p_2(x_2) \dots p_M(x_M)}{p_0(x_1) p_1(x_2) \dots p_{M-1}(x_M)}$$

Application to normalizing flows and the α -divergence, for $\alpha = 2$ (to limit mode collapse)

$$D_\alpha(p||q) = \frac{1}{\alpha(1-\alpha)} \int p(x)^\alpha q(x)^{1-\alpha} dx$$

$$D_0(p||q) = \text{KL}(q||p)$$

$$D_1(p||q) = \text{KL}(p||q)$$

Conditional random fields: an introduction
H.M. Wallach (2004)

A *conditional random field* (CRF) is a conditional probability distribution on sequences of labels, often used to tag text (e.g., POS tagging, NER, etc.), of the form

$$P(Y|X) = \frac{1}{Z(X)} \sum_j \lambda_j \underbrace{\sum_i f_j(y_{i-1}, y_i, x, i)}_{F_j(y, x)}$$

where the f_j are binary features of y_i , or y_i and y_{i-1} , possibly involving x . It is a log-linear probabilistic graphical model.

The log-likelihood is

$$\ell(\lambda) = \sum_{(x, y) \sim \text{data}} -\log Z(x) + \sum_j \lambda_j F_j(y, x).$$

Its gradient is

$$\frac{\partial \ell}{\partial \lambda_j} = \mathbb{E}_{(x, y) \sim \text{data}} F_j(y, x) - \sum_{x \sim \text{data}} \mathbb{E}_{y \sim p(y|x, \lambda)} F_j(y, x).$$

The normalization factor can be computed with a matrix product

$$Z(x) = [\prod M_i(x)]_{\text{start, end}}$$

where

$$M_i(x)_{y', y} = \exp \sum_j \lambda_j (y', y, x, i)$$

after adding labels $y_0 = \text{start}$, $y_{n+1} = \text{end}$.

The second term in the gradient can be computed with dynamic programming (forward-backward algorithm)

$$\mathbb{E}_{y \sim p(y|x, \lambda)} F_j(y, x)$$

$$= \sum_y p(y|x, \lambda) F_j(y, x)$$

$$= \sum_i \sum_{y, y'} p(Y_{i-1} = y', Y_i = u|x, \lambda) f_j(y', y, x)$$

$$\alpha_0(y|x) = \mathbf{1}_{y=\text{start}} \quad \alpha_i(x) = M_i(x)' \alpha_{i-1}(x)$$

$$\beta_{n+1}(y|x) = \mathbf{1}_{y=\text{end}} \quad \beta_i(x) = M_{i+1}(x) \beta_{i+1}(x)$$

$$P(Y_{i-1} = y', Y_i = y|x, \lambda) = \frac{\alpha_{i-1}(y'|x) M_i(y', y|x) \beta_i(y|x)}{Z(x)}$$

Implicit MLE: backpropagating through discrete exponential family distributions
M. Niepert (2021)

To train a model involving sampling from discrete random variables

$$x \xrightarrow{h_V} \theta \mapsto z \sim p_\theta(z) \xrightarrow{f_U} y$$

$$\text{loss}(u, v) = \mathbb{E}_{z \sim p_{n_v}(x)} [\ell(f_u(z), y)]$$

implicit MLE uses

$$\begin{aligned} \text{forward:} \quad & \varepsilon \sim \rho \\ & \hat{z} = \text{MAP}(\theta + \varepsilon) \\ \text{backward:} \quad & \theta' = \theta - \lambda \nabla_z \ell \\ & \hat{\nabla}_\theta \ell = \hat{z} - \text{MAP}(\theta' + \varepsilon). \end{aligned}$$

DIGRAC: Digraph clustering based on flow imbalance
Y. He et al.

DMPA finds clusters in a directed graph, assuming that the directionality contains relevant information: identify the clusters from the imbalance between them.

n : number of nodes

K : number of clusters

$P \in \mathbf{R}^{n \times k}$: cluster membership

$W_{k\ell} = P'_{\cdot k} A P_{\cdot \ell}$: probabilistic cut

$|W_{k\ell} - W_{\ell k}|$: imbalance flow

$V_k = (\mathbf{1}'(A + A')P)_k$: volume

$$C_{k\ell} = 2 \frac{|W_{k\ell} - W_{\ell k}|}{V_k + V_\ell} \in [0, 1]$$

loss = Mean $C_{k\ell}$
 $k < \ell$

or loss = Top- β Mean $C_{k\ell}$ (with $\beta = 1$ or 3)
 $k < \ell$

Use a GNN to compute P .

MagNet: a neural network for directed graphs
X. Zhang et al.

Graph convolution assumes the graph is undirected. For directed graphs, consider the magnetic Laplacian instead (a complex Hermitian matrix, which depends

on a parameter q).

$$A_s = \frac{1}{2}(A + A')$$

$$D_s = \text{diag}(A_s \mathbf{1})$$

$$\Theta^{(q)} = 2\pi q(A - A')$$

$$H^{(q)} = A_s \odot \exp(i\Theta^{(q)}) \text{ (element-wise)}$$

$$L^{(q)} = D_s - H^{(q)}$$

$$\tilde{L}^{(q)} = I - (D_s^{-1/2} A_s D_s^{-1/2}) \odot \exp(i\Theta^{(q)})$$

Statistical inference on random dot product graphs: a survey
A. Athreya et al. (2017)

The adjacency matrix of an *independent-edge random graph* is

$$A_{ij} \sim \text{Bernoulli}(P_{ij})$$

where $P \in [0, 1]^{n \times n}$.

For a *latent position* random graph, $p_{ij} = \kappa(x_i, x_j)$, $x_i \in \mathbf{R}^d$, $\kappa : \mathbf{R}^d \times \mathbf{R}^d \rightarrow [0, 1]$.

For a *random dot product* graph, $\kappa(x, y) = x'y$, i.e., $P = XX'$.

For a *stochastic block model* (SBM), X has repeated rows.

The Erdős-Rényi graph is even simpler: $p_{ij} = p$ is constant.

The latent positions can be recovered by clustering the *adjacency spectral embedding*.

$$\hat{X} = U_A S_A^{1/2}$$

$$|A| = (A'A)^{1/2}$$

$$|A| \approx U_A S_A U_A' \text{ truncated spectral decompositions}$$

or the *Laplacian spectral embedding*

$$\check{X} = U_L S_L^{1/2}$$

$$|L| \approx U_L S_L U_L'$$

Digraph inception convolutional networks
Z. Tong et al. (2020)

Spectral graph convolution (GCN) assumes the graph is undirected.

$$X \mapsto \hat{A} X \Theta$$

$$\tilde{A} = A + I$$

$$\tilde{D} = \text{diag}(\tilde{A} \mathbf{1})$$

$$\hat{A} = \tilde{D}^{-1/2} \tilde{A} \tilde{D}^{-1/2}$$

For a directed graph, the page-rank Laplacian is dense, because of the teleportation to arbitrary nodes.

$$P_{\text{rw}} = D^{-1} A$$

$$P_{\text{pr}} = (1 - \alpha) P_{\text{rw}} + \frac{\alpha}{n} \mathbf{1}_{n \times n}$$

π_{pr} : stationary distribution for P_{pr} (unique if $\alpha \in (0, 1)$)

$$\Pi_{\text{pr}} = \text{diag}(\pi_{\text{pr}})$$

$$P_{\text{pr}} = I - \frac{1}{2} [\Pi^{1/2} P \Pi^{-1/2} + \Pi^{-1/2} P' \Pi^{1/2}]$$

Instead, add a node, connected to all other nodes, and only teleport to it (*i.e.*, consider its personalized page rank)

$$P_{\text{ppr}} = \begin{pmatrix} (1-\alpha)\tilde{D}^{-1}\tilde{A} & \alpha\mathbf{1} \\ \frac{1}{n}\mathbf{1}' & 0 \end{pmatrix}.$$

Multiscale directed graph convolution uses the k th order proximity matrix

$$\begin{aligned} P_0 &= I \\ P_1 &= \tilde{D}^{-1}\tilde{A} \\ P_{k+1} &= (P_1)^k (P_1')^k \cap (P_1'')^k (P_1)^k. \end{aligned}$$

Stability of China's stock market: measure and forecast by Ricci curvature on network
X. Wang et al. (2022)

The average curvature (Ollivier, Forman, Menget or Haantjes – compute all 4) of the truncated graph ($\rho = 0.75$) of the correlation matrix of daily stock returns (on a 1-month window) is a measure of market stability.

Graph neural networks are dynamic programmers
A. Dudzik and P. Veličković (2022)

Dynamic programming, *i.e.*, algorithms of the form

$$d[x] \leftarrow \text{Aggregate}_{y \in \text{Expand}(x)} [\text{score}(d[y], d[x])]$$

are very similar to GNNs. This similarity can be formalized.

$$\begin{array}{ccc} X \xrightarrow{p} Y & & [X, R] \xrightarrow{p \otimes} [Y, \text{list}(R)] \xrightarrow{\otimes} [Y, R] \\ i \downarrow & \searrow \scriptstyle (R, \otimes, \oplus) & \downarrow \scriptstyle o \oplus \\ W & & Z \\ & \nearrow \scriptstyle i^* & [Z, \text{bag}(R)] \\ & & \downarrow \oplus \\ & & [W, R] & & [Z, R] \end{array}$$

Exact combinatorial optimization with graph convolutional neural networks
M. Gasse et al. (2019)

Imitation learning of branch-and-bound selection policies, with a GCN on the variable-constraint bipartite graph.

Neural combinatorial optimization with reinforcement learning
I. Bello et al. (2017)

A *pointer network* can generate a permutation $\sigma \in \mathfrak{S}_n$ of a set of points x_1, \dots, x_n :

- First, an encoder processes the points in sequence, with an LSTM;
- Then, a decoder generates the $\sigma(i)$'s, one at a time: at each step, it generates a distribution on the x_i 's (attention), picks a point from that distribution, and gives it to the next step.

Solve the TSP with RL (A3C, with policy gradient, and REINFORCE to compute the gradient), with a pointer network for the policy (actor).

Graph neural networks inspired by classical algorithms
Y. Yang et al.

The energy

$$\ell(Y) = \|Y - f_w(X)\|^2 + \lambda \text{tr}(Y'LY)$$

where Y are candidate node embeddings, X are node features, and $L = D - A$ is the Laplacian, is minimized by

$$Y^*(w) = (I + \lambda L)^{-1} f_w(X);$$

it is an approximation of $f_w(X)$ smoothed by the graph structure.

It can be used for node classification

$$\text{loss}(\theta, w) = \sum_i D[g_\theta(y_i^*(w)), t_i].$$

Instead of inverting $I + \lambda L$, do a few gradient steps on ℓ ; they can be interpreted as GNN layers.

The penalty $\text{tr}(Y'LY) = \sum_{ij \in E} \|y_i - y_j\|^2$ can be generalized to $\sum_{ij \in E} \rho(\|y_i - y_j\|^2)$ to increase robustness (to adversarial edges).

On the ability of graph neural networks to model interactions between vertices
N. Razin et al.

The *walk index* of a graph (V, E) wrt a partition $V = I \cup I^c$ is the number of length- L walks starting on the boundary of the partition. The *walk index edge sparsification* algorithm

- Starts with a set of partitions across which we want to keep interactions
- Computes the walk indices wrt each of those partitions if we remove one edge, for each edge;
- Removes the edge with the maximum walk indices (aggregated with max, min or mean).

The disruption index is biased by citation inflation
A.M. Petersen et al.

A disruptive node, in a citation network, looks like

(widely cited, but the papers it cites are no longer widely cited).

***Training spiking neural networks
using lessons from deep learning***
J.K. Eshraghian et al.

The leaky integrate-and-fire (LIF) neuron takes as input a spike train , smooths it into a “potential”, e.g., with exponential decay, , and, each time it exceeds a prescribed threshold, emits a spike, each emission resetting the potential.

$$\begin{aligned} X_t &: \text{input} \\ U_t &= \beta U_{t-1} + W x_t - \theta S_{t-1} \text{ latent state} \\ S_t &= \mathbf{1}_{U_t \geq 0} \text{ output} \end{aligned}$$

The input needs to be converted into a spike train, e.g., as the firing rate (rate coding), or the time to the first spike (latency coding).

Spiking neural nets (SSN) can be trained with

- Shadow training (SSN in the forward pass, ANN in the backward pass);
- Back-propagation through time (BPTT);
- Local learning rules.

***SpykeTorch: Efficient simulation
of convolutional spiking neural networks
with at most one spike per neuron***
M. Mozafari et al. (2019)

In unsupervised learning with STDP (spike timing dependent plasticity), increase $w_{j \rightarrow i}$ if j fires before i . For supervised learning, use STDP or anti-STDP depending on whether the output is correct.

***StyleGAN-NADA: CLIP-guided
domain adaptation of image generators***
R. Gal et al.

***Brax: a differentiable physics engine
for large scale rigid body simulation***
C.D. Freeman et al.

JAX alternative to MuJoCo.

***Gotta go fast when generating data
with score-based models***
A. Jolicœur-Martineau et al.

Better SDE solver for denoising diffusions

***Agent57:
outperforming the Atari human benchmark***
A.P. Badia et al.

NGU (never give up) provides intrinsic motivation by augmenting the reward to promote novelty, both within and between episodes.

Agent57 does not learn a single policy, but a family of policies, from very exploratory to purely exploitative.

***STaR: self-taught reasoner
Bootstrapping reasoning with reasoning***
A. Zelikman et al.

To turn few-shot learning into many-shot learning, give a few examples to the LLM, ask it to generate more, prune those leading to incorrect answers, and use the rest for fine-tuning.

***Towards mental time travel: a hierarchical
memory for reinforcement learning agents***
A.K. Lampinen et al. (2021)

To help RL agents remember, store the past in chunks, perform attention on chunk summaries, then attention on relevant chunks (hierarchical attention).

***Training data-efficient image transformers
and distillation through attention***
H. Touvron et al.

Vision transformers add a (learned) class token to the patch tokens (not unlike the [CLS] token for language) and use it to forecast the true label.

“Distillation through attention” adds another “distillation” token, and uses it to forecast the teacher’s hard label (rather than the teacher’s softmax).

***An optimal control perspective
on diffusion based generative modeling***
J. Berner et al. (2022)

The marginals of a time-reversed Itô process can be represented as the marginals of another Itô process. If

$$\begin{aligned} Y_0 &\sim \mathcal{D} \\ dY &= f(Y, s)ds + \sigma(s)dB_s \\ X_0 &\sim Y_T \\ dX &= \mu(X, s)ds + \sigma(s)dB_s \\ \mu &= \sigma\sigma' \nabla_x \log p_Y - f \\ f &: \mathbf{R}^d \times [0, T] \longrightarrow \mathbf{R}^d \\ \sigma &: [0, T] \longrightarrow \mathbf{R}^{d \times d}, \end{aligned}$$

then $X_T \sim \mathcal{D}$. More generally, $p_T = \tilde{p}_X$ a.e., i.e., $Y_{T-t} \stackrel{d}{=} X_t$ a.e.

***Language models
(mostly) know what they know***
S. Kadavath et al.

Their self-evaluation is better calibrated if they are provided with several of their own samples.

**Non-adversarial training of neural SDEs
with signature kernel scores**
Z. Issa et al.

Find θ such that the SDE

$$dX_t = \mu_\theta(X_t, t)dt + \sigma_\theta(X_t, t)dW_t$$

minimizes

$$\mathcal{L}(\theta) = \mathbb{E}_{Y \sim \text{data}} \left[\mathbb{E}_{x, x' \sim p_\theta} k(x, x') - 2 \mathbb{E}_{x \sim p_\theta} k(x, y) \right]$$

where the *signature kernel* is defined by a PDE

$$\begin{aligned} k(x, y) &= \langle S(x), S(y) \rangle = f(T, T) \\ f(s, t) &= \int_0^t \int_0^s f(u, v) \langle dx_u, dx_v \rangle. \end{aligned}$$

**Higher order kernel mean embeddings
to capture filtrations of stochastic processes**
C. Salvi et al.

The signature kernel is

$$k(x, y) = \langle S(x), S(y) \rangle$$

where x, y are paths $[0, T] \rightarrow \mathbf{R}^d$ and S is the signature transform. It can be computed as $k(x, y) = u(T, T)$, where u is the solution of

$$\begin{aligned} \frac{\partial^2 u}{\partial s \partial t} &= \langle \dot{x}(s), \dot{y}(t) \rangle u \\ u(0, \cdot) &= u(\cdot, 0) = 1 \end{aligned}$$

**Deep into the domain shift: transfer learning
through dependence regularization**
S. Ma et al.

Domain adaptation learns domain-invariant features.

Separately penalize differences in the dependence structure (copula) and in the marginals.

**Sophia: a scalable stochastic second-order
optimizer for language model pretraining**
H. Liu et al.

Use the diagonal Hessian as preconditioner; only update it every few iterations; clip the updates.

Estimate the diagonal Hessian as (Hutchinson, unbiased)

$$\begin{aligned} H &\approx u \odot \nabla \langle \text{loss}, u \rangle \\ u &\sim N(0, I) \end{aligned}$$

or (Gauss-Newton-Bartlett, biased)

$$\begin{aligned} \hat{g} &= \nabla \frac{1}{B} \sum_b \text{loss}(f_\theta(x_b), \hat{y}_b) \\ \hat{y}_b &\sim \text{softmax } f_\theta(x_b). \end{aligned}$$

Transformers can do Bayesian inference
S. Müller et al.

A Prior data fitted network (PFN) forecasts the (posterior) distribution

$$q_\theta : y_{n+1} \mid (x_1, y_1), \dots, (x_n, y_n), x_{n+1}.$$

The distribution q_θ is modeled as a “Riemann distribution”: a discretized continuous distribution with equal (prior) probability bins (if the marginal distribution of y is not bounded, use a half-Gaussian for the tails). Use a transformer encoder (with no positional encoding): it is \mathfrak{S}_n -invariant.

Applications include sampling from Gaussian processes (with a hyper-prior), tabular data, Bayesian neural nets.

Guided generation of cause and effect
Z. Li et al.

Train a model which, given a sentence, generates possible causes and consequences; to ensure diversity, constrain them to contain words from the CEG.

Datasets:

- Causal bank: cause-effect pairs, obtained from Common Crawl by pattern matching;
- Cause-effect graph (CEG): directed graph, with words as nodes, and links when they appear on either side of a causal statement.

**Span-based joint entity and relation extraction
with transformer pretraining**
M. Eberts and A. Ulges (2021)

SpERT uses fine-tuned BERT embeddings to filter and classify spans (NER) and relations

$$[i, i+k] \mapsto f(e_i, \dots, e_{i+k}) \sqcup w_{k+1} \sqcup c$$

where $[i, i+k]$ is the candidate span, e_i, \dots, e_{i+k} are the token embeddings, $k+1$ is the span length, w_{k+1} is a learned embedding of the span length, c is the embedding of the CLS token (of the whole sentence), \sqcup is concatenation.

For relations, use the max-pooling of the spans and of the context.

**SpanBERT: improving pre-training
by representing and predicting spans**
M. Joshi et al.

BERT variant which masks spans rather than isolated tokens.

**Causal inference using invariant prediction:
identification and confidence intervals**
J. Peters et al. (2015)

Causal models are robust against interventions: in particular, a causal model has the same predictive accuracy under different experimental settings or regimes

(i.e., various interventions – we do not need to know what those interventions are).

gCastle: a Python toolbox for causal discovery
K. Zhang et al.

GRAPE for fast and scalable graph processing and random-walk-based embedding
L. Cappelletti et al. (2021)

Python library for graph features (like `networkx`, `igraph`, `networkkit`, `graph_tool`), random-walk-based node embeddings, and edge prediction.

An empirical evaluation of time series feature sets
T. Henderson and B.D. Fulcher

In Python, check `catch22`, `tsfresh` (raw Fourier coefficients: real and imaginary parts, angle), `kats`, `tsfel`. In R, check `catch22`, `feats`, `tsfeatures`. Compare them on the “1000 empirical time series” dataset.

Multilevel nested simulation for efficient risk estimation
M.B. Giles et al.

To compute $E[H(E[X|Y])]$, where H is the Heaviside function, we can use a coarse Monte Carlo approximation of $E[X|Y]$ if it is far away from zero, and a finer one if it is closer.

Portfolio optimization rules beyond the mean-variance approach
M. Markov and V. Markov (2023)

The asymmetric Laplace distribution is

$$p_{\mu, \sigma_+, \sigma_-}(x) \propto \exp - \frac{|x - \mu|}{\sigma_{\text{sign}(x - \mu)}}.$$

Linear time GPs for inferring latent trajectories from neural spike trains
M. Dowling et al. (2023)

The Hida-Matérn kernel is

$$\kappa(\tau) = \cos(b\tau) \kappa_{\text{Matérn}}(\tau, \nu + \tfrac{1}{2}).$$

Large non-stationary noisy covariance matrices: a cross-validation approach
V.W.C. Tan and S. Zohren (2020)

The sample covariance matrix with exponential

weights

$$\begin{aligned} \hat{E} &= \frac{\sum_{t=0}^{T-1} \beta^t x_{\tau-t} x'_{\tau-t}}{\sum \beta^t} \\ &= \frac{1}{T} C' B X \\ B &= T \text{diag} \left(\frac{\beta^t}{\sum \beta^s} \right)_t \\ &= T \frac{1 - \beta}{1 - \beta^T} \text{diag}(\beta^t)_t \\ \hat{E} &= \text{Cov} \tilde{X} \\ \tilde{X} &= X B^{1/2} \\ N/T &\longrightarrow q \\ N(1 - \beta) &\longrightarrow q_e \end{aligned}$$

can account for non-stationarity, but its limiting spectral distribution is slightly different from the Marchenko-Pastur one: the eigenvalues of \hat{E} are biased estimators of the true eigenvalues. Keep the eigenvectors, but use cross-validation (on \tilde{X}) to remove the bias of the eigenvalues.

Let ρ be the asymptotic distribution of the eigenvalues of a random matrix; its *Stieltjes transform* is

$$G(z) = \int_{\mathbf{R}} \frac{\rho(t)}{z - t} dt = \lim_{N \rightarrow \infty} \frac{1}{N} \text{E tr}[(X - zI)^{-1}].$$

The *R-transform* is defined by

$$R(G(z)) + \frac{1}{G(z)} = z$$

and satisfies $R_{A+B} = R_A + R_B$ (assuming the eigenvectors are in “general position”). To compute the spectrum of $A + B$:

- Compute G_A, G_B, R_A, R_B ;
- Compute $R_{A+B} = R_A + R_B$;
- Compute G_{A+B} ;
- Compute ρ_{A+B}

Data-driven distributionally robust risk parity portfolio optimization
G. Costa and R.H. Kwon (2021)

To estimate expected returns and variance matrix from weighted historical data, with weights in a user-specified ambiguity set, alternate between:

- Gradient ascent, to find adversarial weights;
- Risk parity minimization.

Portfolio optimization using predictive auxiliary classifier generative adversarial networks with measuring uncertainty
J. Kim and M. Lee

GANs can be used as predictive models: they do not output a single value, but (samples from) a distribution, accounting for prediction uncertainty.

**Multi-modal deep learning
for credit rating prediction
using text and numerical data streams**
M. Tavakoli et al.

Cross-attention for multimodal learning, viz, predicting credit ratings from structured (financial ratios) and unstructured (earnings calls transcripts) data.

The virtue of complexity in return prediction
B. Kelly et al. (2022)

Simple models understate return predictability: do not shy away from complex ML models.

**Embedding and correlation tensor for XRP
transaction networks**
A. Chakraborty et al. (2022)

Take XRP transactions:

- For each week, compute a network, with wallets as nodes and transactions as edges;
- Compute node embeddings (deepwalk or node2vec);
- Only keep nodes present each week;
- Compute the correlations

$$M_{ij}^{\alpha\beta} = \text{Cor}_{[t-\Delta T, t+\Delta T]}[V_i^\alpha, V_j^\beta]$$

where i, j are nodes, and α, β coordinates.

- Compute a double SVD

$$\begin{aligned} M_{ij}^{\alpha\beta} &= U_{ik} \Delta_k^{\alpha\beta} V_{kj} \\ \Delta_k^{\alpha\beta} &= L^{\alpha\gamma} D_k^\gamma R^{\gamma\beta} \\ \text{i.e., } M_{ij}^{\alpha\beta} &= D_k^\gamma (U_{ik} V_{kj}) (L^{\alpha\gamma} R^{\gamma\beta}) \end{aligned}$$

**Generative AI in active management:
QesGFT**
Wolfe Research

Model trained on a point-in-time corpus (Wikipedia, books, news, policy documents (UN, OECD, etc.), preprints, regularoty filings, conference calls, corporate websites), from GPT-3, with self-instruct, flash attention (GPU tiling), 8-bit quantization, RoPE.

**A graph theory approach
to portfolio optimization**
D. Cajas (2023)

From the correlation matrix, build the MST or the TMFG; add a constraint to the optimization problem, to invest (on average) in low-centrality assets

$$w' \cdot \text{centrality} = c.$$

To increase diversity further, do not invest in nearby assets: this can be formulated as a MIP, or relaxed to a SDP: $B \odot (ww') = 0$, where B_{ij} indicates if there is a path of length at most ℓ between i and j , is a quadratic non-convex constraint, but ww' can be replaced by a positive semidefinite approximation X

$$ww' = \underset{X: \begin{bmatrix} X & w \\ w' & 1 \end{bmatrix} \succcurlyeq 0}{\text{Argmin}} \text{tr } X$$

by adding a $\lambda \text{tr } X$ penalty to the objective.

**Post-covid inflation and the monetary policy
dilemma: an agent-based scenario analysis**
M.S. Knicket et al.

The *Mark-0 agent-based model* is a macro-economic model accounting for savings, wages, energy sector, interest, inflation expectation, consumption, non-matched demand and production, several goods, several firms, price, target production.

Maximally machine-learnable portfolios
P.G. Coulombe et al. (2022)

ACE (alternating conditional expectation) finds and easy-to-forecast transformation of the target variable

$$g(Y) = f(X) + \varepsilon$$

(iteratively estimate g fixing f , and f fixing g , with backfitting polynomials). With time series, this becomes

$$g(Y_{t+h}) = f(X_t) + \varepsilon_{t+h}.$$

This can be generalized to portfolios (MACE, multi-variate ACE): find a portfolio w whose returns

$$g(Y_{t+h}) = w'Y_{t+h}$$

are easy to forecast with a random forest (from market variables, macro variables, or the characteristics (returns, earnings yield, etc.) of the portfolio itself).

$$\begin{aligned} &\underset{w, f}{\text{Minimize}} \sum_t [w' r_{t+h} - f(X_t)] + \lambda \|w\|^2 \\ &\text{such that } w \geq 0, w' \mathbf{1} = 1. \end{aligned}$$

The model can be estimated by alternatingly fitting a random forest to get f , and a ridge regression to get w .

**Comparing deep learning models for volatility
prediction using multivariate data**
W. Ge et al.

Temporal fusion transformers (TFT) and temporal convolution networks (TCN) outperform GARCH-like models.

Temporal fusion transformers for interpretable multi-horizon time series forecasting
B. Lim et al.

Stack:

- LSTM
- GRN (gated residual network)

$$\text{GLU} = \sigma((W_1x + b_1) \odot (W_2x + b_2))$$

- Multi-head attention;
- GRN

to forecast several quantities, at several horizons.

GFlowNet Foundations
Y. Bengio et al.

Contrary to MCMC, GFlowNets can efficiently sample from multimodal distributions, on discrete objects that can be constructed incrementally, e.g., set, graphs or molecules. They can be trained, not from data, but from an unnormalized probability distribution (the *reward*).

A *flow network* is a DAG, with a single source and a single sink, with a non-negative function $F : \mathcal{T} \rightarrow \mathbf{R}_+$ on the set of complete trajectories. This defines:

- State flow: $F(s) = \sum_{\tau : s \in \mathcal{T}} F(\tau)$;
- Edge flow: $F(s \rightarrow s') = \sum_{\tau : (s \rightarrow s') \in \mathcal{T}} F(\tau)$;
- Total flow: $Z = \sum_{\tau} F(\tau)$;
- Forward transition probability:

$$P_F(s' | s) = \frac{F(s \rightarrow s')}{F(s)};$$

- Backward transition probability:

$$P_B(s | s') = \frac{F(s \rightarrow s')}{F(s')}.$$

State and edge flows define a flow if they satisfy the *flow matching conditions*

$$\begin{aligned} \hat{F}(s') &= \sum_{s \rightarrow s'} \hat{F}(s \rightarrow s') \\ \hat{F}(s') &= \sum_{s' \rightarrow s''} \hat{F}(s' \rightarrow s''). \end{aligned}$$

State flow and forward and backward transition probabilities correspond to a flow if they satisfy the *detailed balance conditions*

$$\hat{F}(s) \hat{P}_G(s' | s) = \hat{F}(s') \hat{P}_B(s | s').$$

A flow is *Markovian* if

$$P(s \rightarrow s' | s_0 \rightarrow \dots \rightarrow s) = P(s \rightarrow s' | x) = P_F(s' | s).$$

Each flow function (on paths) is equivalent to (has the same edge flow as) a unique Markovian flow. The edge flows determine a unique Markovian flow.

A GFlowNet parametrized by edge flows $\hat{F}(s \rightarrow s')$ can be trained with the *flow matching loss*

$$\sum_{s'} \left[\log \frac{\delta + \sum_{s \in \text{Par}(s')} \hat{F}(s \rightarrow s')}{\delta + R(s') + \sum_{\substack{s'' \in \text{Child}(s') \\ s'' \neq \text{final}}} \hat{F}(s' \rightarrow s'')} \right]^2$$

A GFlowNet parametrized by vertex flows $\hat{F}(s)$ and transition probabilities $\hat{P}_F(s' | s)$, $\hat{P}_B(s | s')$ can be trained with the *detailed balance loss*

$$\sum_{s \rightarrow s'} \left[\log \frac{\delta + \hat{F}(s) \hat{P}_F(s' | s)}{\delta + \hat{F}(s') \hat{P}_B(s | s')} \right]^2$$

(replace the denominator with $\delta + R(s)$ if $s' = \text{final}$).

A GFlowNet parametrized by total flow \hat{Z} and transition probabilities $\hat{P}_F(s' | s)$, $\hat{P}_B(s | s')$ can be trained with the *trajectory balance loss* (preferred)

$$\sum_{\tau} \left[\log \frac{\hat{Z} \prod_t \hat{P}_F(s_t | s_{t-1})}{R(s_T) \prod_t \hat{P}_B(s_{t-1} | s_t)} \right]^2.$$

Flow network based generative models for non-iterative diverse candidate generation

GFlowOut: dropout with generative flow networks
D. Liu et al. (2023)

Learn the distribution of the dropout binary masks, in a sample-dependent or sample-independent way, with a GFlowNet.

Deep neural networks with dropout perform approximate Bayesian inference and approximate the posterior of a deep Gaussian network.

Direct parametrization of Lipschitz-bounded deep networks
R. Wang and I.R. Manchester (2023)

γ -Lipschitz neural nets

$$\begin{aligned} z_0 &= x \\ z_{k+1} &= \sigma(W_k z_k + b_k) \\ y &= W_L z_L + b_L \end{aligned}$$

can be parametrized as

$$\begin{aligned} b_k &\in \mathbf{R}^{n_{k+1}} \\ d_j &\in \mathbf{R}^{n_j} \\ X_k &\in \mathbf{R}^{n_{k+1} \times n_{k+1}} \\ Y_k &\in \mathbf{R}^{n_k \times n_{k+1}} \\ \Psi_k &= \text{diag}(e^{d_k}) \\ \begin{bmatrix} A'_k \\ B_k \end{bmatrix} &= \text{Cayley} \begin{bmatrix} X_k \\ Y_k \end{bmatrix} \\ A_{-1} &= I \\ \Psi_{-1} &= \sqrt{\frac{\gamma}{2}} I \\ W_k &= 2\Psi_{k-1}^{-1} B_k A'_{k-1} \Psi_{k-1} \end{aligned}$$

where the Cayley transform is

$$\begin{aligned} \text{Cayley} \begin{bmatrix} X \\ Y \end{bmatrix} &= \begin{bmatrix} (I + Z)^{-1}(I - Z) \\ -2Y(I - Z)^{-1} \end{bmatrix} \\ Z &= X - X' + Y'Y \end{aligned}$$

Equivalently, the model can be written with *Lipschitz sandwich layers*

$$\begin{aligned} h_0 &= \sqrt{\gamma}x \\ h_{k+1} &= \sqrt{2}A'_k \Psi_k \sigma(\sqrt{2}\Psi_k^{-1} B_k h_k + b_k) \\ y &= \sqrt{\gamma}B_L h_L + b_L, \end{aligned}$$

**Recurrent equilibrium networks:
flexible dynamic models
with guaranteed stability and robustness**
M. Revay et al.

A recurrent equilibrium network (REN) is a state space model

$$\begin{aligned} x_{t+1} &= Ax_t + B_1 w_t + B_2 u_t + b_x \\ y_t &= C_2 x_t + D_{21} w_t + D_{22} u_t + b_y \end{aligned}$$

whose weights are given by an equilibrium network

$$w_t = \sigma(D_{11}w_t + C_1 x_t + D_{12}u_t + b_v).$$

Sufficient conditions for the model to be Lipschitz can be translated into direct parametrizations.

A cookbook of self-supervised learning
R. Balestrierio et al.

There are 4 families of self-supervised learning (SSL) models:

- Contrastive loss (SimCLR);
- Self-distillation (BYOL, SimSiam, DINO);
- Canonical correlation (VICReg, Barlow Twins);
- Maxed image modeling.

The projection introduced in SimCLR is needed because the training task is different from the downstream task.

**On the representation and learning
of monotone triangular transport maps**
R. Baptista et al.

A *Triangular transport map* S between two probability distributions μ and ν on \mathbf{R}^d is a map of the form

$$S : \begin{cases} \mathbf{R}^d \longrightarrow \mathbf{R}^d \\ x \longmapsto \begin{bmatrix} S_1(x_1) \\ S_2(x_1, x_2) \\ \vdots \\ S_d(x_1, \dots, x_d) \end{bmatrix} \end{cases}$$

such that $X \sim \mu \Rightarrow Z = S(X) \sim \nu$, i.e., $\mu = S^\# \nu$ (this is an alternative to normalizing flows).

If the $x_k \mapsto S_k(x_{<k}, x_k)$ are increasing, then S is invertible.

If $\mu \ll \text{Lebesgue}$ and $\nu = N(0, I)$, then S is essentially unique.

The *rectification operator* R_k transforms a smooth function into a monotonic one

$$R_k(f_k)(x_{<k}, x_k) = f_k(x_{<k}, 0) + \int_0^{x_k} g[\partial_k f_k(x_{<k}, t)] dt$$

for some $g : \mathbf{R} \rightarrow \mathbf{R}_{>0}$, e.g., softplus.

To find the S_k 's from data sampled from μ (for the reference distribution $\nu = N(0, I)$), minimize

$$\hat{J}_k(S) = \frac{1}{n} \sum_i \frac{1}{2} S(x_{\leq k}^i)^2 - \log |\partial_k S(x_{\leq k}^i)|$$

(the KL divergence, up to a constant), under the constraint $\partial_k S(x_{\leq k}) > 0$ (use the rectification operator to remove the constraint). Under reasonable assumptions, there are no spurious local minima: they are all global.

Look for S_k of the form

$$\begin{aligned} S_k(x_{\leq k}) &= \sum_{\alpha \in \Lambda} c_\alpha \psi_\alpha(x_{\leq k}) \quad \alpha \text{ multi-index} \\ \psi_\alpha(x_{\leq k}) &= \prod_{j=1}^k \psi_{\alpha_j}(x_j) \end{aligned}$$

where the ψ_α are:

- Hermite polynomials (orthogonal wrt the Gaussian density)

$$\phi_\alpha(x) = (-1)^\alpha e^{x^2/2} \frac{d^\alpha}{dx^\alpha} e^{-x^2/2},$$

modified to be linear outside some compact interval $[a, b]$

- or wavelets

$$\begin{aligned} \psi_{\ell, q}(x) &= 2^{\ell/2} \psi(2^\ell x - q) \\ \psi(x) &= (1 - x^2) e^{-x^2/2} \quad (\text{Mexican hat}). \end{aligned}$$

Greedy build the multi-index set Λ by adding the multi-index α giving the best improvement to \hat{J}_k

$$\Lambda_{t+1} = \Lambda_t \cup \{\alpha_t^*\}$$

ensuring that $(\Lambda_t)_{t \geq 0}$ remains downward closed

$$\forall \alpha \in \Lambda_t \quad \forall \alpha' \leq \alpha \quad \alpha' \in \Lambda_t,$$

i.e., α_t^* is in the reduced margin of Λ_t

$$\alpha_t^* = \underset{\alpha \in \Lambda_t^{\text{RM}}}{\text{Argmin}} \left| \nabla_{\alpha} \hat{J}_k \right|.$$

The sparsity structure of Λ defines a graphical model.

The triangular structure of the transport map

$$S(x_1, x_2) = \begin{bmatrix} S_1(x_1) \\ S_2(x_1, x_2) \end{bmatrix}$$

gives the conditional distribution

$$X_2 | X_1 = x_1 \sim S_2(x_1, \cdot)^{\#} \nu_2.$$

Implementation: MPaT.

Categorical reparametrization with Gumbel softmax E. Jang et al.

Sampling from a categorical distribution

$$z \sim \text{Categorical}(\pi_1, \dots, \pi_k)$$

is equivalent to (*Gumbel max trick*)

$$g_1 \stackrel{\text{iid}}{\sim} \text{Gumbel}(0, 1) \\ z = \underset{i}{\text{one-hot Argmax}}(g_i + \log \pi_i)$$

where the Gumbel distribution can be sampled as

$$u \sim \text{Unif}(0, 1) \\ g = -\log -\log u.$$

The *Gumbel softmax* replaces argmax with softmax.

$$g_1 \stackrel{\text{iid}}{\sim} \text{Gumbel}(0, 1) \\ z = \text{softmax}_{\tau}(g + \log \pi) \in \Delta$$

It is a reparametrization trick for an approximate categorical distribution.

In practice:

- Slowly decrease the temperature τ to approach 1-hot vectors;
- If you need a discrete output (e.g., discrete actions in reinforcement learning), use argmax in the forward pass and the Gumbel softmax in the backward pass.

The concrete distribution: a continuous relaxation of discrete random variables C.J. Maddison et al.

Earlier paper on the Gumbel softmax (initially called “concrete”).

Learning with differentiable perturbed optimizers Q. Berthet et al. (2020)

The optimization problem

$$y^*(\theta) = \underset{y \in \text{Conv } Y}{\text{Argmax}} \langle y, \theta \rangle,$$

for a finite set Y , can be perturbed into

$$y_{\varepsilon}^*(\theta) = \underset{z \sim \mu}{\text{E}} [y^*(\theta + \varepsilon Z)];$$

the Jacobian is

$$J_{\theta} y_{\varepsilon}^*(\theta) = \underset{z \sim \mu}{\text{E}} [y^*(\theta + \varepsilon Z) \nabla_Z \nu(Z)' / \varepsilon]$$

where $d\mu(z) = e^{-\nu(z)} dz$.

This generalizes the Gumbel softmax:

$$\mu = \text{Gumbel}(0, 1) \\ Y = \{\text{1-hot vectors}\} \\ \text{Conv } Y = \Delta$$

Many problems can be put in this form (maximizing a linear quantity over a polytope):

- Ranking: $Y = \{\sigma \cdot v : \sigma \in \mathfrak{S}_n\}$, for some vector v ; $\text{Conv } Y$ is then the *permutohedron*;
- Shortest path, etc.

The perturbed solution y_{ε}^* minimizes the *Fenchel-Young loss*

$$L_{\varepsilon}(\theta; y) = F_{\varepsilon}(\theta) + \varepsilon \Omega(y) - \langle \theta, y \rangle \\ F_{\varepsilon}(\theta) = \underset{Z \sim \mu}{\text{E}} \underset{y \in \text{Conv } Y}{\text{Max}} \langle y, \theta + \varepsilon Z \rangle \\ \Omega = F_1^* \quad (\text{Fenchel dual}).$$

Differentiation of blackbox combinatorial solvers M. Vlastelica et al.

To back-propagate through a combinatorial solver

$$y(w) = \underset{y \in Y}{\text{Argmin}} \langle w, y \rangle$$

(*linear* objective, arbitrary constraints), use the actual (discrete) solution in the forward pass and a continuous interpolation of (a linearization of) the loss in the backward pass.

$$\hat{y} = \text{solver}(\hat{w}) \\ \frac{dL}{dy}(\hat{y}) : \text{gradient to back-propagate}$$

$$w' = \hat{w} + \lambda \frac{dL}{dy}(\hat{y})$$

$$y_{\lambda} = \text{solver}(w')$$

$$\nabla_w f_{\lambda}(\hat{w}) = -\frac{1}{\lambda}(\hat{y} - y_{\lambda})$$

**Optimizing rank-based metrics
with blackbox differentiation**
M. Rolínet et al.

Application of blackbox differentiation to ranking problems, maximizing

- Recall: proportion of relevant items ($y_i^* = 1$) among the top k (for a fixed value of k);
- Average precision: average of recall_k , as k varies;
- Mean average precision: average of the average precision, as the class varies.

$$\begin{aligned} y &\in \mathbf{R}^n && \text{scores} \\ y^* &\in \{0, 1\}^n && \text{ground truth} \end{aligned}$$

**Backpropagation through combinatorial
algorithms: identity with projection works**
S.S. Sahoo et al.

To back-propagate through a blackbox solver $w \mapsto t(w) = \text{Argmin}_{y \in Y} \langle w, y \rangle$, use $-I$, apply a projection P accounting for invariances $\forall w \ y^*(w) = y^*(P(w))$, $d\ell/dy \mapsto -P'(w)d\ell/dy$ and add noise to w before feeding it to the solver.

**Fenchel-Young losses with skewed entropies
for class-posterior probability estimation**
H. Bao and M. Sugiyama (2021)

The optimization problem $\hat{y}(\theta) = \text{Argmax}_{y \in Y} \theta y$ can be regularized into

$$\hat{y}_\Omega(\theta) = \text{Argmax}_y \theta y - \Omega(y).$$

The corresponding *Fenchel-Young loss* is

$$\begin{aligned} \ell_\Omega(\theta, y) &= \Omega^*(\theta) + \Omega(y) - \theta y \\ \Omega^*(\theta) &= \sup_\eta \theta \eta - \Omega(y). \end{aligned}$$

Under reasonable assumptions (Ω strictly convex), ℓ is convex, smooth, and reaches its minimum 0 at $y = \hat{y}_\Omega(\theta)$.

A cdf F defines a Fenchel-Young loss

$$\begin{aligned} \ell_F(\theta, y) &= \Omega_F^* + \Omega_F(y) - y\theta \\ \Omega_F(y) &= \int_0^y F^{-1}(q) dq \\ \Omega_F^*(\theta) &= \int_{-\infty}^\theta F(s) ds. \end{aligned}$$

Because of the symmetry of the logit link, logistic regression tends to underestimate the probability of rare events. Skewed links address that problem but, with maximum likelihood estimation (MLE), they lead to non-convex optimization problems. Instead, use the generalized eigenvalue distribution (GEV) link and the corresponding (convex) Fenchel-Young loss

$$F_\xi(\theta) = \exp -(1 + \xi\theta)_+^{-1/\xi}.$$

Learning with Fenchel-Young losses
M. Blondel et al.

The optimization problem

$$\text{Maximize}_{y \in Y} \langle \theta, y \rangle$$

can be relaxed to

$$\hat{y}_\Omega(\theta) = \text{Argmax}_{y \in \text{Conv } Y} \langle \theta, y \rangle - \Omega(y).$$

Examples include

$$\begin{aligned} \text{Argmax} & \quad \Omega = I_\Delta \\ \text{Softmax} & \quad \Omega = -H + I_\Delta \\ \text{Sparsemax} & \quad \Omega = \frac{1}{2} \|\cdot\|^2 + I_\Delta \\ \text{Sigmoid} & \end{aligned}$$

The *Fenchel-Young loss*

$$\begin{aligned} L_\Omega(\theta, y) &= \Omega^*(\theta) + \Omega(y) - \langle \theta, y \rangle \\ &= f_\theta(y) - f_\theta(\hat{y}_\Omega(\theta)), \end{aligned}$$

where $f_\theta(y) = \Omega(y) - \langle \theta, y \rangle$, is convex, and reaches its minimum at $y = \hat{y}_\Omega(\theta)$.

A *generalized entropy* is a function $H : \Delta_n \rightarrow \mathbf{R}$, strictly concave, \mathfrak{S}_n -symmetric, zero on the corners of Δ_n ; it is maximal for the uniform distribution.

$$\begin{aligned} \text{Shannon} & \quad -\sum p_i \log p_i \\ \text{Tsallis} & \quad \frac{1}{\alpha(\alpha-1)} \left(1 - \sum p_i^\alpha\right) \\ \text{Rényi} & \quad \frac{1}{1-\beta} \log \sum p_i^\beta \\ \text{Norm} & \quad 1 - \|p\|_q \\ \text{Squared norm} & \quad \frac{1}{2} (1 - \|p\|_q^2) \end{aligned}$$

**Differentiable clustering and partial
Fenchel-Young losses**
L. Stewart et al. (2023)

Given a similarity matrix $\Sigma \in \mathbf{R}^{n \times n}$, the adjacency matrix of the k -spanning forest with maximum similarity is the solution of a linear program

$$\text{Maximize}_{A \in C_k} \langle A, \Sigma \rangle$$

where C_k is the set of adjacency matrices of forests with k connected components; it corresponds to single linkage clustering.

**Distributions for compositionally
differentiating parametric discontinuities**
J. Michel et al. (2023)

Integral primitive for differentiable programming languages, to differentiate integrals with discontinuous integrands.

**Cold analysis of
Rao-Blackwellized straight-through
Gumbel-softmax gradient estimator
A. Shekhovtsov (2023)**

There are many estimators of $J = \frac{d}{d\eta} \mathbb{E}_{x \sim p_\eta} [\ell(\phi(x))]$.

$$J^{\text{RF}} = \ell(\phi(x)) \cdot \frac{d}{d\eta} \log p_\eta(x)$$

$$J^{\text{ST}} = \frac{d}{d\eta} \ell(\phi(x)) \cdot \frac{d}{d\eta} \bar{\phi}, \quad \bar{\phi} = \mathbb{E}[\phi(x)]$$

$$J^{\text{DARN}} = \frac{d}{d\eta} \ell(\phi(x)) \cdot (\phi(x) - \bar{\phi}) \cdot \frac{d}{d\eta} \log p_\eta(x)$$

$\bar{\phi}$ = your choice

$$J^{\text{GS}} = \frac{d}{d\phi} \ell(\tilde{\phi}) \cdot \frac{d\tilde{\phi}}{d\eta}$$

$G_k \sim \text{Gumbel}(0, 1)$
 $\tilde{\phi} = \text{softmax}_\ell(\log p_\eta + G)$

$$J^{\text{GS-ST}} = \frac{d}{d\phi} \ell(\phi(x)) \cdot \frac{d\tilde{\phi}}{d\eta}$$

$$J^{\text{GR}} = \frac{d}{d\phi} \ell(\phi(x)) \cdot \mathbb{E}_{G \sim \text{Gumbel}} \left[\frac{d\tilde{\phi}}{d\eta} \right]$$

**Automatic differentiation of programs
with discrete randomness
G. Arya et al.**

Given a family of discrete random variables $X(p) : \Omega \rightarrow E$ for $p \in I = [a, b] \subset \mathbf{R}$, we want another one, $\tilde{X}(p)$, such that

$$\mathbb{E}[\tilde{X}(p)] = \frac{d}{dp} \mathbb{E}[X(p)].$$

We cannot use the reparametrization trick

$$\frac{d\mathbb{E}[X(p)]}{dp} \stackrel{?}{=} \mathbb{E} \left[\frac{dX(p)}{dp} \right]$$

because $dX(p)/dp = 0$ a.s. Instead, let

$$\delta = \lim_{\varepsilon \rightarrow 0} \frac{X(p + \varepsilon) - X(p)}{\varepsilon} = \frac{dX(p)}{dp}$$

$$B > |\delta|$$

$$A_B(\varepsilon) = \left\{ \omega \in \Omega : \left| \frac{X(p + \varepsilon) - X(p)}{\varepsilon} \right| > B \right\}$$

$$= \{\text{large jumps}\}$$

$$w = \frac{dP[A_B(\varepsilon)]}{d\varepsilon} \Big|_{\varepsilon=0} = \frac{dP[\text{large jump}]}{d\varepsilon} \Big|_{\varepsilon=0}$$

$$Y_\varepsilon \stackrel{d}{=} X(p + \varepsilon) - X(p) | A_B(\varepsilon), X(p)$$

$$Y = \lim_{\varepsilon \rightarrow 0} Y_\varepsilon.$$

Then,

$$\frac{d\mathbb{E}[X(p)]}{dp} = \mathbb{E}[\delta + w(Y - X(p))].$$

Concretely, with dual numbers, this gives results like

$$\begin{aligned} X &\sim \text{Bernoulli}(0.6 + \varepsilon) \\ 0 + 1 &\text{ with probability } 2.5\varepsilon \end{aligned}$$

More generally, for random variables with jumps, sampling returns *stochastic triples* (a, b, c, d)

$$a + b\varepsilon + (c \text{ with probability } d\varepsilon).$$

This is amenable to automatic differentiation. Implementation in `StochasticAD.jl`.

**SurCo: learning linear surrogates for
combinatorial nonlinear optimization problems
A. Ferber et al. (2023)**

Solve nonlinear optimization problems

$$\underset{x \in \Omega}{\text{Minimize}} f(x, y)$$

by reducing them to linear problems, by training a neural net to find the closest linear program.

(The linear solver can be an MIP solver.)

**MIPaaL: Mixed integer program as a layer
A. Ferber et al.**

To compute surrogate gradients for an MIP solver, solve the problems by relaxing the integral constraints and progressively adding cutting planes, and use the final (continuous, convex) optimization problem KKT conditions.

**Differentiation of
blackbox combinatorial solvers
M. Vlastelica et al.**

We want to backprop through a blackbox (combinatorial) optimizer with a linear objective.

$$w \mapsto \hat{y} = \underset{y \in Y}{\text{Argmin}} w \cdot \phi(y) \mapsto L(\hat{y})$$

Consider the first order approximation of the loss

$$L(y) \approx L(\hat{y}) + \frac{dL}{dy}(y - \hat{y}) = f(y).$$

Define a relaxation of f

$$y_\lambda(w) = \underset{y \in Y}{\text{Argmin}} w \cdot \phi(y) + \lambda f(y)$$

$$f_\lambda(w) = f(y_\lambda(w)) - \frac{1}{\lambda} [w \cdot \phi(y(w)) - w \cdot \phi(y_\lambda(w))].$$

The surrogate gradient can be computed as

$$w' = \hat{w} + \lambda \cdot \frac{dL}{dy}(\hat{y})$$

$$y_\lambda = \text{solver}(y')$$

$$\nabla_w f_\lambda(\hat{w}) = -\frac{1}{\lambda}(\hat{y} - y_\lambda).$$

Try $\lambda \approx \frac{\langle w \rangle}{\left\langle \frac{dL}{dy} \right\rangle}$ where $\langle \cdot \rangle = \text{avg}$.

Differentiable Monte Carlo samplers with piecewise deterministic Markov processes **R. Seyer**

The ergodic theorem states

$$\mathbb{E}_{X \sim \mu} [f(X)] = \lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T f(Z_t) dt$$

but, in general, we do not have

$$\frac{d}{d\theta} \mathbb{E}_{X \sim \mu_\theta} [f(X)] \stackrel{?}{=} \lim_{T \rightarrow \infty} \frac{d}{d\theta} \frac{1}{T} \int_0^T f(Z_t^\theta) dt.$$

To differentiate $\mathbb{E}_{X \sim \mu_\theta} [f(X)]$, there are several approaches:

- The reparametrization trick (aka pathwise derivative) to get a *coupling* between μ_θ and $\mu_{\theta+\varepsilon}$, but it only gives an unbiased estimator if the reparametrization is Lipschitz – this excludes discrete variables or jumps;
- Stratified derivatives, which handle the discontinuities separately (e.g., the “stochastic triples”);
- The score method (REINFORCE).

A *piecewise deterministic Markov process* has 3 components:

- Between jumps, it follows a deterministic flow,

$$\frac{dz}{dt} = \xi(z)$$

for some drift $\xi : E \rightarrow E$;

- The timing of the jumps follow an inhomogeneous Poisson process with rate $\lambda_t = \lambda(z_t)$ for some $\lambda : E \rightarrow \mathbf{R}_+$;
- The jumps are given by a transition kernel $Q(z, dz)$.

The main examples are the *zigzag* sampler on \mathbf{R}

state space	$E = \mathbf{R} \times \{\pm 1\}$
drift	$\xi(x, v) = (v, 0)$
event rate	$\lambda(x, v) = \text{Max}\{0, c\nabla_x - \log \pi(x)\}$
transition kernel	deterministically flip sign(v)

and its generalization, the *bouncy particle* sampler

$$\begin{aligned} E &= \mathbf{R}^d \times \mathbf{R}^d \\ \xi(x, v) &= (v, 0) \\ \lambda(x, v) &= \text{Max}\{0, v' \nabla_x - \log \pi(x)\} \\ Q: &\text{elastic reflection of } v \text{ tangentially} \\ &\text{to the potential } \nabla_x - \log \pi \end{aligned}$$

(there is also a “refreshment rate” in λ , corresponding to resetting the velocity to $v \sim N(0, I)$.)

Those continuous-time non-invertible Markov chains tend to mix faster than the classic discrete-time reversible ones.

To couple the zig-zag processes Z_t^θ and $Z_t^{\theta+\varepsilon}$ on $[0, T_\theta]$ and $[0, T_{\theta+\varepsilon}]$, use the unter-arrival times

$$\tau'_i = \Lambda_t^\leftarrow(\Lambda_i(\tau_i, \theta), \theta + \varepsilon)$$

where

$$\Lambda(t) = \int_0^t \lambda(r) dr$$

$$\Lambda^\leftarrow(\omega) = \inf\{t \geq 0 : \Lambda(t) \geq \omega\} \quad \text{pseudo-inverse}$$

(they have the same number of events). Under reasonable assumptions (Λ invertible, with smooth inverse), we can swap $d/d\theta$ and $\lim_{T \rightarrow \infty}$.

Reformer: the efficient transformer **N. Kitaev et al.**

The attention matrix is quadratic in the context length, but its rows are softmaxes and tend to be sparse: instead of computing the whole matrix, only compute, for each row (query), the k largest entries, corresponding to the k closest keys, with an approximate nearest neighbour (ANN) algorithm, e.g., LSH (locality sensitive hashing).

The Reformer also uses reversible layers.

Linformer: self-attention with linear complexity **S. Wang et al.**

The attention matrix has low rank: reduce the dimension of the key and value matrices before using them.

Random feature attention **H. Peng et al.**

The attention $\text{Att}(q, K, V) = \text{softmax}(qK'/\sqrt{d})V$ is the expectation of a quantity whose computation is linear in time and space; estimating it with a single sample is good enough.

The Gaussian kernel can be estimated as

$$\exp - \frac{\|x - y\|^2}{2\sigma^2} = \mathbb{E}_{w_i \sim N(0, \sigma^2 I)} [\phi(x) \cdot \phi(y)]$$

where

$$\phi : \begin{cases} \mathbf{R}^d & \longrightarrow \mathbf{R}^{2D} \\ x & \longmapsto \begin{bmatrix} \sin(w_1 \cdot x) \\ \vdots \\ \sin(w_D \cdot x) \\ \cos(w_1 \cdot x) \\ \vdots \\ \cos(w_D \cdot x) \end{bmatrix} \end{cases}$$

The softmax appearing in the attention formula can be approximated as

$$\begin{aligned} \exp\left(\frac{x \cdot y}{\sigma^2}\right) &= \exp\left(\frac{\|x\|^2 + ny^2 - nx - y^2}{2\sigma^2}\right) \\ &= \exp\left(\frac{\|x\|^2}{2\sigma^2}\right) \exp\left(\frac{\|y\|^2}{2\sigma^2}\right) \exp\left(\frac{\|x - y\|^2}{2\sigma^2}\right) \\ &= \exp\left(\frac{1}{\sigma^2}\right) \mathbb{E}_w[\phi(x) \cdot \phi(y)] \text{ if } \|x\| = \|y\| = 1 \\ &\approx \exp\left(\frac{1}{\sigma^2}\right) \phi(x) \cdot \phi(y) \end{aligned}$$

The attention operator can therefore be approximated without large intermediate matrices,

$$\begin{aligned} \text{Att}(q, K, V) &= \sum_i \frac{\exp(q \cdot k_i / \sigma^2)}{\sum_j \exp(q \cdot k_j / \sigma^2)} v'_i \\ &\approx \sum_i \frac{\phi(q) \cdot \phi(k_i)}{\sum_j \phi(q) \cdot \phi(k_j)} v'_i \\ &= \sum_i \frac{\phi(q)' \phi(k_i) v'_i}{\sum_j \phi(q)' \phi(k_j)} \\ &= \frac{\phi(q)' \sum_i \phi(k_i) v'_i}{\phi(q)' \sum_i \phi(k_i)} \end{aligned}$$

where σ^2 is the softmax temperature.

Rethinking attention with performers **K. Choromanski et al.**

Attention is defined as

$$\begin{aligned} \text{Att}(Q, K, V) &= D^{-1}AV \\ A &= \kappa(Q, K) = \exp(QK' / \sqrt{d}) \\ D &= \text{diag}(A\mathbf{1}). \end{aligned}$$

The kernel can be written

$$\kappa(x, y) = \mathbb{E}_{\phi}[\phi(x)' \phi(y)]$$

and the attention can be approximated as

$$\begin{aligned} \widehat{\text{Att}}(A, K, V) &= \hat{D}^{-1} \hat{Q} \hat{K}' V \\ \hat{D} &= \text{diag}(\hat{Q} \hat{K}' \mathbf{1}) \\ \hat{Q} &= \phi(Q) \quad (\phi(q'_i)' \text{ as rows}) \\ \hat{K} &= \phi(K) \end{aligned}$$

For the random features ϕ , do not use the trigonometric random features (they have negative values, which increases the variance), but *positive random features*.

$$\phi(x) = \frac{h(x)}{\sqrt{m}} [f_1(\omega'_1 x), \dots, f_1(\omega'_m x), \dots, f_\ell(\omega'_1 x), \dots, f_\ell(\omega'_m x)]$$

$$h(x) = \exp - \frac{\|x\|^2}{2}, \quad \ell = 1, \quad f_1 = \exp$$

$$h(x) = \frac{1}{\sqrt{2}} \exp - \frac{\|x\|^2}{2}, \quad \ell = 2, \quad f_1 = \exp, \quad f_2 = 1/f_1$$

$$\exp(x'y) = \mathbb{E}_{\omega \sim N(0, I)} [\phi(x)' \phi(y)]$$

Use *orthogonal random features* (apply Gram-Schmidt to $\omega_1, \dots, \omega_n$) to further reduce variance.

A survey of transformers **T. Lin et al. (2022)**

Efficient transformers: a survey **Y. Tay et al. (2022)**

List of transformer variants.

Efficient and robust approximate nearest neighbor search using hierarchical navigable small world graphs **Y.A. Malkov and D.A. Yashunin**

NSW (navigable small world) adds the points, in a random order, linking each one to its M closest (approximate) neighbours (greedy search with multiple random entry nodes). The construction can be parallelized. The first nodes are better connected than later ones.

HNSW (hierarchical NSW) uses n subgraphs, containing an increasing fraction of the nodes:

- Start the search at the top (smallest) one, at a high degree node;
- Greedily find the node closest to the query;
- Start a new search in the next graph, from this node;
- Continue down the stack of graphs.

This is similar to the *probability skip list* (a stack of sorted linked lists).

Implementation in **faiss**.

Double descent demystified: identifying, interpreting and ablating the sources of a deep learning puzzle **R. Schaeffer et al.**

Double decent for linear regression suggests the phenomenon requires:

- Small but nonzero singular values in the training data features;
- The test data varies in different directions from the training data (it is not in the span of the first singular values);
- The best model possible makes errors on the training data (the training data is noisy).

**Multiple descent:
design your own generalization curve**
L. Chen et al.

**Lost in the middle:
how language models use long contexts**
N.F. Liu et al.

LLMs struggle to use information in the middle of their context: performance is higher when relevant information is at the beginning or end – models with a smaller context perform better.

**Path neural networks:
expressive and accurate graph neural networks**
G. Micher et al. (2023)

Do not aggregate just neighbours, but paths:

- Single shortest paths;
- All shortest paths;
- All single paths of length up to k .

Use recurrent layers to encode paths into vectors.

**Leveraging label non-uniformity for node
classification in graph neural networks**
F. Ji et al. (2023)

Train a GNN for node classification and compute, for each node v , its label non-uniformity

$$w(v) = \left\| \mu_v - \frac{1}{n} \mathbf{1} \right\|_1,$$

where μ_v is the label distribution for v from the model. Nodes with low w are close to class boundaries. To improve model performance,

- Add nodes with low w to the training set, with their *predicted* labels, and retrain;
- Pick a proportion η_1 of nodes with the smallest w ; build a spanning tree on them; drop a proportion η_2 of edges (between those nodes) not in that tree (to preserve connectivity) and re-train.

**Graph positional encoding
via random feature propagation**
M. Eliasof et al. (2023)

Adding node features from the first power iterations combines the advantages of random features (before the first iteration) and spectral positional encoding (limit of the power iterations).

**Towards deep attention in graph neural
networks: problems and remedies**
S.Y. Lee et al. (2023)

GATv2 learns edge attention $\alpha_{ij}^{(k)} \in (0, 1)$, and suffers from over-smoothing; DAGCN learns $\alpha_{ij}^{(k)} \in (-1, 1)$ and does not.

**Understanding convolutions
on graphs via energies**
F. Di Giovanni et al.

The Dirichlet energy is

$$\mathcal{E}(F) = \frac{1}{2} \sum_{ij \in E} \|(\nabla F)_{ij}\|^2$$

$$(\nabla F)_{ij} = \frac{f_j}{\sqrt{d_j}} - \frac{f_i}{\sqrt{d_i}}.$$

It can be generalized to

$$\begin{aligned} \mathcal{E}_\theta(F) &= \sum_i \langle f_i, \Omega f_i \rangle - \sum_{ij} A_{ij} \langle f_i, W f_j \rangle + \phi(F, F(0)) \\ &= \sum_i \langle f_i, (\Omega - W) f_i \rangle + \\ &\quad \frac{1}{2} \sum_{ij} \|\Theta_+(\nabla F)_{ij}\|^2 - \frac{1}{2} \sum_{ij} \|\Theta_-(\nabla F)_{ij}\|^2 + \\ &\quad \phi(F, F(0)) \\ W &= \Theta'_+ \Theta_+ - \Theta'_- \Theta_- . \end{aligned}$$

Graph convolutions do not necessarily oversmooth the data: the negative eigenvalues of W can provide over-sharpening.

**Node embedding from neural Hamiltonian
orbits in graph neural networks**
Q. Kang et al. (2023)

Graphs are not flat: embedding them in hyperbolic space preserves more information. Their *Gromov δ -hyperbolicity distributions* show they do not have constant curvature. Do not embed the nodes in a constant negative curvature space: embed them in (\mathbf{R}^d, g) , where the metric g is learned.

The *Hamiltonian GNN*

- Learns an embedding $(q_n^{(0)}, p_n^{(0)}) \in \mathbf{R}^{2d}$ for each node n ;
- Learns a metric g_{ij} on \mathbf{R}^d (with inverse g^{ij});
- Moves those embeddings along the Hamiltonian flow

$$\begin{aligned} H(p, q) &= \frac{1}{2} g^{ij}(q) p_i p_j \\ \dot{q}_i &= g^{ij} p_j \\ \dot{p}_i &= -\frac{1}{2} \partial_i g^{jk} p_j p_k \\ (q_n^{(0)}(0), p_n^{(0)}(0)) &\rightsquigarrow (q_n^{(0)}(T), p_n^{(0)}(T)) \end{aligned}$$

- Aggregates the resulting embeddings

$$q_n^{(1)} = q_n^{(0)}(T) + \text{Mean}_{m \in \mathcal{N}(n)} q_m^{(0)}(T)$$

(the momentum of the next layer, $p_n^{(1)}$ is learned – it does not come from $p_n^{(0)}(T)$);

The Gromov δ -hyperbolicity of a graph G is

$$\max_{\substack{a,b,c,d \in V \\ d(a,b)+d(c,b) \geq \\ d(a,c)+d(b,d) \geq \\ d(a,d)+d(b,c)}} [d(a,b) + d(d,c)] - [d(a,c) + d(b,d)]$$

Implementation (slightly more efficient than the naive $O(n^4)$) in `sage.graphs.hyperbolicity.*`.

***Can large language models
reason about program invariants***
K. Pei et al. (2023)

Alternative to dynamic analysis tools (e.g., Daikon, for Java, which needs access to several program traces).

***Data representations' study
of latent image manifolds***
I. Kaufman and O. Azencot (2023)

To assess the geometry of latent representations learned by a neural net:

- Compute its intrinsic dimension;
- Augment the data around one of the training samples, to have a dense neighbourhood: for image data, consider the image as a width×height matrix (separately for each channel), compute its SVD, and remove some of the 10 smallest singular values – this produces 2^{10} points;
- Compute the mean absolute principal curvature (MAPC).

The curvature increases sharply in the first few layers, then plateaus, and (only in well-trained networks) increases again in the last layers.

***Intrinsic dimension of data representations
in deep neural networks***
A. Ansuini et al.

To measure the *intrinsic dimension* (ID) of a cloud of points, fit a Pareto distribution to the ratios $\mu_i = r_i^{(2)}/r_i^{(1)}$, where $r_i^{(1)}$ and $r_i^{(2)}$ are the distances between a point i and its first and second nearest neighbours.

$$p(\mu_i) = d \cdot \mu_i^{-(d+1)}$$

$$p(\mu) = d^N \prod_{1 \leq i \leq N} \mu_i^{-(d+1)}$$

It is robust, even if the points are not really sampled uniformly, provided $d \leq 20$ – otherwise it underestimates the dimension. Measure it at different scales (by decimating the data) to check if it is scale-invariant.

The ID of the latent representations in trained neural nets are much lower (10 to 100 times) than the number of neurons; it increases sharply in the first layers, then decreases slowly (“hunchback” shape). The ID of the last layer is a good predictor of performance (lower is better).

The data manifolds are not flat: they cannot be recovered by linear projections.

***Estimating the intrinsic dimension of datasets
by a minimal neighbourhood information***
E. Facco et al.

Since $F_{\text{Pareto}}(\mu) = (1 - \mu^{-d})\mathbf{1}_{[\mu \geq 1]}$, the intrinsic dimension can also be estimated with an (intercept-free) linear regression

$$\frac{\log[1 - F(u)]}{\log \mu} = d.$$

Curvature-aware manifold learning
Y. Li (2017)

To estimate the curvature of a set of points:

- Compute its intrinsic dimension;
- Take a neighbourhood of the point of interest (100 times as many points as the dimension);
- Use PCA to find local coordinates;
- Compute a quadratic approximation of the chart of the manifold in those coordinates;
- The eigenvalues of the Hessian of that quadratic approximation are the *principal curvatures*;
- The mean absolute principal curvature (MAPC) is the average of their absolute values (this is an extrinsic notion of curvature, for submanifolds of a Riemannian manifold).

LLE (local linear embedding) can be generalized to account for (intrinsic) curvature.

Dink-Net: Neural clustering on large graphs
Y. Liu et al. (2023)

Learn node embeddings with a contrastive loss, and cluster the nodes, with a “shrinking” loss bringing the node representations close to the cluster centers, and a “dilation” loss keeping the centers apart, end-to-end.

***Dirichlet diffusion score model
for biological sequence generation***
P. Avdeyev (2023)

Diffusion process on the probability simplex to generate discrete sequences (sudoku puzzles, sudoku solutions, DNA sequences). Jacobi diffusion

$$dx = \frac{s}{2} [a(1-x) - bx] dt + \sqrt{sx(1-x)} dW$$

has $\text{Beta}(a, b)$ as stationary distribution. This can be generalized to a diffusion with a Dirichlet stationary distribution (stick-breaking construction with $k-1$ Jacobi diffusions).

Conformal inference is (almost) free for neural networks trained with early stopping
Z. Liang et al. (2023)

Conformal inference for models selected by early stopping requires a 3-way split of the data:

- To train the models;
- To decide when to stop;
- For conformal inference.

It is possible to use only two subsets, by storing all (or 100) the models, delaying the model selection, and choosing one, anew, for each new observation.

Why random pruning is all we need to start sparse
A. Gadhikar et al. (2023)

Randomly pruned (Erdős-Rényi) neural networks contain a lottery ticket.

Synthetic data for model selection
A. Shishan et al.

Synthetic data is often used for data augmentation (StyleGAN, GAN-GP). You can also use it instead of the validation set, for model selection (early stopping, random seed choice, hyperparameter optimization). Reweight the synthetic dataset using a holdout set of classifiers.

Large language models as optimizers
C. Yang et al.

Ask an LLM to generate a prompt template for the problem you want to solve – not just once, but iteratively, each time providing the previous prompts and their performance, to progressively improve it.

Ask for several prompts, each time, for more exploration. Change the LLM sampling temperature to tune the exploration-exploitation tradeoff.

Applications include linear regression, traveling salesman problem, reasoning (GSM8k, BigBenchHard: arithmetic, commonsense).

Scaling transformer to 1M tokens and beyond with RMT
A. Bulatov et al.

To increase the context length of a transformer, split the input into segments, and concatenate the latent representation of segment $i - 1$ to segment i .

Recurrent memory transformer
A. Bulatov et al.

RWKV: reinventing RNNs for the transformer era
A. Albalak et al.

Time mixing

$$\begin{aligned} r_t &= W[\mu x_t + (1 - \mu)x_{t-1}] \\ k_t &= W[\mu x_t + (1 - \mu)x_{t-1}] \\ v_t &= W[\mu x_t + (1 - \mu)x_{t-1}] \\ w_t &= \frac{\sum_{i < t} e^{-(t-1-i)w+k_i} v_i + e^{u+k_t} v_t}{\sum_{i < t} e^{-(t-1-i)w+k_i} + e^{u+k_t}} \\ o_t &= W[\sigma(r_t) \odot w_t] \end{aligned}$$

followed by channel mixing

$$\begin{aligned} r_t &= W[\mu x_t + (1 - \mu)x_{t-1}] \\ k_t &= W[\mu x_t + (1 - \mu)x_{t-1}] \\ o_t &= \sigma(r_t) \odot [W \text{Max}(k_t, 0)^2]. \end{aligned}$$

Precise zero-shot dense retrieval without relevance labels
L. Gao et al.

Instead of computing the similarity between a query and the documents in the database, HyDE (hypothetical document embeddings) asks an LLM to produce a hypothetical (potentially hallucinated) document answering the query, and retrieve the (actual) documents most similar to the hypothetical document.

Pysentimiento: a Python toolkit for sentiment analysis and social NLP tasks
J.M. Pérez et al.

Transformer-based models (RoBERTa) for sentiment and emotion detection, for en, es, it, pt.

Visualizing graph neural networks with CorGIE: corresponding a graph to its embedding
Z. Liu et al.

To assess the quality of the node embeddings learned by a GNN, compare the distance matrices of:

- The latent representations (node embeddings), using the cosine distance;
- The graph, with the inverse Jaccard index of the k -hop neighbours;
- The node features, with the Euclidean distance.

Supervised probabilistic principal component analysis

Probabilistic PCA (PPCA) estimates the parameters of the data generation process

$$\begin{aligned} z &\sim N(0, I) && \text{latent} \\ \varepsilon &\sim N(0, \sigma^2 I) \\ x &= Wz + \varepsilon && \text{observed} \end{aligned}$$

Supervised probabilistic PCA (SPPCA) adds another observed variable.

$$\begin{aligned} z &\sim N(0, I) && \text{latent} \\ \varepsilon &\sim N(0, \sigma_1^2 I) \\ \eta &\sim N(0, \sigma_2^2 I) \\ x = W_1 z + \varepsilon && \text{observed} && y = W_2 z + \eta && \text{observed} \end{aligned}$$

It can be estimated with EM.

A new approach to decomposition of economic time series into permanent and transitory components with particular attention to measurement of the business cycle
S. Beveridge and C.R. Nelson

SAITS: self-attention-based imputation for time series
W. Du et al. (2023)

Impute missing values in time series with diagonally masked self-attention, and two losses, for:

- Reconstruction of artificially masked values;
- Reconstruction of observed values (which may be different from the original ones, as the network also tries to “denoise” the data).

Also check: GRUI-GAN, E²GAN, M-RNN, BRITS, GP-VAE.

BRITS: bidirectional recurrent imputation for time series
W. Cao et al.

Bidirectional RNN for the imputation of missing values in time series, with a consistency loss (the reconstructed values in the forward and backward directions should be close).

Learning representations for incomplete time series clustering
Q. Ma et al. (2021)

CRLI combines:

- (Bidirectional) RNN to impute missing values and compute a latent representation of the time series (concatenation of the last hidden states of the forward and backward RNNs);
- Discriminator, predicting which values were imputed;
- Decoder of the latent representation, attempting to reconstruct the original time series;
- Soft- k -means loss on the latent representation H :

$$\ell(H) = \min_{F'F=I} \text{tr}(H'H) - \text{tr}(F'H'HF)$$

(F is the truncated SVD of H).

Graph-guided network for irregularly sampled multivariate time series
X. Zhang et al.

To classify irregularly sampled multivariate time series (or perform some other downstream task), compute latent representations of each time series at each time step:

- With a (feature-specific) nonlinear transformation, if it is observed;
- As a combination of its neighbours’ features (cross-attention) otherwise.

The graph structure used to define the neighbours is initialized as a complete graph; the edge weights are updated using the cumulated attention weight for each edge; the least important edges (bottom $k\%$) are pruned.

Estimating missing data in temporal streams using multi-directional recurrent neural networks
J. Yoon et al. (2017)

M-RNN first interpolates the missing values with a bidirectional RNN, separately for each time series, then refines the imputed values with a cross-sectional fully-connected network.

Powerful p -value combination methods to detect incomplete association
S. Yoon et al. (2021)

To combine p -values,

- The *Fisher* method converts them to χ^2 :

$$\begin{aligned} p_i &\stackrel{\text{iid}}{\sim} U(0, 1) \\ T &= -2 \sum \log p_i \sim \chi^2(2n); \end{aligned}$$

- The *Lancaster* method uses the sample sizes s_i as weights

$$L = \sum F_{\chi^2(s_i)}^{-1}(p_i) \sim \chi^2(\sum s_i)$$

but the excessive degrees of freedom decrease the power;

- The *weighted Fisher* method rescales the sample sizes to keep the same degrees of freedom, using $\chi^2(\text{df} = 2n) = \Gamma(k = n, \theta = 2)$;
- The *roP method* uses the r -th ordered (smallest) p -value

$$p_{(r)} \sim \text{Beta}(r, n - r + 1)$$

but it is very sensitive to the choice of r ;

- *OrdMeta* uses $x = \min_r F_{(r)}(p_{(r)})$ as statistic

$$p = 1 - n! \int_{F_{(n)}^{-1}}^1 \cdots \int_{F_{(2)}^{-1}}^{t_3} \int_{F_{(1)}^{-1}}^{t_2} dt_1 \dots dt_n.$$

R implementation in `metapro`, with `SymPy` for the integral.

Combining dependent p-values with an empirical adaptation of Brown's method
W. Poole et al. (2016)

To combine p -values, the Fisher method uses

$$p_i \stackrel{\text{iid}}{\sim} U(0, 1)$$

$$\Psi = \sum -2 \log p_i \sim \chi^2(2k).$$

If the p -values are not independent, the Brown (Kost) method posits $\Psi \sim c \cdot \chi^2(2f)$, estimates c and f by matching the first two moments

$$f = \frac{E[\Psi]^2}{\text{Var}[\Psi]}$$

$$c = \frac{\text{Var}[\Psi]}{2E[\Psi]}$$

$$E[\Psi] = 2k$$

$$\text{Var}[\Psi] = 4k + 2 \sum_{i < j} \text{Cov}[-2 \log p_i, -2 \log p_j]$$

and approximates the covariance as

$$\text{Cov}[-2 \log p_i, -2 \log p_j] = a\rho_{ij} + b\rho_{ij}^2 + c\rho_{ij}^3$$

$$a = 3.263 \quad b = -.719 \quad c = 0.027$$

$$\rho_{ij} = \text{Cor}(X_i, X_j)$$

$$X_i = \Phi^{-1}(p_i)$$

(in particular, this also assumes a Gaussian copula).

Instead, approximate the covariance with the ecdf.

How good are convex hull algorithms?
D. Avis et al. (1996)

There are several convex hull algorithm, each library implementing only one of them:

- Double description: `cddlib`, `porta`,
- Reverse search: `lrslib`,
- Quick hull: `qhull`.

Each of them has trouble dealing with some type of polytopes:

- Fat lattice: $\#\text{facets} \gg \text{size}$;
- Intricate: $\#\text{triangles} \gg \text{size}$;
- Dwarfed: $P = Q \cap H$, $\#\text{facets}_P < \#\text{facets}_Q$, $\text{size}_Q \gg \text{size}_P$, where the size is the space required to store both representations of the polytope (set of vertices, set of half-spaces) and \gg means “super-polynomial”.

Quasi-stable coloring for graph compression
M. Kayali and D. Suciu

The Weisfeler-Leman (WL) algorithm (aka colour refinement) produces a *stable colouring*, which can be used for graph reduction (merge all the nodes with the same colour), but the reduction is rather modest. Quasi-stable colourings allow two nodes to have the same colour if the number of neighbours they have in each colour is at most q . Applying the WL algorithm until there are n colours is a good heuristic.

Applications include betweenness centrality, maximum flow.

Adaptive hierarchical regular binning of data point features
D. Floros et al.

Efficient construction of a k -d-tree from the dyadic encoding of the point coordinates.

QUBO.jl: a Julia ecosystem for quadratic unconstrained binary optimization
P.M. Xavier et al.

Many optimization problems can be converted (automatically) to QUBO form (quadratic unconstrained binary optimization), which can be solved by many quantum computers.

Learning QUBO models for quantum annealing: a constraint-based approach
F. Richoux et al.

To convert a combinatorial optimization problem to QUBO form, we need to convert the constraints into quadratic terms in the objective function.

- For the 1-hot constraint, since $\sum x_i = 1 \Leftrightarrow (\sum x_i - 1)^2 = 0$, we can add $(\sum x_i - 1)^2$;
- Permutation constraints are handled similarly.

$$\forall \sigma \in \{0, 1\}^{n \times n} \quad \sigma \in \mathfrak{S}_n \Leftrightarrow \sigma \mathbf{1} = \mathbf{1} \wedge \sigma' \mathbf{1} = \mathbf{1}$$

Multi-fidelity covariance estimation in the log-Euclidean geometry
A. Maurais et al. (2023)

The Euclidean multi-fidelity covariance estimator

$$\hat{\Sigma}_n^{(0)} + \sum_{\ell} \alpha_{\ell} (\hat{\Sigma}_{n_{\ell}}^{(\ell)} - \hat{\Sigma}_{n_{\ell-1}}^{(\ell)})$$

is not guaranteed to be positive definite. Replace the Euclidean geometry with the log-Euclidean one (*i.e.*, use $\text{Log } \Sigma$ instead of Σ , and Fréchet average); the Bures-Wasserstein geometry, or the log-Cholesky geometry are alternative choices. (One can compute the optimal sizes n^* and the optimal weights α^* to maximize the MSE with a constraint on the total cost.)

The generalized variance and correlation are

$$\sigma_X^2 = \text{tr Cov}[XX']$$

$$\rho_{XY} = \frac{\text{tr Cov}[XX', YY']}{\sigma_X \sigma_Y}.$$

**Correlation matrix clustering
for statistical arbitrage portfolios
A. Cartea et al. (2023)**

- Take daily returns, for 600 stocks, over 4 years;
- Remove the market (adjusting for the CAPM beta);
- Compute the correlation matrix C ;
- View it as a weighted graph, with potentially negative weights; compute the Laplacians

$$\bar{A}_{ij} = |A_{ij}|$$

$$\bar{D}_{ii} = \sum_j |A_{ij}|$$

$$D_{ii} = \sum_j A_{ij}$$

$$L = \bar{D} - \bar{A}$$

$$\bar{L}_{rw} = I - \bar{D}^{-1}A$$

$$\bar{L}_{sym} = I - \bar{D}^{-1/2}A\bar{D}^{-1/2}$$

$$A = A^+ - A^-$$

$$D_{ii}^+ = \sum_j A_{ij}^+, \quad D_{ii}^- = \sum_j \bar{A}_{ij}$$

$$L^\pm = D^\pm - A^\pm$$

$$L_{sym}^\pm = (D^\pm)^{-1/2}L^\pm(D^\pm)^{-1/2}$$

$$(L_1, L_2) = (L^+ + \tau D^-, L^- + \tau D^+), \quad \tau > 0$$

$$(L_{1,sym}, L_{2,sym}) = (L_{sym}^+ + \tau I, L_{sym}^- + \tau I)$$

- Reduce the dimension using the k smallest (generalized) eigenvalues of \bar{L} or \bar{L}_{rw} or \bar{L}_{sym} or (L_1, L_2) or $(L_{1,sym}, L_{2,sym})$;
- Cluster the resulting points using k -means (with the same k);
- Choose k using random matrix theory (RMT), as the number of eigenvalues of C beyond $\lambda_+ = (1 + \sqrt{N/T})^2$, or the proportion of variance explained by the top eigenvalues of C .

**Is there a replication crisis in finance?
T. Engerslev et al. (2022)**

Apparently, no:

- Do not use returns, but risk-adjusted returns (CAPM alpha);
- Adjust for multiple testing, either with BY or, better, a Bayesian model, to account for correlation between factors (set the prior expected alpha to zero, and select the other with empirical Bayes, using only out-of-sample data to overcome the publication bias);
- Use that Bayesian model to compute the FDR.

**Constrained monotonic neural networks
D. Runje and S.M. Shankaranarayana (2023)**

Neural networks with positive weights and 3 activation functions (in different channels) $\not\prec \not\bowtie \not\bowtie$ can approximate any monotonic function (with ReLU alone,

we only get convex functions, and with $\not\prec$ alone, the network is difficult to train).

Previous solutions used complicated architectures (lattice networks), or a gradient penalty followed a search for non-monotonicity (MILP, SMT).

**How to address monotonicity
for model risk management
D. Chen and W. Ye**

There are several notions of monotonicity between features (e.g., past and present values of the same feature)

$$\forall c \geq 0 \quad f(x) \leq f(x + c)$$

$$\forall c \geq 0 \quad f(x, x + c) \leq f(x + c, x)$$

$$\forall c \geq 0 \quad f(x, y + c) \leq f(x + c, y)$$

(for instance, the probability of recidivism is strongly monotonic wrt felonies and dismeanors). For individual or weak monotonicity, used a GAM with $f'_i \geq 0$ or $f'_i \geq f'_j$. For strong pairwise monotonicity, use a GAM or a NAM (neural additive model), with univariate and bivariate features (groves of NAMs, GNAM) and penalties to ensure the required monotonicities.

**LinSATNet:
the positive linear satisfiability neural networks
R. Wang et al. (2023)**

The *Sinkhorn algorithm* converts a positive matrix $S \in \mathbf{R}_{\geq 0}^{m \times n}$ to a doubly stochastic one by alternatively normalizing its rows and columns to match marginal distributions $u \in \mathbf{R}_{\geq 0}^m, v \in \mathbf{R}_{\geq 0}^n$. It can be generalized to multiple sets of marginal distributions (it still converges).

To enforce constraints $Ax \leq B, Cx \geq D, Ex = F$, where A, B, C, D, E, F have nonnegative entries, to some input y , apply the generalized Sinkhorn algorithm to S

$$S = \exp(W/\tau)$$

$$W = \begin{bmatrix} y' & \beta \\ \beta \mathbf{1}' & \beta \end{bmatrix} = \left[\begin{array}{c|c} y_1 \cdots y_\ell & \beta \\ \hline \beta & \beta \end{array} \right]$$

with marginals encoding the constraints

$$a'x \leq b \quad u = [a' \ b] \quad v = \begin{bmatrix} b \\ a' \mathbf{1} \end{bmatrix}$$

$$c'x \geq d \quad u = [c' \ \gamma d] \quad v = \begin{bmatrix} (\gamma + 1)d \\ c' \mathbf{1} - d \end{bmatrix} \quad \gamma = \left\lfloor \frac{c' \mathbf{1}}{d} \right\rfloor$$

$$e'x = f \quad u = [e' \ 0] \quad v = \begin{bmatrix} f \\ e' \mathbf{1} - f \end{bmatrix}$$

**Autocoreset: an automatic practical
coreset construction framework
A. Maalouf et al.**

A *coreset* is a (weighted) subset of the training data on which the loss function takes similar values. Given a matrix $M \in \mathbf{R}^{n \times m}$, a vector summarization ε -coreset

is a subset $J \subset [n]$ and a weight function $w : J \rightarrow \mathbf{R}_+$ such that

$$\left\| \sum_{i \in [n]} M_i - \sum_{j \in J} w(j) M_j \right\|_2^2 \leq \varepsilon.$$

Given

$$\begin{aligned} &\theta_1, \dots, \theta_m \\ \text{Data} &= \{x_1, \dots, x_n\}, \\ M_{ij} &= \ell(x_i, \theta_j) \end{aligned}$$

iterate

$$\begin{aligned} (I, w) &= \text{Coreset}_m(M) \\ \theta^* &= \underset{\theta}{\text{Argmin}} \sum_{i \in I} w(i) f(x_i, \theta) \\ M_{i, m+1} &= \ell(x_i, \theta^*). \end{aligned}$$

***Lowering the pre-training tax
for gradient-based subset training:
a lightweight distributed pre-training toolkit***
Y. Ro et al. (2023)

Pretrain using all the data, in a distributed fashion, as a model soup, with each model trained independently on a subset of the data (to limit communication); then, find a subset of the data with the same gradient distribution as the whole data, and finish training on that.

***Compositional exemplars
for in-context learning***
Y. Ye et al. (2023)

Determinantal point process (DPP) to select (with maximum a posteriori (MAP) estimators) examples for few-shot learning.

$$\begin{aligned} P(S) &= \frac{\det L_S}{\det(L_I)} \\ L_{ij} &= k(a_i, a_j) \end{aligned}$$

modified to include a relevance term:

$$\begin{aligned} a_i &: \text{exemplar} \\ x &: \text{task} \\ r_i &= g(a_i, x) \text{ relevance of } a_i \text{ to } x \\ \tilde{L} &= \text{diag}(r) L \text{diag}(r) \\ \log \det \tilde{L}_S &= \sum_{i \in S} \log r_i^2 + \log \det L_S \end{aligned}$$

DPPy: DPP sampling with Python
G. Gautier et al. (2019)

***Data-driven subgroup identification
for linear regression***
Z. Izzo et al. (2023)

To find a region where the relation $x \mapsto y$ is almost linear,

- Fit a linear model on the k nearest neighbours of each point;
- Pick the model with the lowest training error
- Enlarge the neighbourhood to include all points with a low error for that model
- Pick the largest ball (or polytope) containing only points in that subset.

***XTab: cross-table pretraining
for tabular transformers***
B. Zhu et al. (2023)

Self-supervised learning for tabular data can use the following losses:

- Reconstruction: reconstruct a corrupted row (60% of the entries have been replaced by resampling from the corresponding column)
- Contrastive loss: the positive pairs are (x, \tilde{x}) , where x is a row and \tilde{x} a corrupted version of it; the negative pairs are different rows.
- Supervised loss: predict the value of a column.

You can pretrain a single model and fine-tune it on different tables and tasks:

- Featurize a row into a sequence of “tokens” (embeddings), ending with CLS: for qualitative columns, learn an embedding, for quantitative columns, learn an affine transformation $\mathbf{R} \rightarrow \mathbf{R}^d$;
- Feed it to an FT-transformer (or some other transformer variant);
- Finish with a projection head.

The transformer is shared across tasks and frozen after pretraining; the featurizers and projection heads are task-specific and have to be re-trained.

***TransTab: learning transferable tabular
transformers across tables***
Z. Wang and J. Sun

Earlier paper with a similar idea and a *gated transformer*, *i.e.*, a transformer followed by a gated feedforward layer: $x \mapsto W_1(W_2 \odot x \oplus W_3x)$.

***Revisiting deep learning models
for tabular data***
Y. Gorishniy et al.

The FT-Transformer tokenizes the rows (*i.e.*, converts them to sequences of embeddings) before feeding them to the transformer:

- For qualitative columns, learn an embedding of the possible values;
- For quantitative columns, learn an affine transform $\mathbf{R} \rightarrow \mathbf{R}^d$;
- Append a CLS token,

Also try a ResNet.

Fastformer:
additive attention can be all you need
 C. Wu et al.

Efficient transformer variants use:

- Hashing (Reformer)
- Low-rank factorizations (Linformer)
- A mixture of local and global attention (Longformer, BigBird)

The FastFormer reduces the dimension of the attention matrix.

by adding linear transformations.

Big Bird: *transformers for longer sequences*
 M. Zaheer et al.

BigBird makes transformers more scalable by combining:

- Moving window attention;
- Sparse (random) attention – random graphs are good approximations of complete graphs;
- Global attention, either allowing a few random tokens to attend to all other tokens, or by adding a few CLS tokens.

BigBird is still a Turing-complete universal approximator.

SAINT: *improved neural networks for tabular data via row attention and contrastive pre-training*
 G. Somepalli et al.

Transformer on tabular data, alternating between:

- Within-row attention,
- Between-row attention, concatenating the embeddings of all the columns (limited to rows in the current batch).

Pre-train in a self-supervised way (contrastive learning with the InfoNCE loss and/or denoising).

CoDi: *co-evolving contrastive diffusion models for mixed type tabular synthesis*
 C. Lee et al. (2023)

The *diffusion probabilistic model* can be defined for continuous

$$q(x_t|x_{t-1}) = N(x_t; \sqrt{1 - \beta_t}x_{t-1}, \beta_t I)$$

$$p_\theta(x_{t-1}|x_t) = N(x_{t-1}; \mu_\theta(x_t, t), \Sigma_\theta(x_t, t))$$

or discrete variables

$$q(x_t|x_{t-1}) = (1 - \beta_t)\mathbf{1}_{x_t=x_{t-1}} + \beta_t \text{Unif}(x_t)$$

$$p_\theta(x_{t-1}|x_t) = \sum_{x_0} q(x_{t-1}|x_t, x_0) p_\theta(x_0, x_t)$$

$$q(x_{t-1}|x_t, x_0) = (\text{Bayes}).$$

Both minimize

$$\text{KL}(q(x_{t-1}|x_t, x_0) \| p_\theta(x_{t-1}|x_t)).$$

For tabular data, use two models, one continuous, one discrete, each conditioned on the other one at each step.

TabDDPM: *modeling tabular data with diffusion models*
 A. Kotelnikov

Similar idea, with a quantile transformation of quantitative columns.

Compressing tabular data via latent variable estimation
 A. Montanari and E. Weiner (2023)

To compress tabular data, first cluster the rows and columns (*k*-means on the SVD).

Tromp: *towards a better deep neural network for tabular data*
 K.Y. Chen et al. (2023)

Use task- (prompt-) specific feature importances.

Learning deep time-index models for time series forecasting
 G. Woo et al. (2023)

Learn a “time-index” model, *i.e.*, a 1-dimensional implicit neural representation (INR, NeRF – these generalize the classical structural time series models decomposing a time series into trend, cycle and holiday components)

$$\hat{y}_t = f_{\theta, \phi}(\tau(t))$$

where τ are random Fourier features and the parameters are separated into curve-fitting θ and forecasting/extrapolating (inductive bias) ϕ :

$$\begin{aligned}\theta &\leftarrow \underset{\theta}{\text{Argmin}} \text{fitting error}(\theta, \phi) && \text{on } [t-h, t] \\ \phi &\leftarrow \underset{\phi}{\text{Argmin}} \text{forecasting error}(\theta, \phi) && \text{on } [t, t+h].\end{aligned}$$

Non-autoregressive conditional diffusion models for time series prediction
L. Shen and J.T. Kwok (2023)

TimeDiff forecasts a time series using a diffusion model using, as conditioners:

- An AR model of the past, computed as

$$\sum w_i \odot x_{t-i} + b;$$

- A mixture of the past, $x_{\leq t}$, transformed with a conv-net, and the future, $x_{>t}$ (a kind of teacher forcing).

The sigmoid-weighted linear unit is

$$\text{SiLU}(z) = \sigma(z) \odot z.$$

Also check: CSDI, SSSD, FedFormer, NBeats.

CSDI: conditional score-based diffusion models for probabilistic time series imputation
Y. Tashiro et al. (2021)

Diffusion model to impute the missing values in a time series, conditioning on the observed values, trained with self-supervised learning.

Efficiently modeling long sequences with structured state spaces
A. Gu et al.

The three ways of representing a state space model (SSM), continuous time, recurrent, and convolutional, are related.

$$\begin{aligned}x' &= Ax + Bu \\ y &= Cx \\ x_k &= \bar{A}x_{k-1} + \bar{B}u_k \\ y_k &= Cx_k \\ \bar{A} &= (I - \tfrac{1}{2}hA)^{-1}(I + \tfrac{1}{2}hA) \\ \bar{B} &= (I - \tfrac{1}{2}hA)^{-1}hB \\ y &= K * u \\ K &= (C\bar{A}^0\bar{B}, C\bar{A}^1\bar{B}, \dots, C\bar{A}^{n-1}\bar{B}, C\bar{A}^n\bar{B})\end{aligned}$$

With the HiPPO matrix

$$A_{nk} = - \begin{cases} (2n+1)^{1/2}(2k+1)^{1/2} & \text{if } n > k \\ n & \text{if } n = k \\ 0 & \text{otherwise} \end{cases}$$

the SSM (S4) memorizes its input u .

It is possible to efficiently compute the convolution with K if A is normal ($AA^* = A^*A$; equivalently, $A = UDU^*$, D diagonal, $UU^* = I$). The HiPPO matrix is the sum of a normal and a low-rank matrix; it is still possible to efficiently compute the convolution with K . With a change of basis, we can replace the normal matrix with a diagonal one.

HiPPO: recurrent memory with optimal polynomial projections
A. Gu et al. (2020)

To compress the information contained in a function $f|_{[0,t]}$, online (*i.e.*, progressively, updating the compressed information as t increases), project it on a finite-dimensional subspace, e.g., that of polynomials of degree less than N , for some measure μ_t on $[0, t]$,

$$g_t = \underset{\substack{g \in \mathbf{R}[X] \\ \deg g < N}}{\text{Argmin}} \left\| f_{\leq t} - g \right\|_{L^2(\mu_t)}.$$

The measure μ_t defines orthogonal polynomials $(g_n)_{n < N}$; the coefficients of g_t in this basis are

$$c_k(t) = \langle f_{\leq t}, g_k \rangle_{\mu_t}.$$

They are solution of an ODE.

$$\frac{dc(t)}{dt} = A_t c(t) + B_t f(t)$$

For instance:

- Legendre (LMU, Legendre memory unit)

$$\begin{aligned}\mu_t &= \frac{1}{\theta} \mathbf{1}_{t-\theta, t} \\ A_{nk} &= \frac{1}{\theta} \begin{cases} (-1)^{n-k}(2n+1) & \text{if } n \geq k \\ (2n+1) & \text{if } n \leq k \end{cases} \\ B_n &= \frac{1}{\theta} (2n+1)(-1)^n\end{aligned}$$

- Laguerre

$$\begin{aligned}\mu_t(x) &= e^{-(t-x)} \mathbf{1}_{x \leq t} \\ A_{nk} &= \mathbf{1}_{n \geq k} \\ B_n &= 1\end{aligned}$$

- Scaled Legendre

$$\begin{aligned}\mu_t &= \frac{1}{t} \mathbf{1}_{[0,t]} \\ A_{nk} &= \begin{cases} (2n+1)^{1/2}(2k+1)^{1/2} & \text{if } n > k \\ n+1 & \text{if } n = k \\ 0 & \text{if } n < k \end{cases} \\ B_n &= (2n+1)^{1/2}\end{aligned}$$

- Fourier recurrent unit (FRU): orthogonal polynomials on the unit circle $\{z : |z| = 1\}$.

This can be used inside an RNN, to increase memory.

It's raw!

Audio generation with state space models
K. Goel et al.

UNet with S4 blocks for audio generation; can be bidirectional.

S4 is a state-space model, not computed iteratively, but all at once, with a convolution – this can be done efficiently if the matrix is diagonal-plus-low-rank (1 or 3); it is initialized with a HiPPO matrix. Parametrizing the matrix as $\Lambda - pp^*$, Λ diagonal, $p \in \mathbf{R}^{N \times r}$, instead of $\Lambda + pq^*$, ensures it is Hurwitz (its eigenvalues have a negative part), *i.e.*, the corresponding SSM is stable.

Diffusion-based time series imputation and forecasting with structured state space models
J.M. Lopez and N. Strodthoff

SSSD is a diffusion model with S4 blocks for missing value imputation in time series.

Deep latent state space models for time series generation
L. Zhou et al.

Variant of S4 with an extra latent variable.

Simple hardware-efficient long convolutions for sequence modeling
D.Y. Fu et al. (2023)

The *butterfly decomposition* decomposes the FFT on $n = n_1 n_2$ values into FFTs on n_1 and n_2 values (by reshaping the input as an $n_1 \times n_2$ matrix and applying the FFT on the rows and columns – you can also fine-tune the FFT coefficients, keeping the same sparsity patterns, to get an FFT-like transformation). To improve the performance of the long convolution (S4), tweak the kernel: dropout, smoothing (moving average), quashing of small values.

Neural continuous-discrete state space models for irregularly-sampled time series
A.F. Ansari et al.

If the observations, in a state space model (SSM) (observed at irregular intervals) are high-dimensional, use lower-dimensional auxilliary variables.

Use linear or locally linear dynamics, which interpolate

between SSMs.

$$\begin{aligned} dz &= f(z, t)dt + G(z, t)dB \\ f(z, t) &= F(z)z \\ G(z, t) &= I \\ F(z) &= \sum \alpha_j(z)F_j \\ \alpha(z) &= \text{softmax}(g(z)) \\ g &: \text{neural net} \\ F_j &: \text{basis matrices} \end{aligned}$$

Feature programming for multivariate time series prediction
A. Reneau et al. (2023)

Automatically generate features for multivariate time series by combining operators $\text{Diff}(x_i, x_j) = x_i - x_j$, Lag , Δ , Δ^2 , MA .

The Ising model

$$\begin{aligned} P(\sigma) &\propto \exp -\beta \left(\sum_{(i,j) \in E} J_{ij} \sigma_i \sigma_j + \sum_{i \in V} h_i \sigma_i \right) \\ \sigma_i &\in \{\pm 1\} \end{aligned}$$

can be turned into a dynamic process (Glauber dynamics).

$$\begin{aligned} P(\sigma_{i,t+1}) &\propto \exp(\sigma_{i,t+1} \gamma_{it}) \\ \gamma_{it} &= \sum_j J_{ij} \sigma_j + h_i \end{aligned}$$

Learning perturbations to explain time series predictions
J. Enguehard (2023)

To explain a model f , one can use: a local linear approximation, the gradient of the output wrt the features, or a perturbation: modify the input on a mask, as small/large as possible, to decrease/preserve the performance as much as possible. Instead of a fixed perturbation (average, moving average, Gaussian blur, etc.) use a neural network:

$$\begin{aligned} \text{Find} & \quad m, \text{NN} \\ \text{To minimize} & \quad d[f(x), f(\Phi(x, m))] + \|m\|_1 + \|\text{NN}(x)\|_1 \\ \text{Such that} & \quad 0 \leq m \leq 1 \\ \text{Where} & \quad \Phi(x, m) = m \odot x + (1 - m) \odot \text{NN}(x) \end{aligned}$$

FaDIn: fast discretized inference for Hawkes processes with general parametric kernels
G. Staerman et al. (2023)

To speed up the estimation of multivariate Hawkes processes with parametric (non-exponential) kernels (which is quadratic in general), assume the kernel has bounded support (limit on the influence of a past event) and discretize the temporal point process.

FEDformer: frequency-enhanced decomposed transformer for long-term series forecasting
T. Zhou et al.

Use a transformer in Fourier (or wavelet) space, but only keep a random subset of the Fourier components. For the wavelets, process the different scales separately.

To extract the trend, use average filters of different sizes, and combine them.

Self-interpretable time series prediction with counterfactual explanations
J. Yan and H. Wang

CountTS is a variational Bayes model for time series tasks (classification, regression, etc.).

Data generation:

$$\begin{aligned} u &\sim N(0, I) \\ z &\sim N(\mu(u, x), \sigma^2(u, x)) \\ y &\sim N(\mu(u, z), \sigma^2(u, z)) \end{aligned}$$

Inference:

$$\begin{aligned} y &\sim x \\ u &\sim x, y \\ z &\sim x, y \end{aligned}$$

Feasible counterfactual explanations only change non-constant parts of the input (e.g., they do not suggest to change the age of the patient).

Sequential multi-dimensional self-supervised learning for clinical time series
A. Raghu et al. (2023)

Use both a global and a cross-sectional self-supervised learning (SSL) loss, e.g, NX-Xent (SimCLR)

$$\text{Mean}_i - \log \frac{\exp(\text{sim}_{ij}/\gamma)}{\sum_{k \neq i} \exp(\text{sim}_{ik}/\gamma)}$$

or VICReg.

Modeling temporal data as continuous functions with stochastic process diffusion
M. Biloš et al. (2023)

DDPM (denoising diffusion probabilistic model) for time series in function space, with noise given by

- A Gaussian process (GP) with RBF kernel $\kappa(\tau) = \exp(-\gamma\tau^2)$;
- An OR diffusion

$$d\varepsilon_t = -\gamma\varepsilon_t dt + dW_t,$$

sampled as a time-changed, scaled Wiener process $\exp(-\gamma t)W_{\exp(2\gamma t)}$, i.e., a GP with a Matérn kernel, $\nu = 1/2$, $\kappa(\tau) = \exp -\gamma |\tau|$.

Applications: forecasting and imputation, for irregular time series.

Probabilistic imputation for time series classification with missing data

VAE-like model for multiple imputation in time series, in the MNAR setup.

Sequential Monte Carlo learning for time series structure discovery
F.A. Saad et al. (2023)

Particle filter (SMC) to select a GP kernel, from a probabilistic context-free grammar (PCFG)

$$\begin{aligned} B &= \text{Linear} \mid \text{Periodic} \mid \text{Gamma} \mid \dots \\ \oplus &= + \mid \times \mid \text{ChangePoint} \\ K &= B \mid (K_1 \oplus K_2) \end{aligned}$$

to model a univariate time series.

I²SB: Image-to-image Schrödinger bridge
G.H. Liu et al.

The Schrödinger bridge generalizes diffusion models.

Provably convergent Schrödinger bridge with applications to probabilistic time series imputation
Y. Chen et al.

The Schrödinger bridge from measure μ to measure ν wrt the prior stochastic process q is the stochastic process

$$p = \underset{\substack{p_0=\mu \\ p_1=\nu}}{\text{Argmin}} \text{KL}(p||q).$$

It generalizes diffusions.

$$\begin{aligned} dx_t &= f(x_t, t)dt + g(t)dW_t \\ dx_t &= [f(x_t, t) - g(t)^2 \nabla \log p_t(x_t)]dt + g(t)d\bar{W}_t \\ dx_t &= [f(x_t, t) - g(t)^2 \nabla \log \vec{\psi}(x_t)]dt + g(t)dW_t \\ dx_t &= [f(x_t, t) + g(t)^2 \nabla \log \vec{\psi}(x_t)]dt + g(t)d\bar{W}_t \end{aligned}$$

**Regions of reliability in the evaluation
of multivariate probabilistic forecasts**
É. Marcotte et al.

A *scoring rule* measures if an observation $y \sim \mathcal{D}$ is consistent with a forecasted distribution $\hat{\mathcal{D}}$; for instance,

$$\text{NLL}(y, \hat{\mathcal{D}}) = -\log p_{\hat{\mathcal{D}}}(y)$$

$$\text{ES}(y, \hat{\mathcal{D}}) = \mathbb{E}_{x \sim \hat{\mathcal{D}}} \|y - x\|^2 - \frac{1}{2} \mathbb{E}_{x, x' \sim \hat{\mathcal{D}}} \|x - x'\|^2$$

$$\text{CRPS}(y, \hat{\mathcal{D}}) = \int_{-\infty}^{+\infty} (\Phi_{\hat{\mathcal{D}}}(x) - \mathbf{1}_{x \geq y})^2 dx$$

$$\text{VG}(y, \hat{\mathcal{D}}) = \sum_{a,b} \left(|y_a - y_b|^p - \mathbb{E}_{x \sim \hat{\mathcal{D}}} |x_a - x_b|^p \right)^2$$

$$\text{DS}(y, \hat{\mathcal{D}}) = \log |\det \Sigma_{\hat{\mathcal{D}}}| + (y - \mu_{\hat{\mathcal{D}}})' \Sigma_{\hat{\mathcal{D}}}^{-1} (y - \mu_{\hat{\mathcal{D}}}).$$

A scoring rule S is *proper* if

$$\forall \hat{\mathcal{D}} \quad \mathbb{E}_{y \sim \mathcal{D}} S(y, \mathcal{D}) \leq \mathbb{E}_{y \sim \mathcal{D}} S(y, \hat{\mathcal{D}}).$$

With small samples, they may fail to spot forecasts with significant imperfections.

**Learning the dynamics
of sparsely observed interacting systems**
L. Bleistein et al. (2023)

Given a controlled differential equation (CDE) $dy_t = G(y_t, x_t)dt$, its solution map $\Psi : (x_{[0,t]}, t) \mapsto y_t$ is linear in signature space: $\Psi(x_{[0,t]}, t) = S_N(x_{[0,t]})'\theta$. The signature transform allows x and y to be irregularly observed time series; y can be sparser.

**Sequential predictive
conformal inference for time series**
C. Xu and Y. Xie (2023)

Conformal inference assumes the data is exchangeable: this assumption does not hold for time series. One could adjust the significance level α to recover the desired coverage (AdaptCI), or leverage the serial dependence of the non-conformity scores with (random forest) quantile regressions (SPCI).

**Resurrecting recurrent neural networks
for long sequences**
A. Orvieto et al. (2023)

Stacking linear recurrent units (LRU – no non-linearity)

$$x_t = \text{diag}(\lambda)x_{t-1} + \gamma \odot u_t$$

$$\lambda_j = \exp(-e^{\nu_j} + ie^{\theta_j})$$

$$\gamma_j = \sqrt{1 - \lambda_j^2}$$

$$u = \text{input}$$

and non-linear MLP blocks recovers the long-range performance of S4.

**Generalized teacher forcing
for learning chaotic dynamics**
F. Hess et al. (2023)

To model (chaotic) dynamical systems and avoid exploding gradients, use:

- Generalized teacher forcing, $\tilde{z}_t = (1 - \alpha)z_t + \alpha\hat{z}_t$, where z_t is from the model and \hat{z}_t is observed;
- A 1-layer RNN, with skip-connection, and clipped ReLU 

**D-CODE: discovering closed form ODEs
from observed trajectories**
Z. Qian et al.

To find an ODE $\dot{x} = f(x)$ from trajectories x , when the data is noisy and/or infrequently sampled (so that we cannot reliably estimate \dot{x} and use symbolic regression, **gplearn**), use the *variational formulation* of $\dot{x} = f(x)$ (multiply by a test function g such that $g(0) = g(T) = 0$, integrate between 0 and T , integrate by parts to remove \dot{x}):

$$C = \int_0^T x(t)\dot{g}(t)dt + \int_0^T f(x(t))g(t)dr.$$

**Understanding over-squashing and bottlenecks
on graphs via curvature**
J. Topping et al.

The *balanced Forman curvature* of an edge $i-j$ counts:

- The number of triangles containing that edge (positive curvature);
- The number of 4-cycles with no diagonal, containing that edge (zero curvature);
- The number of remaining outgoing edges (negative curvature).

Oversquashing is caused by negatively curved edges (bottlenecks).

To limit it, rewire the graph using the stochastic discrete Ricci flow (SDRF):

- Pick the edge $i-j$ with the minimum curvature;
- Add the edge $k-\ell$ increasing the curvature the most, where k and ℓ are neighbours of i and j (or i and j themselves);
- Remove edges with curvature above some threshold.

The *Ollivier curvature* of an edge $i-j$ is

$$\kappa(i, j) = \lim_{\alpha \rightarrow 1} \frac{1 - W_1(\mu_i^\alpha, \mu_j^\alpha)}{1 - \alpha}$$

where

- μ_i^α is the measure on $B_1(i)$ (the ball of radius 1 centered on i , *i.e.*, i and its immediate neighbours) putting weight α on i and $(1 - \alpha)/d_i$ on its neighbours;
- W_1 is the Wasserstein distance (for the geodesic distance on the graph)

$$W_1(\mu_i, \mu_j) = \inf_{\sum_k M_{kw} = \mu_j(w)} \sum_{k,w} M_{kw} d(k, w)$$

The augmented *Forman curvature* only considers triangles.

$$F(i, j) = 4 - d_i - d_j + 3\#_{\Delta}^{ij}$$

Rewiring networks for graph neural network training using discrete geometry
J. Bober et al.

Same algorithm, but the edge added is picked at random, using the softmax of the curvature improvement.

The *Ricci flow* on a manifold

$$\frac{\partial g}{\partial t} = -2\text{Ric}(g)$$

“smooths” a manifold:

In dimension 2, $\text{Ric}(g) = kg$, where k is the Gauss curvature.

Diffusion improves graph learning
J. Gasteiger et al. (2019)

The generalized diffusion matrix is

$$S = \sum_{k \geq 0} \theta_k T^k,$$

for instance PPR (personalized page rank), $T = AD^{-1}$, $\theta_k = \alpha(1 - \alpha)^k$, or heat diffusion, $T = AD^{-1}$, $\theta_k = e^{-t} t^k / k!$ (add weighted self-loops to the adjacency matrix A ; you can also use the symmetric transition matrix $T_{\text{sym}} = D^{-1/2} A D^{-1/2}$ instead of the random walk one $T_{\text{rw}} = AD^{-1}$).

Truncate it (keeping the top k entries in each column, or the entries above some threshold) and use the resulting (weighted) graph instead of the original one (graph diffusion convolution, GDC, DIGL).

DRew: dynamically rewired message passing with delay
B. Gutteridge et al. (2023)

To limit oversquashing in GNNs, have each node at layer k directly receive input from nodes k hops away (instead of via its immediate neighbours) either their current (DRew) or initial (ν DRew) state.

Expander graph propagation
A. Deac et al. (2022)

The *Cheeger constant* of a connected graph $G = (V, E)$ is

$$h(G) = \min_{\substack{A \subset V \\ 0 < |A| < \frac{1}{2}|V|}} \frac{|\partial A|}{|A|}.$$

Let $0 = \lambda_0 < \lambda_1 < \lambda_2 < \dots$ be the eigenvalues of the Laplacian of a graph G .

An *expander family* is a family of graphs $(G_i)_{i \in I}$ such that $\forall i \lambda_1(G_i) \geq c$, for some $c > 0$; equivalently, $\forall i h(G_i) \geq \varepsilon$, for some $\varepsilon > 0$. In an expander family with bounded degree,

$$\text{diam}(G_i) = O(\log |V_i|).$$

The *Cayley graph* of a group G wrt a generating set S has the elements of G as nodes, and edges $g \rightarrow gs$ for $g \in G, s \in S$.

$$G_n = \text{Cayley} \left(\text{SL}_2(\mathbf{Z}/n), \left\{ \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}, \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix} \right\} \right)$$

is an expander family with $O(n^3)$ nodes. G_n is locally tree-like, up to distance $O(\log n)$.

All the edges have negative curvature, but not enough to produce oversquashing – in any case, expansion, sparsity and non-negative curvature are incompatible: if there is a bound on the degree and the Cheeger constant, there are only finitely many such graphs.

To address oversquashing, interleave a GNN on the input graph with a GNN on the Cayley graph (build it breadth-first, and only keep the first $|V|$ nodes – it is connected).

Other ways of addressing oversquashing include:

- Adding a master node;
- Feature augmentation;
- Graph rewiring (personalized page-rank, stochastic discrete Ricci flow).

Relevant walk search for explaining graph neural networks
P. Xiong et al. (2023)

With the max-product algorithm, layerwise relevance propagation (LRP) can return the top- k most relevant walks in polynomial time.

Brauer’s group equivariant neural network
E. Pearce-Crump (2023)

Description of a generating set of

$$\text{hom}_G((\mathbf{R}^n)^{\otimes k}, (\mathbf{R}^n)^{\otimes \ell})$$

for $G = \text{O}(n)$, $\text{SO}(n)$ or $\text{Sp}(n)$, where the action of G on $(\mathbf{R}^n)^{\otimes k}$ is

$$g \cdot (x_1 \otimes \dots \otimes x_k) = (gx_1) \otimes \dots \otimes (gx_k).$$

In an equivariant neural net, the layers are representations (rather than just vector spaces) and the maps between them are equivariant (representation morphisms).

Neural execution of graph algorithms
P. Veličković et al.

Train a graph neural net to learn, simultaneously, several graph algorithms (e.g., breadth-first search and Bellman-Ford shortest paths) with a shared “processor” and task-specific encoders and decoders; reuse this processor for other graph tasks.

The *Prüfer sequence* of a tree with nodes labeled 1 to n is obtained as follows: in step i , remove the leaf with the smallest label and store the label of its neighbour in position i .

Neural priority queues for graph neural networks
R. Jain et al. (2023)

Differentiable priority queue.

Recursive algorithmic reasoning
D. Jayalath et al.

Augment GNNs with a stack, for recursive tasks, e.g., depth-first search.

Learning to boost training by periodic nowcasting near future weights
J. Jang et al. (2023)

The weight nowcaster network forecasts future (short-term) weights and allows to intermittently skip a few epochs.

A unifying causal framework for analyzing dataset shift-stable learning algorithms
A. Subbaswamy et al. (2022)

When using a causal graph, pay attention to “unstable edges” – edges whose conditional probability distribution may change.

Breaking the curse of depth in graph convolutional networks via refined initialization strategy
S. Wang et al. (2023)

To check if the initialization of a (graph) neural net is satisfactory, look at forward signal propagation, backward signal propagation, and diversity propagation,

$$\frac{\mathbb{E} \|H^{(L)}\|_F^2}{\mathbb{E} \|X\|_F^2} \quad \mathbb{E} \left\| \frac{\partial L}{\partial W^{(1)}} \right\| \quad \mathbb{E} \frac{\text{Dir } H^{(L)}}{\|H^{(L)}\|_F^2}$$

where the Dirichlet energy is $\text{Dir } H = \text{tr}(H' L H)$ and L is the normalized Laplacian.

We do not want those quantities to vanish or explode as $L \rightarrow \infty$; with traditional initialization schemes (Kaiming, Xavier), they do.

MetaInit and SPoGInit scale the weights, layerwise, to improve propagation (make the signal propagations close to 1, and the diversity propagation large).

Adding residual connections, initialized at (0,1), also helps (ReZero, ReZeroGCN)

Model soups: averaging weights of multiple fine-tuned models improves accuracy without increasing inference time
M. Wortsman et al. (2022)

When fine-tuning, instead of selecting the best model after hyperparameter search, or averaging the predictions of all the models (ensembling), average the weights, either of all the models (uniform soup), or by adding the models to the soup only if they improve the test set accuracy (greedy soup).

Robust fine-tuning of zero-shot models
M. Wortsman et al.

Fine-tuning improves accuracy on the target distribution, but reduces robustness to distribution shifts. Instead, ensemble the weights of the zero-shot (not fine-tuned) and fine-tuned models (WiSE-FT).

Categorizing variants of Goodhart’s law
D. Manheim and S. Garrabrant (2019)

There are several categories of Goodhart’s law:

- The metric is a noisy version of the intended goal – the optimization may be misled by the noise;
- The metric is a good approximation of the intended goal, but only in a small region of the search space – the optimizer may leave that region;
- The causal relation between the metric and the intended goal is not direct, and someone (the regulator, or the agent – in particular if his own goal is different (cobra effect)) manipulates X .

TRAK: Attributing model behaviour at scale
S.M. Park et al. (2023)

Data attribution decomposes the output of a model $z \mapsto f(z, \theta)$ into a sum of contributions of the training samples S .

$$f(x, \theta^*(S')) \approx \tau(z, S) \cdot \mathbf{1}_{S'} \quad \text{for } S' \subset S$$

This can be done with a lasso linear regression (data-model)

$$\tau(z, S) = \underset{\beta \in \mathbf{R}^n}{\text{Argmin}} \sum_i [\beta' \mathbf{1}_{S_i} - f(z, \theta^*(S_i))]^2 + \lambda \|\beta\|_1$$

for random subsets $S_1, \dots, S_n \subset S$ of sizes $\alpha |S|$, $\alpha \in S$, but this requires fitting n models (thousands).

Instead:

- Linearize the model;
- Reduce the dimension (random projection)

$$\phi(z_i) = P' \nabla_{\theta} f(z_i, \theta^*(S));$$

- The model has become a logistic regression: we can directly compute the approximate leave-out-one influence;
- Ensemble (over random subsets $S_i \subset S$);
- Soft-threshold.

Eigen memory trees
M. Rucker et al. (2022)

High-dimensional variant of quad-trees:

- The data is stored in the leaves of a binary tree;
- Routing is done by testing if

$$\langle x, \text{node.router} \rangle \geq \text{node.boundary};$$

- When a leaf has become too large, it is split using the first principal component of the points it contains.

Application: memory for episodic replay in reinforcement learning (contextual bandits).

Automated search for conjectures on mathematical constants using analysis of integer sequences
O. Razon et al.

Continued fractions can be written

$$\begin{aligned} c &= a_0 + \frac{b_1}{a_1 + \frac{b_2}{a_2 + \frac{b_3}{a_3 + \dots}}} \\ &= a_0 + \sum_{i=1}^{\infty} \frac{b_i}{a_i} \\ &= a_0 + \frac{b_1}{a_1 +} \frac{b_2}{a_2 +} \frac{b_3}{a_3 +} \dots \end{aligned}$$

In a sign-interlaced continued fraction, $(b_i)_{i \geq 1}$ is periodic and $\forall i \ b_i \in \{\pm 1\}$.

The non-terminating Euclidean algorithm for $(\alpha, 1)$ computes the simple ($\forall i \ b_i = 1$) continued fraction of α . It can be extended to allow for sign variation ($\forall i \ b_i \in \{\pm 1\}$), *i.e.*, negative remainders.

The Berlekamp-Massey algorithm finds the minimal linear recurrence sequence with integer coefficients producing a given integer sequence.

Given a constant α (e.g., $\tan 1$), generate its sign-interlaced continued fractions (for all sign patterns up to period T) and look for a linear recurrence for the a_i 's.

Refining generative process with discriminator guidance in score-based diffusion models
D. Kim et al. (2023)

Given a pre-trained diffusion model, train a discriminator $d_{\phi}(x, t)$ to distinguish between real images and generated ones, at all noise levels t . Adjust the learned score function by adding

$$\nabla \log \frac{d_{\phi}(x_t, t)}{1 - d_{\phi}(x_t, t)}.$$

Understanding deep generative models with generalized empirical likelihoods
S. Ravuri et al.

Given n independent samples $x_1, \dots, x_n \sim p$, the *empirical likelihood* method checks if their mean is $c \in \mathbf{R}^d$

$$\underset{x \sim p}{\text{E}} [x] \stackrel{?}{=} c$$

using the weighted empirical distribution $\hat{p}_{\pi} = \sum \pi_i \delta_{x_i}$ maximizing $\text{KL}(\hat{p}_{\pi} \| p)$ with the prescribed mean, where $\hat{p}_n = \sum_i \frac{1}{n} \delta_{x_i}$.

$$\begin{array}{ll} \text{Find} & \pi \in \mathbf{R}^n \\ \text{To maximize} & \sum_i \log \pi_i \\ \text{Such that} & \forall i \ \pi_i \geq 0 \\ & \sum \pi_i = 1 \\ & \sum \pi_i x_i = c \end{array}$$

The *generalized empirical likelihood* uses a moment condition instead,

$$\underset{x \sim p_{\pi}}{\text{E}} [m(x, c)] = 0$$

and a Cressie-Read divergence instead of the KL divergence.

Such divergences include

$$\begin{array}{ll} \text{KL}(\hat{p}_n \| p_{\pi}) & \text{Maximize } \prod \pi_i \\ \text{KL}(p_{\pi} \| \hat{p}_n) & \text{Maximize } - \sum \pi_i \log \pi_i \\ \frac{1}{2} \sum \left(\pi_i - \frac{1}{n} \right)^2 & \text{Minimize } \left(\pi_i - \frac{1}{n} \right)^2. \end{array}$$

Moments include

$$\begin{array}{ll} x - c & \text{mean} \\ \nabla_{\theta} \log p_{\theta}(x) & \text{score function} \\ [\phi(x), \phi(x) \phi(x)'] - c & \text{Fréchet inception distance} \\ k(x, t_i) - k(y, t_i) & \text{mean embedding} \end{array}$$

The mean embedding, which minimizes

$$\sum_i \left[\mathbb{E}_{x \sim p} k(x, t_i) - \mathbb{E}_{x \sim q} k(x, t_i) \right]^2$$

for “witness points” $t_i \sim r$, for some distribution r , is related to the *maximum mean discrepancy* (MMD)

$$\mathbb{E}_{x_1, x_2 \sim p} [k(x_1, x_2)] + \mathbb{E}_{y_1, y_2 \sim q} [k(y_1, y_2)] - 2 \mathbb{E}_{\substack{x \sim p \\ y \sim q}} [k(x, y)].$$

Try the mean embedding, with the exponential kernel $k(x, y) = \exp(x'y/d)$ and the reverse KL divergence (exponential tilting).

With inception, VGG16 or BYOL features ϕ , you can compare images from a generative model with those from the training data, and highlight those unlikely in the other set (e.g., missing modes).

DreamFusion: text-to-3D using 2D diffusion B. Poole et al.

Generate a 3D object as a NeRF (neural radiance field) from text using a pretrained text-to-image diffusion model (CLIP); the model is optimized anew for each new text.

OCD: learning to overfit with conditional diffusion models S. Lutati and L. Wolf (2023)

Diffusion process to generate the weights of another network (hypternetwork); ensemble several of the resulting models.

Evaluating self-supervised learning via risk decomposition Y. Dubois et al. (2023)

For a supervised learning model, the error can be decomposed into that coming from the limited model class and that coming from the finiteness of the training data:

$$\text{test error} = \text{training error} + (\text{test error} - \text{training error}).$$

For self-supervised learning, there are two models, the representation and the probe; the decomposition is finer, accounting for:

- The representation model class, the probe model class;
- Whether the representation can be used by the probe (e.g., linear separability);
- The finiteness of the training data, for the representation and/or the probe.

Efficient self-supervised learning with contextualized target representations for vision, speech and language A. Baevski et al. (2023)

Datavec2.0 is a SimSiam-based multimodal self-supervised learning model.

Unsupervised embedding quality evaluation A. Tsitsulin et al. (2023)

To assess the quality of an unsupervised embedding $M \in \mathbf{R}^{n_1 \times n_2}$:

- α -ReQ: exponent of a power law fit of the singular values, $\lambda_i \propto i^{-\alpha}$ (linear regression on a log-log scale); $\alpha = 1$ suggests good generalization;
- RankMe: effective rank, *i.e.*, entropy of the normalized singular values;
- NESum: flatness of the eigenspectrum of the covariance matrix, $\sum \lambda_i / \lambda_0$; we want the representation to be “whitened”, *i.e.*, $\forall i \lambda \approx \lambda_0$;
- Incoherence: alignment of the singular vectors with the standard basis: $\text{Max}_i \|U'e_i\|$, $\text{Max}_i \|V'e_j\|$;
- Pseudo-condition number $\kappa_2 = \sigma_1 / \sigma_n$;
- Numerical rank: $\|M\|_F / \|M\|_2^2$;
- Clustering (compared with a random distribution on a sphere), from the norm of the pairwise dot product matrix $\|WW'\|_F$.

Self-cluster and coherence give more consistent results.

DataComp: in search of the next generation of multimodal datasets S.Y. Gadre et al.

Multimodal dataset (13b text-image pairs from CommonCrawl, more than ImageNet (1m), CLIP (400m), or StableDiffusion’s LAION-2B (2b)) for *data-centric ML*: how to best filter/preprocess the training data, for a fixed model, training code, and compute budget, for 40 evaluation tasks. The data was sanitized:

- NSFW text filtering: detoxify (multilingual XML-Roberta, threshold 0.1);
- NSFW image filtering (LAION-5B’s CLIP-based NSFW binary classifier, threshold 0.1);
- Deduplication (Yokoo);
- Face blurring (SCRFD face detector)

**Neural algorithmic reasoning
with causal regularization
B. Bevilacqua et al. (2023)**

Data augmentation for neural algorithmic reasoning: different inputs leading to the same intermediate computations.

Recall feeds the input back into the model at each step, as a constant reminder of the problem to solve.

**Interventional and counterfactual inference
with diffusion models
P. Chao et al.**

Estimate a structural causal model (with known DAG)) using a diffusion (DDIM) for each node. Experiment using simulated data (e.g.,

10-node random DAG, additive noise, non-additive noise) or real data (2-node graph $\bullet \rightarrow \bullet$).

**Causality inspired representation learning
for domain generalization
F. Lv et al.**

Define augmentations of an image in Fourier space, by keeping the phase, and mixing the amplitude with that of another image.

$$\mathcal{F}(x) = A(x)e^{-iP(x)}$$

$$A(x^{\text{aug}}) = (1 - \lambda)A(x) + \lambda A(x').$$

Learn latent features r such that $\text{Cor}(r, r^{\text{aug}}) \approx I$.

Learn a mask $m = \text{GumbelSoftmax}(w)$ to distinguish between relevant (“causal”) and irrelevant features: the classifiers try to have good performance on both $m \odot r$ and $(1 - m) \odot r$, while the mask tries to have good performance on $m \odot r$ and bad performance on $(1 - m) \odot r$.

$$\mathcal{L}_c = \|C - I\|^2$$

$$\mathcal{L}_{\text{sup}} = \ell(\hat{y}_1, y) + \ell(\hat{y}_1^{\text{avg}}, y)$$

$$\mathcal{L}_{\text{inf}} = \ell(\hat{y}_2, y) + \ell(\hat{y}_2^{\text{avg}}, y)$$

$$\text{Minimize}_{g, f_1, f_2} \mathcal{L}_c + \mathcal{L}_{\text{sup}} + \mathcal{L}_{\text{inf}}$$

$$\text{Maximize}_w \mathcal{L}_{\text{sup}} - \mathcal{L}_{\text{inf}}$$

The *Gumbel softmax* is an approximate, differentiable k -hot vector of size N ; it can be computed as follows.

$$\tau = 0.5$$

$$N : \text{ size of the vector}$$

$$k : \text{ desired number of 1's}$$

$$p \in \Delta_N \text{ probability vector (to be learned)}$$

$$U_{ij} \sim \text{Unif}(0, 1)$$

$$\xi_{ij} = -\log(-\log U_{ij}) \text{ Gumbel}$$

$$m_j = \text{Max}_i \frac{\exp \frac{\log p_j + \xi_{ij}}{\tau}}{\sum_{j'} \exp \frac{\log p_{j'} + \xi_{ij'}}{\tau}}$$

**On unimodal feature learning
in supervised multimodal learning
C. Du et al. (2023)**

To fit a model on multimodal data (e.g., image and text), compare

- Distillation of pretrained unimodal models

- Average of unimodal models

**Fast Poisson disk sampling
in arbitrary dimensions
R. Bridson**

Poisson disk distributions (samples are at least at distance r from one another) are an example of *blue noise*. To generate such samples:

- Keep track of the locations of the points in a grid, with cell size r/\sqrt{n} , where n is the dimension, so that there is at most one point per cell;
- Add a first point, at random, to the active list (and to the grid);
- Pick a point at random in the active list, and generate 30 random points in the spherical annulus of radii r and $2r$ around it; if one of those points is at distance at least r from all the other points (you only need to check adjacent cells), add it to the active list (and to the grid), if not, remove the point from the active list.

[The centroidal Voronoi tessellation computed from uniformly distributed points also gives blue noise.]

Scientific visualization: Python and Matplotlib
N. Rougier (2021)

How to do everything you thought was impossible with Matplotlib.

A survey of graphical languages for monoidal categories
P. Selinger (2009)

String diagrams (objects and morphisms represented as wires and boxes) for *many* monoidal categories.

Expectile risk quadrangle and applications
V. Kuzmenko et al. (2023)

A *quadrangle* associated to a statistic is a set of 4 functionals, e.g.,

Statistic	$S(x) = \text{VaR}_\alpha(X)$
Risk	$R(X) = \text{CVaR}_\alpha(S)$
Deviation	$D(X) = \text{CVaR}_\alpha[X - EX]$
Regret	$V(X) = (1 - \alpha)^{-1} E[X^+]$
Error	$E(X) = E \left[\frac{\alpha}{1 - \alpha} X^+ + X^- \right]$

One can define quadrangles (they are not unique) for the *expectile*

$$e_q(X) = \underset{c \in \mathbf{R}}{\text{Argmin}} E[X - c]$$

where the asymmetric quadratic error is

$$E_q[X] = q E[(X^+)^2] + (1 - q) E[(X^-)^2].$$

It is the solution of (first order condition)

$$q E[(X - c)^+] = (1 - q) E[(X - c)^-].$$

This leads to estimators of expectile as solutions of linear programs.

The fundamental risk quadrangle in risk management, optimization and statistical estimation
R.T. Rockafellar and S. Uryasev (2013)

More examples (e.g., S = mean, D = standard deviation, or S = mean, D = variance).

Constructing time-series momentum portfolios with deep multi-task learning
J. Ong and D. Herremans (2023)

Train a neural network fo forecast:

- 21-day forward volatility (5 estimators) using negative correlation as loss (auxiliary tasks);
- Portfolio weights, to maximize the Sharpe ratio

using, as inputs, past log-returns (15, 21, 63, 126, 252), past realized volatility, past vol-of-vol.

Latent factor analysis in short panels
A.P. Fortin et al. (2023)

Test for the number of factors using the norm and eigenvalues of \hat{S} ,

$$\hat{S} = \Sigma^{-1/2} M(V - \Sigma) M' \Sigma^{-1/2}$$

$$V = \frac{1}{n} Y Y' \quad (Y \text{ centered})$$

$$\Sigma = \frac{1}{n} \varepsilon \varepsilon'$$

where the factor model is

$$y_i = \mu + F \beta_i + \varepsilon_i.$$

It can be estimated using

- $\text{diag } V = \text{diag}(F F' + \Sigma)$;
- F contains the first k eigenvectors of $V \Sigma^{-1}$, with eigenvalues $1 + \hat{\gamma}_j$, normalized so that $F' \Sigma^{-1} F = \text{diag}(\hat{\gamma}_1, \dots, \hat{\gamma}_k)$.

A simple method for predicting covariance matrices of financial returns
K. Johansson et al. (2023)

The iterated EWMA estimator of the covariance matrix combines an EWMA for the volatilities and one for the correlation matrix, with a smaller half-life for the former. Combine (the Choleski factors of the precision matrices of) several such estimators for different pairs of half-lives (or other estimators) to maximize the log-likelihood – the weights are the solution of a convex optimization problem (implementation: `cvxgrp/cov_pred_finance`).

Use the regret (difference in log-likelihood with the best (in-sample) constant variance matrix) or the performance of some portfolio (minimum variance, maximum diversity, risk parity, etc.) to compare estimators.

Prediction when factors are weak
S. Giglio et al. (2023)

Supervised PCA (SPCA) selects a subset of predictors, correlated with the target, before computing PCA. A variant proceeds one principal component at a time, projecting predictors and target along it each time.

Mining the factor zoo: estimation of latent factor models with sufficient proxies
R. Wan et al. (2022)

Estimate a time series factor model from a large number of proxy time series

$$\begin{aligned} y_t &= Af_t + \varepsilon_t \\ f_t &= B'x_t + u_t \end{aligned}$$

as (I have left out the scaling factor NK^{-1})

$$\begin{aligned} \hat{A}, \hat{B} &= \underset{\substack{A, B \\ A'A = I}}{\text{Argmin}} \|Y - XBA'\|^2 + \lambda \|B\|^2 \\ \hat{f} &= \hat{A}'y_t. \end{aligned}$$

Non-parametric online market regime detection and regime clustering for multidimensional and path-dependent data structures
B. Horvath and Z. Issa (2023)

The maximum mean discrepancy (MMD) between probability distributions p, q on a topological space X is

$$\begin{aligned} d(p, q) &= \sup_{f \in \mathcal{F}} \mathbb{E}_{x \sim p} [f(x)] - \mathbb{E}_{y \sim q} [f(y)] \\ \hat{d}(p, q) &= \sup_{f \in \mathcal{F}} \frac{1}{n} \sum_i f(x_i) - \frac{1}{m} \sum_j f(y_j) \end{aligned}$$

where \mathcal{F} is a set of functions $X \rightarrow \mathbf{R}$, for instance, the unit ball of a RKHS – this is then a distance, and

$$\begin{aligned} \hat{d}(p, q) &= \frac{1}{n(n-1)} \sum_{i \neq j} \kappa(x_i, x_j) - \frac{2}{mn} \sum_{i, j} \kappa(x_i, y_j) + \\ &+ \frac{1}{m(m-1)} \sum_{i \neq j} \kappa(y_i, y_j). \end{aligned}$$

A RKHS on a set X is the datum of:

- A vector space \mathcal{H} of function $X \rightarrow \mathbf{R}$;
- A scalar product $\langle \cdot, \cdot \rangle$ on \mathcal{H} ;
- A positive definite function $\kappa : X \times X \rightarrow \mathbf{R}$ such that:
 - $(\mathcal{H}, \langle \cdot, \cdot \rangle)$ is a Hilbert space;
 - $\forall x \in X \ \kappa(\cdot, x) \in \mathcal{H}$
 - $\forall x \in X \ \forall f \in \mathcal{H} \ \langle f, \kappa(\cdot, x) \rangle = f(x)$.

The *signature kernel* is

$$\kappa(x, y) = \langle S(x), S(y) \rangle$$

where $S(x) \in T((V))$ is the signature transform of $x : [0, 1] \rightarrow V$. It is the solution $\kappa(x, y) = f(1, 1)$ of the hyperbolic PDE

$$f(s, t) = 1 + \int_0^s \int_0^t f(u, v) \langle dx_u, dy_v \rangle_V$$

(there is no need to truncate the signature).

The *kernel scoring rule* compares an observation y with a probability distribution

$$\begin{aligned} s(p, y) &= \mathbb{E}_{x, x' \sim p} \kappa(x, x') - 2 \mathbb{E}_{x \sim p} \kappa(x, y) \\ \hat{s}(p, y) &= \frac{1}{n(n-1)} \sum_{i \neq j} \kappa(x_i, x_j) - \frac{2}{n} \sum_i \kappa(x_i, y) \end{aligned}$$

Apply to changepoint detection, with time-augmented subpaths (normalize the subpaths if needed).

$$\begin{bmatrix} 1 & x_i & x_{i+1} & \cdots & x_{i+h_2-1} \\ 2 & \vdots & \vdots & & \vdots \\ \vdots & \vdots & \vdots & & \vdots \\ h_1 & x_{i+h_1-1} & x_{i+h_1} & \cdots & x_{i+h_1+h_2-2} \end{bmatrix}$$

Risk bounds on aleatoric uncertainty recovery
Y. Zhang et al. (2023)

To estimate the variance in heteroskedastic regression

$$\begin{aligned} Y &= \mu(X) + \varepsilon(X) \\ \mu(X) &= \mathbb{E}[Y|X = x] \\ \sigma^2(x) &= \text{Var}[Y|X = x] \end{aligned}$$

use the Gaussian negative log-likelihood

$$\sum_i \log \sigma^2(x_i) + \frac{(y_i - \mu(x_i))^2}{\sigma_i^2(x_i)}$$

or the generalized method of moments (GMM)

$$\sum [\sigma^2(x_i) - (y - \mu(x_i))^2]^2$$

or a Gaussian process

$$\begin{aligned} g &\sim \text{GP} \quad (\text{prior}) \\ \sigma^2(x) &= \exp g(x). \end{aligned}$$

Never mind the metrics – what about the uncertainty? Visualizing confusion matrix metric distributions
D. Lovell et al.

Exhaustive list of performance metrics; in particular, you should also report balanced accuracy (BA) and the

Matthews correlation coefficient (MCC).

$$\begin{aligned} \text{BA} &= \frac{\text{TPR} + \text{TNR}}{2} \\ \phi = \text{MCC} &= \frac{\text{TP} \cdot \text{TN} - \text{FP} \cdot \text{FN}}{\sqrt{\hat{p}\hat{p}\hat{n}\hat{n}}} \\ p &= \text{TP} + \text{FN} \\ n &= \text{FP} + \text{TN} \\ \hat{p} &= \text{TP} + \text{FP} \\ \hat{n} &= \text{FN} + \text{TN} \\ \text{TPR} &= \text{TP}/p \\ \text{TNR} &= \text{TN}/n \end{aligned}$$

Plot both the ROC and precision-recall curves. Show, in the background, all possible confusion matrices (as a grid) with the same size N and prevalence P/N (proportion of positives), coloured with MCC or BA (you can also add the MCC level curves).

***Fisher-Rao distance
between multivariate normal distributions:
special cases, bounds and applications***
J. Pinele et al. (2020)

There is no known closed formula for the Fisher-Rao distance between Gaussians in general, but there is one in many special cases. For instance, when the mean is the same:

$$d((\mu, \Sigma_1), (\mu, \Sigma_2)) = \sqrt{\frac{1}{2} \sum (\log \lambda_i)^2}$$

where the λ_i are the eigenvalues of $\Sigma_1^{-1/2} \Sigma_2 \Sigma_1^{-1/2}$, *i.e.*, the generalized eigenvalues of (Σ_1, Σ_2) .

***Trust region methods
on Riemannian manifolds***
P.A. Absil et al.

Trust region methods, to minimize $f : \mathbf{R}^n \rightarrow \mathbf{R}$, iteratively solve (e.g., with *truncated conjugate gradient*)

$$\underset{\eta \in \mathbf{R}^n, \|\eta\| \leq \Delta}{\text{Minimize}} \underbrace{f(x) + f'(x)\eta + \frac{1}{2}\eta' f''(x)\eta}_{m(\eta)}$$

updating the radius Δ by looking at the quality of the approximation

$$\rho = \frac{f(x) - f(x + \eta)}{m(0) - m(\eta)},$$

e.g.,

$$\begin{aligned} \rho &\ll 1 && \text{discard the update and decrease } \Delta \\ \rho &< 1 && \text{decrease } \Delta \\ \rho &\approx 1 && \text{increase } \Delta. \end{aligned}$$

It still works if $f''(x)$ is replaced by an approximation of the Hessian.

This generalizes to functions on a Riemannian manifold $f : M \rightarrow \mathbf{R}$, by using the exponential map

$\exp_x : T_x M \rightarrow M$ or (since the exponential may be expensive to compute), a *retraction*

$$\begin{aligned} R_x : T_x M &\rightarrow M \\ R_x(0) &= x \\ DR_x(0) &= \text{Id} \end{aligned}$$

(no condition on the second derivative).

Examples include:

- Minimize $Q \in O_n$ $\text{trace}(Q' A Q N)$, where $N = \text{diag}(1, 2, \dots, n)$ (this gives the eigenvectors of A , sorted) and we can replace $\exp \Omega$ with a product of Givens rotations;
- The extreme eigenspace of (A, B) (the span of the p generalized eigenvectors with the lowest eigenvalues) in $\text{Grass}(p, n) = \mathbf{R}_*^{n \times p} / \text{GL}_p$, which is not naturally a submanifold of \mathbf{R}^N .

***Pymanopt: a Python toolbox for optimization
on manifolds using automatic differentiation***
J. Townsend et al. (2016)

Example: find the best rank- k positive semidefinite approximation of a matrix for the *pseudo-Huber loss* $H(x) = \sqrt{x^2 + \delta^2} - \delta$ (which is quadratic for small x and L^1 for large x) using a Riemannian trust region solver.

Understanding deep learning
S.J.D. Prince (2023)

3. There is a zoo of activation functions:

$$\begin{aligned} \sigma(z) &= (1 + e^{-z})^{-1} \\ \tanh z & \\ \text{PreLU}_a(z) &= \begin{cases} z & \text{if } z \geq 0 \\ az & \text{if } z \leq 0 \end{cases} \\ \text{LReLU} &= \text{PreLU}_a \\ \text{Softplus}(z) &= \log(1 + e^z) \\ \text{GeLU}(z) &= z \cdot \Phi(z) \\ \text{SiLU}(z) &= z \cdot \sigma(z) \\ \text{ELU}_\alpha(z) &= \begin{cases} z & \text{if } z \geq 0 \\ \alpha(e^z - 1) & \text{if } z \leq 0 \end{cases} \\ \text{SELU}(z) &= \lambda \text{ELU}_\alpha(z) \\ \text{Swish}_\beta(z) &= z \cdot \sigma(\beta z) \end{aligned}$$

4. Deep neural networks are easier to train and generalize better than shallow ones.

5. The cross-entropy loss is equal, up to an additive

constant, to the negative log-likelihood.

$$\begin{aligned}\text{KL}(q \parallel p) &= \mathbb{E}_{z \sim q} \left[\log \frac{q(z)}{p(z)} \right] \\ \hat{\theta} &= \underset{\theta}{\text{Argmin}} \text{KL}(\text{data} \parallel \text{model}_{\theta}) \\ &= \underset{\theta}{\text{Argmin}} \mathbb{E}_{z \sim q_{\text{data}}} \left[\log \frac{q_{\text{data}}(z)}{p_{\theta}(z)} \right] \\ &= \underset{\theta}{\text{Argmin}} \mathbb{E}_{z \sim \text{data}} [-\log p_{\theta}(z)]\end{aligned}$$

Many other losses can be used, e.g.,

- Negative log-likelihood from other models;
- Pinball loss (quantile regression);
- Focal loss (downweight well-calssified examples);
- Hinge loss (SVM);
- Exponential loss (AdaBoost);
- Learning-to-rank;
- etc.

6. Adam combines momentum and RMSProp (parameter-specific learning rates); it often makes rapid initial progress, but you may want to switch to SGD after a while. Learning rate warm-up may be needed.

7. To avoid vanishing or exploding gradients, initialize the weights so that the activations have mean 0 and variance 1, e.g., with He initialization

$$\sigma^2 = \frac{4}{d_{\text{in}} + d_{\text{out}}}$$

(initially derived for linear layers) or Glorot initialization (multiply by 2, to account for ReLU activation functions).

8. There are three sources of error:

- Noise: the data generation process is stochastic;
- Bias: the data generation process is not in the family of models considered;
- Variance: the model is estimated from a finite sample.

The *double descent* phenomenon depends on the loss, the initialization, the optimization algorithm (which provides implicit regularization); it is more visible with noisy training data.

Adding more data can have a negative impact on performance – the model is less over-parametrized.

Data drift can manifest itself as:

- Change in x : covariate shift;
- Change in y : prior shift;
- Change in $y|x$: concept shift.

9. The discreteness of the time steps in gradient descent are equivalent to an implicit regularization:

$$\begin{aligned}\text{loss}_{\text{GD}}(\phi) &= \text{loss}(\phi) + \frac{\alpha}{4} \left\| \frac{\partial L}{\partial \phi} \right\|^2 \\ \phi_{t+1} &= \phi_t - \alpha \frac{\partial \text{loss}}{\partial \phi},\end{aligned}$$

i.e., the trajectory avoids places with a steep gradient (and the regularization becomes stronger with larger step sizes α).

The minibatches in SGD introduce another implicit regularization

$$\frac{\alpha}{4B} \sum_{b=1}^B \left\| \frac{\partial \text{loss}_b}{\partial \phi} - \frac{\partial \text{loss}}{\partial \phi} \right\|^2$$

i.e., the trajectory prefers places where gradients do not differ too much between batches.

To improve performance, try early stopping, ensembling, dropout, noise (in the inputs (adversarial training), the weights, or the labels (label smoothing)), pre-training, augmentation, self-supervised learning.

11. Very deep networks suffer from *shattered gradients*: small changes in the input can lead to large changes in the gradient of the loss. Residual (skip) connections address that problem. A ResNet can be seen as an ensemble of smaller networks:

Batch normalization helps with exploding/vanishing gradients.

Variations of ResNets include:

- UNet;
- Stacked hourglass networks (stacked UNets);
- DenseNet (concatenates the outputs of all previous layers to feed the current layer).

13. An *inductive* model sees labeled data at training time and unlabeled data at test time. A *transductive* model sees both labeled and unlabeled data at training time (semi-supervised learning) – node classification models are often transductive.

Graph attention

$$\begin{aligned}S_{mn} &= a \left[\phi' \begin{pmatrix} h_m \\ h_n \end{pmatrix} \right] \\ H &\leftarrow a [H' \cdot \text{Softmask}(S, A + I)]\end{aligned}$$

differs from traditional attention:

- $Q = K = V = H$;
- There is a mask, $A + I$;
- $S \neq K'Q$.

For large graphs, minibatch training is tricky: try adding a subset of the nodes in the receptive field at each stage, or sample a subgraph with random walks.

14. Unsupervised learning includes

- GANs;
- VAEs;
- Normalizing flows;
- Diffusion models.

The inception score (of an image generation model) is the Fréchet distance between the latent representations (penultimate activations of an inception model) of real and generated data, after Gaussian approximation.

$$\|\mu_X - \mu_Y\|^2 + \text{tr}[\Sigma_X + \Sigma_Y - 2(\Sigma_X \Sigma_Y)^{1/2}]$$

15. GANs are difficult to train and suffer from *mode dropping*, or even *mode collapse*. *Minibatch discrimination* adds a penalty to ensure diversity in each minibatch.

If the discriminator is too good (in particular, if it recognizes that real and generated data are disjoint), the gradients are uninformative and the generator cannot improve. The *Wasserstein loss* does not have that problem: the gradients remain informative.

GAN variants include:

- Conditional GAN: generator and discriminator are given the class of the input;
- Classifier GAN: the generator is given the class, and the discriminator tries to recover it;
- InfoGAN: the discriminator tries to recover part of the noise given to the generator (this helps disentangle the latent space);

- Superresolution GAN;
- CycleGAN;
- StyleGAN: add the latent variable (and the noise) at several points in the network, *i.e.*, at different scales;
- MADGAN: several generators, and the discriminator tries to guess which one was used.

16. Normalizing flows are invertible layers (or networks) whose Jacobians have an easy-to-compute determinant. For linear layers, this is easy to obtain with

the LU decomposition

$$\begin{aligned} f(h) &= \beta + \Omega h \\ \Omega &= PL(U + D) \\ P &\in \mathfrak{S}_n \\ L &= \begin{bmatrix} * & & 0 \\ | & \diagdown & \\ * & \text{---} & * \end{bmatrix} \\ U &= \begin{bmatrix} 0 & & * \\ | & \diagdown & \\ 0 & \text{---} & 0 \end{bmatrix} \\ D &= \begin{bmatrix} * & & 0 \\ | & \diagdown & \\ 0 & & * \end{bmatrix} \end{aligned}$$

They can be combined with an invertible elementwise nonlinearity, e.g., LeakyReLU.

Coupling flows generalize the linear invertible transformation

$$\begin{pmatrix} h_1 \\ h_2 \end{pmatrix} \mapsto \begin{pmatrix} 1 & 0 \\ * & 1 \end{pmatrix} \begin{pmatrix} h_1 \\ h_2 \end{pmatrix}$$

to

$$\begin{pmatrix} h_1 \\ h_2 \end{pmatrix} \mapsto \begin{pmatrix} h_1 \\ g_{\phi(h_1)} h_2 \end{pmatrix}$$

with inverse

$$\begin{pmatrix} h_1 \\ g_{\phi(h_1)}^{-1} h_2 \end{pmatrix} \longleftarrow \begin{pmatrix} h_1 \\ h_2 \end{pmatrix}$$

Autoregressive flows generalize this to more blocks.

Residual flows use a similar idea.

$$\begin{aligned} \begin{pmatrix} h_1 \\ h_2 \end{pmatrix} &\mapsto \begin{pmatrix} h'_1 \\ h'_2 \end{pmatrix} = \begin{pmatrix} h_1 + f_1(h_2) \\ h_2 + f_2(h'_1) \end{pmatrix} \\ \begin{pmatrix} h'_1 - f_1(h_2) \\ h'_2 - f_2(h'_1) \end{pmatrix} &\longleftarrow \begin{pmatrix} h_1 \\ h_2 \end{pmatrix} \end{aligned}$$

Multiscale flows generalize them to more than two blocks.

17. To model $p(x)$, latent variable models model $p(x, z)$, often as $p(x, z) = p(x|z)p(z)$, and marginalize z : $p(x) = \mathbb{E}_z p(x, z)$. Examples include:

- Gaussian mixture;

$$\begin{aligned} z &\sim \text{Discrete} \\ x|z &\sim N(\mu_z, \sigma_z^2) \end{aligned}$$

- Nonlinear Gaussian mixtures

$$\begin{aligned} z &\sim N(0, I) \\ x|z &\sim N(f_\phi(z), \sigma^2 I) \end{aligned}$$

The expectation $\mathbb{E}_z p(x, z)$ is intractable, but amenable to variational inference.

$$\begin{aligned} \log p(x) &= \log \int p(x, z) dz \\ &= \log \int q(z) \frac{p(x, z)}{q(z)} dz \quad (q \text{ arbitrary}) \\ &\geq \int q(z) \log \frac{p(x, z)}{q(z)} dz \quad (\text{Jensen}) \\ &= \text{ELBO}(q, p) \end{aligned}$$

$$\begin{aligned} \text{ELBO}(q, p) &= \int q(z) \log \frac{p(x, z)}{q(z)} dz \\ &= \int q(z) \log \frac{p(z|x)p(x)}{q(z)} dz \\ &= \int q(z) \log p(x) dz + \int q(z) \log \frac{p(z|x)}{q(z)} dz \\ &= \log p(x) + \text{KL}(q(z) \| p(z|x)) \end{aligned}$$

$$\begin{aligned} \text{ELBO}(q, p) &= \int q(z) \log \frac{p(x, z)}{q(z)} dz \\ &= \int q(z) \log \frac{p(x|z)p(z)}{q(z)} dz \\ &= \int q(z) \log p(x|z) dz + \int q(z) \frac{p(z)}{q(z)} dz \\ &= \int q(z) \log p(x|z) dz + \text{KL}(q(z) \| p(z)) \\ &= \text{reconstruction loss} + \text{distance to prior} \end{aligned}$$

This is the loss used by VAEs.

For the distributions, use

$$\begin{aligned} p_\phi(x|z) &= \text{Norm}_x(f(z, \phi), \sigma^2 I) \\ q_{\theta, x}(z) &= \text{Norm}_z(g_\mu(x, \theta), g_\Sigma(x, \theta)) \\ p(z) &= \text{Norm}_z(0, I). \end{aligned}$$

The first term is intractable, but can be approximated with Monte Carlo, by sampling $z \sim q_{\theta, x}$ (one sample may be good enough). The second term is the KL divergence between two Gaussians,

$$\text{KL}(N(\mu, \Sigma) \| N(0, I)) = \frac{1}{2} (\text{tr } \Sigma + \mu' \mu - n - \log \det \Sigma).$$

The β -VAE rescales the second term (KL penalty)

$$\text{loss} = \log p_\phi(x, z^*) - \beta \cdot \text{KL}(q_{\theta, x}(z) \| p(z))$$

where z^* is a single sample.

18. Diffusion models progressively add noise to an image

$$\begin{aligned} z_0 &= x \\ z_t &= \sqrt{1 - \beta_t} z_{t-1} + \sqrt{\beta_t} \varepsilon_t \end{aligned}$$

and try to reverse this process. If we knew x , we could compute $q(z_{t-1}|z_t, x)$ – it is Gaussian. Approximate $q(z_{t-1}|z_t)$ with Gaussian distributions

$$z_{t-1}|z_t \sim N(f_t(z_t, \phi_t), \sigma_t^2 I)$$

and use variational inference.

StableDiffusion does this in a latent space (smaller than pixel space).

20. It is not clear why deep learning works:

- It is not because the dataset is easy to learn: one can fit random data almost as easily;
- It is not because of (explicit or implicit) regularization;
- It is not because SGD, with small batches, moves easily between valleys – large batches work equally well;
- Activation functions are important: they should provide informative gradients;
- Initialization is only important for deep networks;
- Inductive bias (CNNs for grid data, transformers for \mathfrak{S}_n -invariance) is important;
- Overparametrization and depth are important (lottery ticket hypothesis: a large network can be seen as an ensemble of smaller subnetworks, one of which may have been initialized near a minimum); overparametrization also allows the model to be smoother between data points;
- Regularization can explain double descent and *grokking* (sudden improvement in generalization long after the training error reached zero)

The loss surface has interesting properties:

- There are many global minima; they seem to be connected by low-loss regions;
- The optimization path lies in a low-dimensional subspace;
- There are few or no bad local minima (but there are many saddle points).

A simple explanation of partial least squares K.S. Ng (2013)

The principal components of X (assuming the data is centered) can be computed from the eigen decomposition of $X'X$.

$$\begin{aligned} X'X &= PDP' && \text{eigen decomposition} \\ P &&& \text{principal components} \\ T &= XP && \text{scores} \\ X &= TP' && (\text{because } P^{-1} = P') \end{aligned}$$

Often, we only keep the first k principal components $P_{\leq k}$.

$$T_{\leq k} = XP_{\leq k}$$

The principal components can also be computed from the singular value decomposition (SVD).

$$X = (U\Sigma)P' = TP'$$

The NIPALS algorithm uses power iterations to find the principal components one by one,

```
Repeat
  t = random
  Repeat
    p ∝ X't
    t = Xp
  X ← X - tp'
```

Given two datasets, X and Y , consider the NIPALS algorithms for them, but swap the scores of X and Y , and interleave the updates.

PCA	PLS
Repeat	Repeat
$t = \text{random}$	$t = \text{random}$
$u = \text{random}$	$u = \text{random}$
Repeat	Repeat
$p \propto X't$	$p \propto X'u$
$t = Xp$	$t = Xp$
$q \propto U'u$	$q \propto U't$
$y = Yq$	$y = Yq$
$X \leftarrow X - tp'$	$X \leftarrow X - tp'$
$X \leftarrow Y - uq'$	$X \leftarrow Y - uq'$

This gives decompositions

$$\begin{aligned} X &= TP' \\ Y &= UQ'. \end{aligned}$$

PLS regression estimates a regression between the scores (latent) $U \sim T$, giving $U \approx T\beta$, and uses it to express Y from X :

$$\begin{aligned} Y &= UQ' \\ &\approx T\beta Q' \\ &= XP\beta Q' \\ &= XB_{\text{PLS}}. \end{aligned}$$

For p , this is the power iteration

$$p \propto X'u \propto X'Yq \propto X'YY't \propto X'YY'Xp$$

to compute the largest eigenvalue of $X'YY'X$, i.e.,

$$\begin{aligned} p &= \underset{\|p\|=1}{\text{Argmax}} p'X'YY'Xp \\ &= \underset{\|p\|=1}{\text{Argmax}} (Y'Xp)Y'Xp \\ &= \underset{\|p\|=1}{\text{Argmax}} \text{Cov}(Y, Xp)' \text{Cov}(Y, Xp) \\ &= \underset{\|p\|=1}{\text{Argmax}} \|\text{Cov}(Y, Xp)\|. \end{aligned}$$

Note that p and q are the right and left singular vectors of $X'Y$:

$$p, q = \underset{\|p\|=\|q\|=1}{\text{Argmax}} \text{Cov}(Xp, Xq).$$

A survey of partial least squares (PLS) methods, with emphasis on the 2-block case **J.A. Wegelin (2000)**

There are (at least) 3 variants of the PLS algorithm. They all use a rank-1 approximation of $A = X'Y$ (from the SVD)

$$\begin{aligned} A &\approx dpq' \\ t &= Xp \\ u &= Yq \end{aligned}$$

but differ on how X and Y (or A) are updated:

PLS-W2A	$X \leftarrow X - t(t't)^{-1}t'X$ $Y \leftarrow Y - u(u'u)^{-1}u'Y$
PLS-SVD	$A \leftarrow A - dpq'$
PLS2	$X \leftarrow X - t(t't)^{-1}t'X$ $Y \leftarrow Y - (t't)^{-1}(t'u)tu'$

PLS1 is the special case of PLS2 where Y only has one variable.

CCA (canonical correlation analysis) replaces the covariance with the correlation:

$$p, q = \underset{\|p\|\|q\|=1}{\text{Argmax}} \text{Cor}(Xp, Xq).$$

This requires inverting $X'X$ and $Y'Y$, which can lead to numeric instabilities.

PLS can be generalized to more than two blocks (PLS-SEM – not recommended) if we posit the relations between the latent variables (path diagram).

Partial least squares methods: partial least squares correlation and partial least squares regression **H. Abdi and L.J. Williams (2013)**

Confusingly, PLS can refer to two things:

- PLS correlation, finding latent factors common to two datasets;
- PLS regression, predicting one dataset from another.

Given two data matrices $X \in \mathbf{R}^{I \times J}$, $Y \in \mathbf{R}^{I \times K}$ (with centered and normalized columns), PLSC finds the unit vectors $u_1 \in \mathbf{R}^K$, $v_1 \in \mathbf{R}^J$ maximizing the covariance $(Xv_1)'(Yu_1)$, then the unit vectors, orthogonal to u_1 and v_1 , maximizing $(Xv_2)'(Yu_2)$, and so on. Those vectors can be computed in one go from the SVD

$$\begin{aligned} Y'X &= U\Delta V' \\ U &: \text{loadings of } Y \\ V &: \text{loadings of } X \\ XV &: \text{factor scores} \\ YU &: \text{factor scores} \end{aligned}$$

To assess significance, compute the sum of the (retained) singular values (inertia) and compare with that obtained after shuffling the rows of X (bootstrap distribution of the inertia).

PLS regression computes latent factors an X , and regresses Y on those factors:

$$\begin{aligned} X &= TP' \\ \hat{Y} &= YBC' = (P')^\dagger BC'. \end{aligned}$$

It can be computed iteratively:

$$\begin{aligned} X'Y &= W\Delta C' && (\text{SVD}) \\ &\approx w\delta c' && (\text{rank 1}) \\ t &= Xw && X \text{ latent} \\ p &= X't && X \text{ loadings} \\ u &= Yc \\ \hat{X} &= tp' \\ \hat{Y} &= uc' \\ &= tt'uc' \\ &= tbc' \\ b &= t'u && \text{slope} \\ X &\leftarrow X - \hat{X} \\ Y &\leftarrow Y - \hat{Y}. \end{aligned}$$

After $L = \text{rank } X$ iterations:

$$\begin{aligned} X &= TP' \\ \hat{Y} &= TBC' \\ &= X(P')^\dagger BC' \end{aligned}$$

This solves the optimization problem

$$\begin{aligned} \text{Find} & \quad w \\ \text{To maximize} & \quad \|\text{Cov}(Xw, Y)\|^2 \\ \text{Such that} & \quad \|w\| = 1. \end{aligned}$$

Supervised linear dimension reduction methods: review, extensions and comparisons
S. Xu et al.

Supervised dimension reduction methods include:

- PCA on the ℓ variables most correlated with y (choose ℓ to get the best performance when predicting y from the top k principal components, k fixed);
- Idem, but iteratively, extracting one principal component at a time;
- k principal components most correlated with y (instead of the top k);
- PLS-W2A

$$\begin{aligned} u &= \underset{\|u\|=1}{\text{Argmax}} u'Xyy'Xu \\ z &= Xu \\ X &\leftarrow X - zu' \\ y &\leftarrow y - \frac{\langle y, z \rangle}{\|z\|^2} z; \end{aligned}$$

- Extended PLS-W2A, *i.e.*, with a PCA penalty,

$$\underset{\|u\|=1}{\text{Maximize}} u'Xyy'Xu - \lambda \|X - Xu u'\|^2$$

- PLS-SVD

$$\underset{U'U=I}{\text{Maximize}} \|\text{Cov}(XU, y)\|$$

- Extended PLS-SVD

$$\underset{U'U=I}{\text{Maximize}} \|\text{Cov}(XU, y)\| - \lambda \|X - XU U'\|^2$$

- LSPCA (least-squares PCA, no closed-form solution)

$$\underset{\beta, U'U=I}{\text{Minimize}} \|y - XU\beta\|^2 - \lambda \|X - XU U'\|^2$$

- Supervised probabilistic PCA (EM algorithm)

$$\begin{aligned} x &= Uz + \varepsilon \\ y &= v'z + \eta \end{aligned}$$

Prefer PLS-W2A and LSPCA.

Supervised dimension reduction for big data
J.T.Vogelstein et al.

PCA can be adapted to include a target qualitative variable. In the case of two classes:

- Compute the mean of each class;
- The difference between the means is the first component;
- Subtract the mean;
- Perform PCA from the covariance matrix of the centered data.

This can be generalized to more than 2 classes, and to robust alternatives of the mean and variance.

SLISEMAP: supervised dimensionality reduction through local explanations
A. Björklund et al. (2022)

Dimension reduction (supervised UMAP), not on the features, but on LIME explanations.

$$\begin{aligned} z_i &: \text{embedding of observation } i \text{ (unknown)} \\ d_{ij} &= d(z_i, z_j) \\ w_{ij} &\propto e^{d_{ij}} \quad \sum_j w_{ij} = 1 \\ L_{ij} &= \text{loss}(g_i(x_j), y_j) \end{aligned}$$

where L_{ij} is the loss of the local model g_i for observation i , applied to observation j . The latent embeddings are

$$\text{Minimize}_z \sum_{ij} w_{ij} L_{ij} \quad \text{s.t.} \quad \langle \|z_i\|^2 \rangle = r^2.$$

Supervised discriminative PCA with adaptive neighbours for dimensionality reduction
Z. Shi et al.

PCA can be written

$$\text{Maximize}_W \text{tr}(X'X'XW) \quad \text{s.t.} \quad W'W = I_k$$

or

$$\text{Minimize}_W \|X - XWW'\|^2 \quad \text{s.t.} \quad W'W = I_k.$$

The variant

$$\text{Maximize}_Q \text{tr}(Q'XX'Q) \quad \text{s.t.} \quad Q'Q = I_k$$

$$\text{Minimize}_Q \|X - XX'X\|^2 \quad \text{s.t.} \quad W'W = I_k$$

is equivalent if the data has been standardized (the projections are respectively $W_{\text{PCA}} = V_{1:k}$ and $W_{\text{vPCA}} = V_{1:k}\Sigma_{1:k}$, where $X = U\Sigma V'$ is the SVD).

SDSPCA adds a target variable,

$$\text{Minimize}_{W,G,Q} \|X - QW'\|^2 + \alpha \|Y - QG\|^2 + \beta \|Q\|_2 \quad Q'Q = I_k$$

(it can be computed from the eigenvectors of $-XX' - \alpha YY' + \beta D$).

PCAN is a PCA variant preserving neighbourhood information

$$\begin{aligned} \text{Find} \quad & W, F, S \\ \text{To minimize} \quad & \sum_{ij} \|W'x_i - W'x_j\|^2 S_{ij} + \gamma_i S_{ij}^2 + \\ & + \lambda \|f_i - f_j\|^2 S_{ij} \\ \text{Such that} \quad & S\mathbf{1} = \mathbf{1} \\ & W'X'XW = I_k \\ & F'F = I_c \end{aligned}$$

One can combine SDSPCA and PCAN.

Financial and macroeconomic data through the lens of a nonlinear dynamic factor model
P.A. Guerrón et al.

The dynamic factor model

$$\begin{aligned} Y_t &= \Lambda F_t + \varepsilon_t \\ F_t &= \Psi(L)F_{t-1} + \eta_t \end{aligned}$$

can be made non-linear

$$\begin{aligned} y_t &= \mathcal{G}(f_t) + \varepsilon_t \\ f_t &= \mathcal{H}(f_{t-1}) + \eta_t. \end{aligned}$$

The pruned second order state space model

$$\begin{aligned} y_t &= Gf_t + \varepsilon_t \\ f_t &= x + a_t + b_t \\ a_t &= \alpha a - t - 1 + \eta_t \\ b_t &= \beta b_{t-1} + \gamma a_{t-1}^2 \end{aligned}$$

can be estimated with a particle filter (you may need hundreds of thousands of particles).

Predicting trends in the quality of state-of-the-art neural networks without access to training or testing data
C.H. Martin et al.

For each weight matrix W , compute (with **weight-watcher**): the eigenvalues of $W'W$ (they tend to look like the eigenvalues of a random matrix, or the eigenvalues of a random matrix with a few outliers, or a heavy-tail distribution), their power law exponent α , and

$$\begin{aligned} & \log \sum \lambda_i \\ & \log \lambda_{\max} \\ & \alpha \log \lambda_{\max} \\ & \log \sum \lambda_i^\alpha \end{aligned}$$

and aggregate those quantities across layers

$$\begin{aligned} & \sum_\ell \log \sum \lambda_{i\ell} \\ & \sum_\ell \log \lambda_{\max, \ell} \\ & \frac{1}{L} \sum_\ell \alpha_\ell \log \lambda_{\max, \ell} \\ & \sum_\ell \log \sum \lambda_{i\ell}^{\alpha_\ell} \\ & \frac{1}{L} \sum_\ell \alpha_\ell. \end{aligned}$$

Trained networks with good accuracy tend to have lower values of those metrics.

Tree-ring watermarks: fingerprints for diffusion images that are invisible and robust
Y. Wen et al.

Embed the watermark into the initial noise vector, in Fourier space, as rings of constant value.

Neural set function extensions: learning with discrete functions in high dimensions
N. Karalias et al. (2022)

A set function $f : \{0, 1\}^{[n]} \rightarrow \mathbf{R}$ can be extended to

$$\tilde{f} : \begin{cases} [0, 1]^n & \rightarrow \mathbf{R} \\ x & \mapsto \tilde{f}(x) = \sum_{S \subset [n]} p_x(S) f(S) \end{cases}$$

where p_x satisfies

$$\begin{aligned} \sum_{S \subset [n]} p_x(S) \mathbf{1}_S &= x \\ \sum_{S \subset [n]} p_x(S) &= 1 \\ \forall S \subset [n] \quad p_x(S) &\geq 0. \end{aligned}$$

It can further be extended to positive semidefinite matrices, \mathbf{S}_+^n , e.g.,

$$\tilde{f}(X) = \sum_{S, T \subset [n]} \sum_i \lambda_i p_{x_i}(S) p_{x_i}(T) f(S \cap T)$$

where $X = \sum \lambda_i x_i x_i'$ is the eigen decomposition of X and p_x is as above. More generally,

$$\tilde{f}(X) = \sum_{S, T \subset [n]} p_X(S, T) f(S \cap T)$$

where p_X satisfies

$$\begin{aligned} X &\preceq \frac{1}{2} p_X(S, T) (\mathbf{1}_S \mathbf{1}_T' + \mathbf{1}_T \mathbf{1}_S') \\ \sum_{S, T} p_X(S, T) &= 1 \\ \forall S, T \quad p_X(S, T) &\geq 0. \end{aligned}$$

Lifting optimization problems to higher dimensions can make them better-behaved (can help overcome the low-dimensional bottleneck).

The big data paradox in clinical practice
P. Msaouel (2022)

The more data you have, the less likely your confidence intervals are to contain the true value: more data reduces variance (and confidence intervals), but the bias remains. Try to:

- Improve data quality;
- Model subject heterogeneity (missing confounders, e.g., in the linear regressions to analyze RCT results);
- Include the bias in the confidence intervals.

Fine-tuning language models with just forward passes
S. Malladi et al.

Backpropagation of large models requires an inordinate amount of memory (with an 80GB GPU, you can use a

30B model, but only train a 3B one). Use a stochastic gradient estimator (SPSA, ZO-SGD).

$$\begin{aligned} z &\sim N(0, I) \\ \hat{\nabla} \ell(\theta) &= \frac{\ell(\theta + \varepsilon z) - \ell(\theta - \varepsilon z)}{2\varepsilon} z \\ &\approx z z' \nabla_{\theta} \ell(\theta) \end{aligned}$$

To reduce memory further, do not store z , but only its random seed, and re-generate it each time it is needed (MeZO).

Keeping gradient history does not require much additional memory ($\Delta \ell$ and the seed for z for each timestep). For more precision, use several vectors z .

Also try variance reduction, or layerwise gradients (if the layer gradients have different scales).

ChatGPT informed graph neural network for stock movement prediction
Z. Chen

ChatGPT for named entity recognition (NER) and sentiment extraction. (Also add stock embeddings from a co-mention graph, and finish with an LSTM.)

FinGPT: open-source financial large language models
H.B. Yang et al.

LoRA over LLaMA, with daily updated financial text data (news (Yahoo finance), social media (Twitter), SEC filings, blogs, etc.).

Temporal data meets LLM: explainable financial time series forecasting
X. Yu et al.

Ask ChatGPT to:

- Describe the business of a company;
- List its risk, growth, etc. factors;
- Summarize recent (time-stamped) news about it;
- Summarize recent macro-economic news related to the keywords;
- Use all of the above to forecast the future stock price, reasoning step by step.

Bloated disclosures: can ChatGPT help investors process financial information?
A.G. Kim et al.

Ask ChatGPT to summarize corporate disclosures:

- Bloated disclosures (smaller summaries) herald bad market events;
- The sentiment is easier to extract from the summaries.

Improved financial forecasting via quantum machine learning
S. Thakkar et al.

Sampling from a determinantal point process (DPP) (which increases diversity) gives an unbiased least squares estimator

$$\mathbb{E}_{S \sim \text{d-DPP}(XX')} [X_S^{-1} y_S] = \underset{w}{\text{Argmin}} \|Xw - y\|^2$$

Apply this to random forests, sampling both observations and features.

**Quantum computer based
feature selection in machine learning
G. Hellstern et al.**

Let ρ_{ij} be the dependency between predictors i and j , and ρ_{iY} the dependency between predictor i and target Y . The feature selection problem can be formulated as a QUBO problem:

$$\begin{aligned} &\text{Find} \quad z \in \{0, 1\}^n \\ &\text{To maximize} \quad \sum_i z_i |\rho_{iY}| - \lambda \sum_{i \neq j} z_i z_j |\rho_{ij}| \end{aligned}$$

This can be solved with gate-based quantum computers (QAOA).

**A unified framework
for fast large-scale portfolio optimization
W. Deng et al. (2023)**

IPCA (instrumental PCA) is a factor model whose loadings β are linear functions of (time-varying) asset characteristics.

Add ℓ^1 and ℓ^2 penalties to your portfolio optimization problem.

Implementation in PyPortOpt.

**Enhanced Bayesian neural network
for macroeconomics and finance
N. Hauzenberger et al. (2023)**

Nowcast a time series using a Bayesian neural net (separating linear and nonlinear effects, allowing for heteroskedasticity)

$$\begin{aligned} y_t &= \gamma' \mathbf{x}_t + f(\mathbf{x}_t) + \varepsilon_t \\ \varepsilon_t &\sim N(0, \sigma_t^2) \\ \log \sigma_t &\sim \text{AR}(1) \end{aligned}$$

where h is a convex combination of ReLU, LeakyReLU, sigmoid and tanh, with priors

– $\beta \sim \text{MGP}$ (multivariate Gamma process)

$$\begin{aligned} \rho_r &\sim \text{Gamma}(a, 1) \\ \phi_q &= \prod_{1 \leq r \leq q} \rho_r \\ \beta_q &\sim N(0, \phi_q^{-1}) \end{aligned}$$

so that the neurons' activations are progressively shrunk to zero ($\phi_q \gg 1$ for $q \gg 1$): you can have a large number of neurons, only those useful will be kept.

– $\kappa \sim \text{Horseshoe}$

$$\begin{aligned} j &: \text{predictor} \\ q &: \text{neuron} \\ \phi_{jq} &\sim \text{HalfCauchy} \\ \lambda_q &\sim \text{HalfCauchy} \\ \kappa_{jq} &\sim N(0, \lambda_q^2 \phi_{jq}^2) \end{aligned}$$

The Horseshoe prior generalizes the (sparsifying) Laplace prior:

Laplace prior	Student t prior
$\lambda^2 \sim \text{Exp}(2)$	$\lambda^2 \sim \text{IG}(a, b)$
$\beta \sim N(0, \lambda^2)$	$\beta \sim N(0, \lambda^2)$.

– $\beta \sim \text{Horseshoe}$.

**Successive one-sided Hodrick-Prescott filter
with incremental filtering algorithm
for nonlinear economic time series
Y. Liu et al.**

The HP filter is

$$F = \begin{bmatrix} 1 & -2 & 1 & 0 \\ & \diagdown & \diagdown & \diagdown \\ 0 & & 1 & -2 & 1 \end{bmatrix}$$

$$S = I + \eta F' F$$

$$\begin{aligned} \text{trend} &= \underset{u}{\text{Argmin}} \|y - u\|^2 + \eta \|Fu\|^2 \\ &= S^{-1} y \\ \text{cycle} &= (I - S^{-1})y. \end{aligned}$$

It can be computed efficiently on an expanding window (Woodbury formula). It can be iterated, to remove any trend remaining in the cycle:

$$\begin{aligned} \text{cycle} &= (I - S^{-1})^n y \\ \text{trend} &= [I - (I - S^{-1})^n] y \end{aligned}$$

**Generating synergistic formulaic alpha
collections via reinforcement learning
S. Yu et al.**

RL-based formulaic alpha mining to maximize the performance, not of each alpha, but of their combination.

**Efficient solution
of portfolio optimization problems
via dimension reduction and sparsification
C.K. Buhler et al.**

To solve large (Markowitz) portfolio optimization problems approximately and efficiently, try:

– LSTM to forecast if a stock is never (0) or sometimes (1) in the optimal portfolio, for no/some value of the risk aversion λ ;

- Change the risk measure from

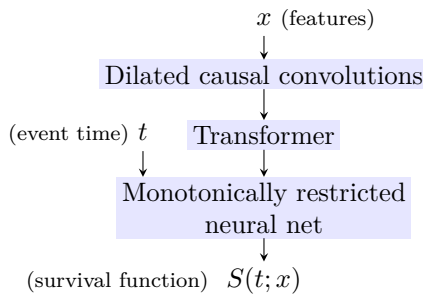

$$w'Vw = w'(X - \bar{X})'(X - \bar{X})w = \|(X - \bar{X})w\|_2^2$$

to $\|(X - \bar{X})w\|_1$, to get a linear program;

- Sparsify the covariance matrix by truncating small values and adding back those in a row or column with a non-zero off-diagonal element (the result is block-diagonal and positive semi-definite).

Deep attentive survival analysis in limit order books: estimating fill probabilities with convolutional-transformers
Á. Arroyo et al.

Use a neural network

for survival analysis, maximizing the right-censored log-likelihood

$$\text{loglik} = \sum_{k \text{ observed}} \log f_{\theta}(t_k; x_k) + \sum_{k \text{ censored}} \log S(t_k; x_k)$$

t_k : event time
 x_k : features

$$S(t) = P[T \geq t] = \exp - \int_0^t h \quad \text{survival function}$$

$$F(t) = 1 - S(t) \quad \text{cdf}$$

$$f(t) = -\frac{dS}{dt} \quad \text{pdf}$$

$$h(t) = \frac{f(t)}{1 - F(t)} \quad \text{hazard rate}$$

Neural likelihoods via cumulative distribution functions
P. Chilinski and R. Silva

To model probability distributions (cdf and pdf), use a neural network, with positive weights and tanh activations; automatic differentiation gives f and F . This can be generalized to higher dimensions. Applications include the tail dependence coefficient (TDC).

Agent market orders representation through a contrastive learning approach
R. Ruan et al.

To cluster traders, *i.e.*, identify trading behaviours, consider sequences of 50 market orders by several traders, and use an LSTM with contrastive learning (triplet loss, with positive/negative pairs if the sequences come / do not come from the same trader) to learn a latent representations, and use k -means on it. Plot with t -SNE, or hour \sim date | cluster.

Causal feature engineering of price directions of cryptocurrencies using dynamic Bayesian networks
R. Amirzadeh et al.

DBN (dynamic Bayesian network) to predict the price direction of 5 altcoins from 23 features (technical analysis, gold, MSCI, S&P, USD, oil, number of tweets).

Random matrix theory and nested clustered portfolios on Mexican markets
A. Garcia and B. Rodríguez

Nested clustered optimization (NCO) for $n = 28$:

- Start with the variance matrix (sample, shrinkage, or cleaned with RMT);
- Compute the corresponding minimum spanning tree, its normalized Laplacian L , and the spectrum of L ;
- Only keep the eigenvectors before the maximum spectral gap, $\text{Max}_k |\lambda_k - \lambda_{k-1}|$;
- Apply k -means on the top eigenvectors;
- Compute the optimal portfolio inside each cluster;
- Compute the optimal portfolio of clusters.

Model-free market risk hedging using crowding networks
V. Zlotnikov et al. (2023)

Crowding measures whether active managers are overweight a stock (other measures include: proportion of

buy ratings, institutional trade persistence, momentum, high but achievable expectations). It can be estimated with the centrality in the overweight (resp. underweight) graph built from holdings data.

Causality between sentiment and cryptocurrency prices
L. Mondal et al.

Fit a topic model on crypto-related tweets (a variant of LDA targetted at shorter texts, only allowing one topic per text) and compute topic-level sentiment (BERTweet and Pysentimiento).

Coloring in R's blind spot
A. Zeileis and P. Murrell

R 4.0.0 provides qualitative palettes in `palette.colors` and sequential and diverging ones in `hcl.colors`.

The little book of deep learning
F. Fleuret (2023)

Non-technical (but broad) introduction to deep learning with clear diagrams for the most common architectures (ResNet, UNet, Transformer, etc.).

Descent steps of a relation-aware energy produce heterogeneous graph neural networks
H. Ahn et al. (2022)

One can learn a latent representation Y of the nodes of a graph as

$$Y_w(X) = \underset{Y}{\operatorname{Argmin}} \|Y - f_w(X)\|^2 + \lambda \operatorname{tr}(Y'LY),$$

i.e., nodes with similar features X have a similar representation (first term), and nodes linked by an edge have a similar representation (second term). The weights w of the neural network f_w are chosen wrt some classification or prediction task

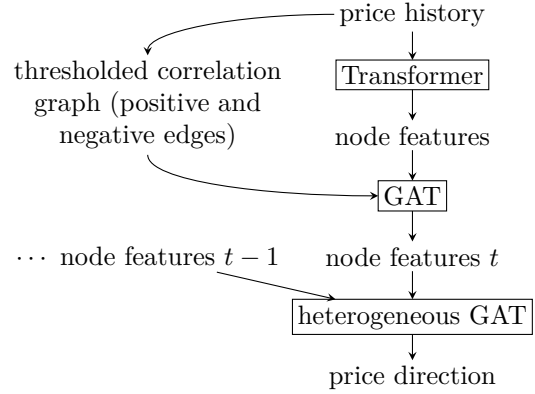

$$\theta, w = \underset{\theta, w}{\operatorname{Argmin}} \sum_i \operatorname{loss}(g_\theta(Y_w(x_i)), y_i).$$

For heterogeneous graphs, consider

$$Y_w(X) = \underset{Y}{\operatorname{Argmin}} \sum_s [\|Y_s - f_{w_s}(X_s)\|^2 + \lambda \sum_{s'} \sum_t \sum_{ij \in E_t} \|Y_i H_t - Y_j\|^2]$$

where s is the node type, t the edge type, H_t compatibility matrices (to allow heterophily).

Temporal and heterogeneous graph neural network for financial time series prediction
S. Xiang et al. (2022)

Limitations of deep learning for inverse problems on digital hardware
H. Boche et al.

There are only countably many computable real numbers (because there are only countably many Turing machines).

There is no computable mapping

$$(A, y) \mapsto \underset{x \in \mathbb{C}^N}{\operatorname{Argmin}} \|x\|_1 \text{ such that } \|Ax - y\|_2 \leq \varepsilon.$$

There are algorithms to solve that problem, but they come without explicit error bounds: they do not have an effective stopping criterion.

The result generalizes to oracle Turing machines: Turing machines dealing with arbitrary real numbers via rational Cauchy sequences provided by an oracle.

Inverse problems are solvable on real number signal processing hardware
H. Boche et al.

Blum-Shub-Smale (BSS) machines (Turing machine operating on real numbers) are more powerful than oracle Turing machines.

All you need is good init
D. Mishkin and J. Matas

LSUV (layer sequential unit variance) first initializes weights with orthogonal matrices, and then adjusts them (via optimization) to ensure the activations have unit variance.

Fixup initialization: residual learning without normalization
H. Zhang et al.

Resnet output variance grows exponentially with depth: fixup (fixed update) initialization

- Initializes the layers with a classical method;
- Rescales the layers in the residual branches (those in the shortest path are left untouched);
- Sets the last layer of each residual branch to 0;

- Adds learnable scalar multiplier (initialized at 1) and bias (0) before each layer (convolution, linear, elementwise nonlinearity).

Improving transformer optimization through better initialization
X.S. Huang et al. (2020)

With T-Fixup initialization, deep transformer networks no longer require learning rate warmup and LayerNorm.

How does batch normalization help optimization
S.Santurkar et al. (2018)

The success of BatchNorm is not so much due to the reduction of the “internal covariate shift” but to the smoothing of the loss landscape.

Identity mappings in deep residual networks
K. He et al. (2016)

Change the order of the layers in ResNet.

TrivialAugment: tuning-free yet state-of-the-art data augmentation
S.G. Müller and F. Hutter

For each image, pick one (instead of several) augmentation, uniformly at random (instead of from a learned distribution), and apply it with a random (instead of learned) strength.

A study on the evaluation of generative models
E. Betze et al.

Do not use the inception score and ImageNet to assess generative models:

- Use NotImageNet32 instead of ImageNet;
- Use CLIP instead of the inception model
- Use several metrics: FID_{∞} (unbiased FID), KID, ClearFID.

Elucidating the design space of diffusion-based generative models
T. Karras et al. (2022)

A denoising diffusion model can be written as an ODE

$$\dot{x} = -\dot{\sigma}_t \sigma_t \nabla_x \log p(x, \sigma_t)$$

(we have many trajectories $(x_t)_t$ from which we want to learn the score function $\nabla \log p$). To sample, use higher-order methods (Euler-Heun, Runge-Kutta). Stochastic sampling (Langevin diffusion) gives better results.

MaskGIT: masked generative image transformer
H. Chang et al.

Vision transformers (ViT) generate image patches sequentially, in raster scan order. Instead, learn to predict randomly masked patches (à la BERT), generate the image all at once, and progressively refine it.

On the importance of noise scheduling for diffusion models
T. Chen

The optimal noise schedule depends on the image size: there is more redundancy in large images.

Texture generation with neural cellular automata
A. Mordvintsev et al.

Train a neural cellular automaton (NCA) (all cells have the same differentiable update rule) to produce a (tilable) pattern given an example, using a style transfer loss (Gram matrix of the latent representation of a classifier) or the inception distance.

Ensemble deep learning: a review
M.A. Ganaie

Ensemble learning is not limited to equal weighted averages of a few models:

- Bagging;
- Boosting;
- Stacking;
- Negative correlation learning, *i.e.*, adding a penalty to make the base learners more diverse (they should not all make the same errors);
- Implicit ensembles (dropout, drop-connect, stochastic depth)
- Homogeneous ensembles (same models, but different training datasets, augmentations, initializations, regularizations, hyperparameters), heterogeneous ensembles;
- Weighted average, with learned weights (mixture of experts), or weights chosen by cross-validation (SuperLearner)
- Voting rules (Condorcet, etc.)

**Loss surfaces, mode connectivity,
and fast ensembling of DNNs**
T. Garipov et al. (2018)

The optima of loss functions are connected by simple curves over which training and test accuracy are nearly constant: learn those curves (e.g., Bézier) ϕ_θ by minimizing

$$\mathbb{E}_{t \sim U(0,1)} [\text{loss}(\phi_\theta(t))].$$

Fast geometric ensembling (FGE) starts with a single solution and looks for a nearby solution (sufficiently away from it) with a similar loss – this can be done using a sawtooth learning rate schedule.

**A convergent ADMM framework
for efficient neural network training**
J. Wang et al. (2015)

The neural network training problem can be written in ADMM form

$$\begin{array}{lll} \text{Find} & w_1, \dots, w_L & \text{weights} \\ & a_1, \dots, a_L & \text{activations} \\ \text{To minimize} & \text{loss}(a_L, y) + \sum_\ell r_\ell(w_\ell) & \\ \text{Such that} & \forall \ell \in \llbracket 1, L \rrbracket \quad a_\ell = g_\ell(w_\ell, a_{\ell-1}) & \end{array}$$

or, by replacing the non-linear constraints with a penalty, minimizing

$$\text{loss}(a_L, y) + \sum_\ell r_\ell(w_\ell) + \beta \sum_\ell \|a_\ell - g_\ell(w_\ell, a_{\ell-1})\|_2^2.$$

Update the parameters first backwards

$$a_L \rightarrow w_L \rightarrow a_{L-1} \rightarrow w_{L-1} \rightarrow \dots \rightarrow a_1 \rightarrow w_1$$

then forwards

$$w_1 \rightarrow a_1 \rightarrow w_2 \rightarrow a_2 \rightarrow \dots \rightarrow w_L \rightarrow a_L.$$

**Fast and flexible ADMM algorithms
for trend filtering**
A. Ramdas and R.J. Tibshirani

Trend filtering solves the problem

$$\text{Minimize}_\beta \frac{1}{2} \|y - \beta\|_2^2 + \lambda \|D^{(k+1)}\beta\|_1.$$

The standard ADMM approach rewrites the problem as

$$\begin{array}{lll} \text{Find} & \beta, \alpha & \\ \text{To minimize} & \frac{1}{2} \|y - \beta\|_2^2 + \lambda \|\alpha\|_1 & \\ \text{Such that} & \alpha = D^{(k+1)}\beta. & \end{array}$$

Instead, rewrite it as

$$\begin{array}{lll} \text{Find} & \beta, \alpha & \\ \text{To minimize} & \frac{1}{2} \|y - \beta\|_2^2 + \lambda \|D^{(1)}\alpha\|_1 & \\ \text{Such that} & \alpha = D^{(k)}\beta. & \end{array}$$

The 0th order trend filtering problem, $k+1=1$, can be solved in linear time, with dynamic programming, or the taut string principle.

**The Gromov-Wasserstein distance between
networks and stable network invariants**
S. Chowdhury and F. Mémoli

Given two metric measure spaces (X, d_X, p_X) , (Y, d_Y, p_Y) , their Gromov-Wasserstein distance is the minimum distortion of a coupling between p_X and p_Y .

$$\inf_{\substack{\pi_1 \# p_X = p_Y \\ \pi_2 \# p_Y = p_X}} \iint_{X \times Y \times X \times Y} |d_X(x, x') - d_Y(y, y')|^q p(dx, dy) p(dx', dy')$$

It can be generalized to *networks* (X, ω_X, p_X) , where X is a Polish space, ω_X a measurable function on $X \times X$ (it need not satisfy the triangle inequality, be symmetric, or have zeros on the diagonal).

Weisfeiler-Lehman meets Gromov-Wasserstein
S. Chen et al.

A *labeled measure Markov chain* (LMMC) is the datum of:

- X , a finite set (states);
- $m : X \rightarrow \mathcal{P}(X)$ (Markov kernel, *i.e.*, transition matrix, where $\mathcal{P}(X)$ is the set of probability distributions on X);
- $\mu \in \mathcal{P}(X)$ a stationary distribution for m ;
- $\ell : X \rightarrow Z$ (label, for some metric space Z).

A labeled graph, and $q \in [0, 1]$, defines an LMMC on the set of nodes, with transition probabilities

$$m(u, v) = \begin{cases} 1 & \text{if } u = v \text{ and } \mathcal{N}_u = \emptyset \\ q & \text{if } u = v \text{ and } \mathcal{N}_u \neq \emptyset \\ \frac{1-q}{\deg u} & \text{if } v \in \mathcal{N}_u \\ 0 & \text{otherwise} \end{cases}$$

and stationary distribution $\mu(v) \propto \text{Max}\{1, \deg v\}$.

The multiset labels in the WL test can be interpreted as probability distributions $\mathcal{L}^1, \mathcal{L}^2, \dots, \mathcal{L}^k$ on $\mathcal{P}(Z)$, $\mathcal{P}\mathcal{P}(Z), \dots, \mathcal{P} \dots \mathcal{P}(Z) = \mathcal{P}^{\circ k}(Z)$. The WL distance between X and Y is

$$d^k(X, Y) = d_W(\mathcal{L}_X^k, \mathcal{L}_Y^k)$$

(Wasserstein distance on $\mathcal{P}^{\circ k}(Z)$).

The open algebraic path problem
J. Master

The shortest path problem on a graph computes the transitive closure of the weight matrix with coefficients in the *rig* $([0, \infty], \text{Min}, +)$. The algebraic shortest path generalizes this to an arbitrary *rig* or even a commutative quantale (monoidal closed poset with all joins).

$$\begin{array}{llll} [0, \infty] & \geq & \inf & + \\ [0, \infty] & \leq & \sup & \inf \\ [0, 1] & \leq & \sup & \times \\ \{\mathbf{T}, \mathbf{F}\} & & \text{OR} & \text{AND} \\ \mathcal{P}(\Sigma^*) & \subset & \cup & \text{CONCAT} \end{array}$$

Uncertainty in deep learning
Y. Gal (2016)

To get a probabilistic forecast (as opposed to a point forecast) from a neural net trained with dropout (or some other stochastic regularization technique), use the network at test time as you did during training, to sample from the distribution of y^* and estimate $E[y^*]$ and $\text{Var}[y^*]$.

**Fourier neural operator
for parametric partial differential equations**
Z. Li et al. (2021)

Neural PDE solver, in Fourier space: repeat 4 times, after increasing the dimension with a linear layer.

Clifford neural layers for PDE modeling
J. Brandsetter et al. (2023)

To solve PDEs involving “correlated fields” (e.g., a scalar field and a vector field: temperature and wind speed), model them jointly, as a multivector, and use Clifford convolutions and Clifford layers.

**Deep learning for solving and estimating
dynamic macro-finance models**
B. Fan et al.

To solve a PDE

$$\begin{cases} f_\theta(x, u, Du) = 0 & x \in \Omega \\ B(x, u) = 0 & x \in \partial\Omega \end{cases}$$

train a neural net to minimize

$$\sum_{x \in T_f} \|f_\theta\|^2 + \sum_{z \in T_b} \|B\|^2$$

(PINN: physically-informed neural net). One can add other conditions

$$I(u, x) = 0 \quad c \in I \subset \Omega$$

and learn the PDE parameters θ as well.

Application to dynamic equilibrium models of the financial sector. Implementation with DeepXDE.

Nowcasting with signature methods
S.N. Cohen et al. (2023)

The Kalman filter can be expressed as a regression on signature transform features (involving only linear features).

Use the signature transform features ψ (on a moving window), which allow for irregular sampling, for nowcasting.

$$y_t = \sum_k (\alpha_k + \beta_k y_{t-}) \psi_{k,t} + \varepsilon_t$$

where y_{t-} is the previous value. Add an elasticnet penalty, and standardize the features (otherwise, they decrease factorially fast).

Implementation in SigNow; also check esig, iisignature, signatory.

**A new approach to decomposition of economic
time series into permanent and transitory
components with particular attention to
measurement of the ‘business cycle’**
S. Beveridge and C.R. Nelson

A stochastic process X , with stationary $\text{MA}(\infty)$ increments $\Delta X = \psi(L)\varepsilon$, can be decomposed into a stochastic trend (a random walk: its increments are independent)

$$\begin{aligned} \text{Trend}_t &= \lim_{s \rightarrow \infty} E[X_{t+1} | \mathcal{F}_t] \\ &= \psi(1) \sum_{s \leq t} \varepsilon_s \end{aligned}$$

and a cycle component.

$$\begin{aligned} (1 - L)X &= \psi(L)\varepsilon \\ &= \psi(1)\varepsilon + [\psi(L) - \psi(1)]\varepsilon \end{aligned}$$

**A unified approach for jointly estimating
the business and financial cycle
and the role of financial factors**
T. Berger et al. (2022)

The Beveridge-Nelson decomposition of a $\text{VAR}(1)$ process $\Delta X_t = A\Delta X_{t-1} + \varepsilon_t$ is

$$\begin{aligned} \text{Trend}_y &= \lim_{s \rightarrow \infty} E[X_{t+1} | \mathcal{F}_t] \\ &= X_t + A(I - A)^{-1} \Delta X_t. \end{aligned}$$

Trend-cycle decompositions
E. Zivot (2005)

In the $\text{MA}(\infty)$ representation of an $\text{ARIMA}(p, 1, q)$ process

$$\begin{aligned} \phi(L)\Delta X &= \theta(L)\varepsilon & \text{ARMA} \\ \Delta X &= \psi(L)\varepsilon & \text{MA}(\infty) \end{aligned}$$

$\psi(1)$ is the permanent effect of a shock ε_t on the level of X_t .

The Beveridge-Nelson trend is

$$\text{Trend}_t = \text{Trend}_0 + \psi(1) \sum_{s=1}^t \varepsilon_s.$$

The unobserved component model (UC-ARMA) is

$$\begin{aligned} X_t &= \text{Trend}_t + \text{Cycle}_t \\ \text{Trend}_t &= \mu + \text{Trend}_{t-1} + \varepsilon_t \quad \varepsilon_t \sim N(0, \Sigma) \\ \phi(L)\text{Cycle} &= \theta(L)\eta \quad \eta_t \sim N(0, S). \end{aligned}$$

If the cycle is a stationary AR process, *i.e.*, $\theta(L) = 1$, and the roots of ϕ are outside the unit circle (and $\varepsilon \perp \eta$), it can be written as a state space model

$$\begin{bmatrix} c_t \\ \vdots \\ c_{t-p+1} \end{bmatrix} = \begin{bmatrix} \phi_1 & \dots & \phi_p \\ 1 & 0 & \dots & 0 \\ 0 & \diagdown & & \\ \vdots & \vdots & \ddots & \vdots \\ 0 & \dots & 0 & 1 & 0 \end{bmatrix} \begin{bmatrix} c_{t-1} \\ \vdots \\ c_{t-p} \end{bmatrix} + \begin{bmatrix} \eta_t \\ 0 \\ \vdots \\ 0 \end{bmatrix}$$

$$\Delta X_t = \mu - \mathbf{1}' \begin{bmatrix} c_{t-1} \\ \vdots \\ c_{t-p} \end{bmatrix} + \varepsilon_t$$

and estimated with a Kalman filter.

The *variance ratio* statistic

$$\begin{aligned} R_k &= V_k / V_1 \\ V_k &= \frac{1}{k} \text{Var}[X_{t+k} - X_t - k\mu] \\ \mu &= E[\Delta X_t] \end{aligned}$$

measures the fraction of variation due to permanent shocks.

Bayesian vector autoregressions

T. Woźniak

A VAR(p) model

$$t_t = \mu + A_1 y_{t-1} + \dots + A_k y_{t-k} + u_t \quad u_t \sim N(0, \Sigma)$$

can be written, by transposing the equation and vertically stacking the resulting row vectors,

$$Y = XA + U \quad U \sim \text{MN}(0, \Sigma, I).$$

With a normal-Wishart prior

$$\begin{aligned} \Sigma &\sim \text{IW}(\underline{S}, \underline{\nu}) \\ A|\Sigma &\sim \text{MN}(\underline{A}, \Sigma, \underline{V}), \end{aligned}$$

the posterior is also normal-Wishart

$$\begin{aligned} \Sigma &\sim \text{IW}(\overline{S}, \overline{\nu}) \\ A|\Sigma &\sim \text{MN}(\overline{A}, \Sigma, \overline{V}), \end{aligned}$$

where

$$\begin{aligned} \overline{V} &= (\underline{V}^{-1} + X'X)^{-1} \\ \overline{A} &= \overline{V}(\underline{V}^{-1}\underline{A} + X'Y) \\ \overline{\nu} &= \underline{\nu} + T \\ \overline{S} &= \underline{S} + Y'Y + \underline{A}'\underline{V}^{-1}\underline{A} - \overline{A}'\overline{V}^{-1}\overline{A}. \end{aligned}$$

The Minnesota prior is

$$A = \begin{bmatrix} 0 & \dots & 0 \\ 1 & & & \\ & \diagdown & & \\ & & 1 & \\ 0 & & & \diagdown & \\ & & & & 0 \\ \vdots & & & & \vdots \\ 0 & & & & \diagdown & \\ & & & & & 0 \end{bmatrix}$$

$$\underline{V} = \text{diag}\left(\lambda_0, \frac{\lambda_1}{1^2 \hat{\sigma}_1^2}, \dots, \frac{\lambda_1}{1^2 \hat{\sigma}_n^2}, \frac{\lambda_1}{2^2 \hat{\sigma}_2^2}, \dots\right)$$

where $\hat{\sigma}_i^2$ is the error term variance of a univariate AR(k) model on variable i . For the other hyperparameters, try

$$\begin{aligned} \underline{S} &= (Y - XA)'(Y - XA) \\ \underline{\nu} &= T - K - N - 1. \end{aligned}$$

Nowcasting with large Bayesian vector autoregressions J. Cimadomo (2020)

A *state space BVAR* is a VAR written in state space form. To sample from it, iterate:

- Sample the missing values given A and Σ , using a Kalman simulation smoother;
- Sample the Minnesota hyperparameters given the data;
- Sample the parameters A , Σ given the data and the hyperparameters.

A *stacking BVAR* deals with mixed frequency data by adding the lags of the high-frequency variables.

The *cube root BVAR* deals with monthly and quarterly data by fitting a VAR(p) on quarterly data, writing it in companion form, $Y_t = AY_{t-1} + \varepsilon_t$ and converting it to a monthly VAR, $Y_t = BY_{t-1} + \eta_t$, where $B^3 = A$. There are many cubic roots of A : for the real eigenvalues, take the real cubic root; for the complex one, take that with the lowest argument (*i.e.*, that leading to the least oscillatory behaviour).

Large Bayesian vector autoregressions M. Bańbura et al. (2007)

The FAVAR model is a VAR model with a small number of variables, augmented with a few principal components from a larger number of variables.

Estimating and accounting for the output gap with large Bayesian vector autoregressions
J. Morley and B. Wong (2019)

To choose the variables to include in a BVAR (reduce their number from 138 to 7), look at the contribution of each to the Beveridge-Nelson cycle (adding (removing) irrelevant (relevant) variables does not (does) change the cycle) and remove the variables one by one, starting with those whose contribution has the lowest variance.

Use a Minnesota prior

$$\begin{aligned} E[\phi_k^{ik}] &= 0 \\ \text{Var}[\phi_k^{ij}] &= \frac{\lambda^2}{k^2} \text{ if } i = j \\ \text{Var}[\phi_k^{ij}] &= \frac{\lambda^2}{k^2} \frac{\sigma_i^2}{\sigma_j^2} \text{ if } i \neq j \end{aligned}$$

where λ is selected to minimize the 1-step ahead RMSE on an expanding window.

The contributions can be computed from

$$\begin{aligned} (\Delta X_t - \mu) &= F(\Delta X_{t-1} - \mu) + He_t \\ \text{Cycle}_t &= -F(I - F)^{-1}(\Delta X_t - \mu) \\ &= \dots \\ &= -\sum_{I \geq 0} F^{I+1}(I - F)^{-1}He_{t-I}. \end{aligned}$$

Vector autoregressions: forecasting and reality
J.C. Robertson and E.W. Tallman (1999)

The VAR(1) model (e.g., a BVAR with a Minnesota prior) $X_t = AX_{t-1} + \varepsilon_t$, $\varepsilon_t \sim N(0, \Sigma)$ can be written $X_t \sim N(AX_{t-1}, \Sigma)$. If some of the coordinates are not observed, their distribution given the observed coordinates is known (*conditional forecasting*) (from the usual formula for the conditional Gaussian distribution).

$$\begin{aligned} E[X_t^{\text{mis}} | X_t^{\text{obs}}] &= \\ &= (AX_{t-1})^{\text{mis}} + \Sigma_{\text{mis,obs}} \Sigma_{\text{obs,obs}}^{-1} [X_t^{\text{obs}} - (AX_t)^{\text{obs}}] \end{aligned}$$

Large Bayesian vector autoregression
J.C.C. Chan

The BVAR with errors $U \sim \text{MN}(0, \Sigma, \Omega)$ can be non-Gaussian and/or have autocorrelated errors:

- Gaussian: $\Omega = I$;
- Common stochastic volatility:

$$\begin{aligned} \Omega &= \text{diag}(e^{h_1}, \dots, e^{h_T}) \\ h_t &= \rho h_{t-1} + \varepsilon_t \end{aligned}$$

- Fat tails (Student T):

$$\begin{aligned} \Omega &= \text{diag}(\lambda_1, \dots, \lambda_T) \\ \lambda_t &\sim \text{InverseGamma} \end{aligned}$$

- Serially dependent errors, e.g., $u_t \sim \text{MA}(2)$, i.e.,

$$\Omega = \begin{pmatrix} & & & 0 \\ & \diagdown & \diagdown & \diagdown \\ & \diagdown & \diagdown & \diagdown \\ 0 & \diagdown & \diagdown & \diagdown \end{pmatrix}$$

Industry classification using a novel financial time series case representation
R. Dolphin et al.

Compute an embedding of stocks from pricing data:

- S_{ij} = similarity between the delay embeddings ($\tau = 5$) of the daily return time series
- C_{ij} = number of times stock i is among the k nearest neighbours of stock j ($k = 1$);
- $C \approx EE'$, low-rank factorization, ignoring the diagonal (after log-transforming the entries of C).

Visualize the truncated graph with t-SNE.

Hedonic prices and quality-adjusted price indices powered by AI
P. Bajari et al. (2023)

Forecast product prices from (time-stamped) unstructured product data (text, image: BERT and ResNet50) and use this model to measure *inflation*.

$$\begin{aligned} \text{Price}_{it} &= h_t(\text{features}_{it}) + \varepsilon_{it} \\ \text{or } \text{Price}_{i,\cdot} &= h(\text{features}_i) + \varepsilon_{i,\cdot} \end{aligned}$$

Precision versus shrinkage: a comparative analysis of covariance estimation methods for portfolio allocation
S. Dutta and J. Jain (2023)

To estimate the variance matrix, for portfolio optimization, prefer Gaussian graphical models:

- Graphical lasso

$$\text{Minimize}_{\Theta \succ 0} \log \det \Theta - \text{tr}(\hat{\Sigma} \Theta) - \lambda \|\Theta\|_1$$

- Nodewise regression;
- Clime

$$\text{Minimize}_{\Theta \succ 0} \|\Theta\|_1 \text{ such that } \left\| \hat{\Sigma} \Theta - I \right\|_{\infty} \leq \lambda$$

- Greedy prune: find the neighbours of i by adding the variable X_j minimizing $\text{Var}[X_1 | X_{\mathcal{N}(i)}, X_j]$, T times, and then pruning those contributing to a proportion less than ν to the variance;
- Hybrid MB: nodewise regression with no L^1 penalty on the nearest neighbour, followed by pruning.

Alternatives include

- Linear shrinkage (for various choices of the target and the shrinkage constant: Ledoit-Wolf, Rao-Blackwell-Ledoit-Wolf, Bodnar, oracle);

- Non-linear shrinkage (shrink the eigenvalues of $\hat{\Sigma}$ separately, to minimize some loss function);
- Thresholding (of the covariances): hard, soft, or adaptive;
- Random matrix theory (rotationally invariant estimators).

Non-parametric cumulants approach for outlier detection of multivariate financial data
F. Cesarone et al. (2023)

The CGF-PCA (cumulant generating function) direction is the solution θ of

$$\underset{\theta : \|\theta\|=1}{\text{Maximize}} \log E[e^{r\theta'X}]$$

for a fixed $r > 0$. We are maximizing (not minimizing) a convex function on the sphere (a non-convex set) – but we can replace $\|\theta\| = 1$ with $\|\theta\| \leq 1$ and solve with multistart and projected gradient.

Identify outliers by looking at the projection onto $\text{Span } \theta$.

Multivariate range value-at-risk and covariance risk measures for elliptical and log-elliptical distributions
B. Zuo et al.

The multivariate range VaR is

$$E[X \mid \forall i \text{ VaR}_{p_i} X_i \leq X_i \leq \text{VaR}_{q_i} X_i].$$

The multivariate range covariance is

$$E[(X - \text{MRVaR}_{pq})(X - \text{MRVaR}_{pq})' \mid \text{VaR}_p X \leq X \leq \text{VaR}_q X].$$

Market making with deep reinforcement learning from limit order books
H. Guo et al.

The state space contains the current LOB (limit order book: price, volume, ask, bid, several levels), order imbalance (several windows), realized volatility, technical indicators, inventory, remaining time. Try to forecast the price direction $[t - k, t]$ vs $[t, t + k]$. The reward includes a damped PnL

$$(1 - \lambda)(\Delta \text{PnL})_+ - (\Delta \text{PnL})_-$$

and an inventory penalty. Train with Dueling DQN or PPO.

Trending fast and slow
E. Cheng et al.

Trend following strategies with a volatility dependent lookback (1m vs 12m): slow momentum in low volatility and fast momentum in high volatility work better.

LLaMa: open and efficient foundation language models
H. Touvron et al. (2023)

LLaMa is a family of large language models (LLM), from 13B to 5B parameters, designed to be inexpensive at inference time, trained using only publically available data:

- CommonCrawl/C4, preprocessed in different ways (deduplication, quality filtering, identification of Wikipedia references);
- Github (BigQuery, filtered for free licences, deduplicated, with boilerplate removal);
- Wikipedia (20 languages, boilerplate removed);
- Arxiv (L^AT_EX files, starting at the first section and ending before the references, with macros removed);
- StackExchange (without HTML, with answers sorted by score);
- Gutenberg and Books3 (deduplicated);

using

- Byte pair encoding (BPE, SentencePiece);
- Prenormalization (normalize the input of the transformers, instead of the output, as GPT3);
- SwiGLU (as PaLM);

$$\text{GLU}(a, b) = a \odot \sigma(b)$$

$$\text{Swish}_\beta(x) = x \odot \sigma(\beta x) = \text{} \quad (\beta \text{ learnable})$$

$$\text{SwiGLU}(x) = \text{Swish}_\beta(xW + b) \odot (xV + c)$$

- Rotary positional embedding (RoPE);
- AdamW (decoupled weight decay regularization), with a cosine learning rate schedule, weight decay, gradient clipping, warmup;

$$\text{Weight decay (Adam)} \quad g = \nabla f(\theta) + w\theta$$

$$\text{Decoupled weight decay} \quad \theta \leftarrow \theta - \eta \left(\frac{m}{\sqrt{v} + \varepsilon} + w\theta \right)$$

- xformers (efficient implementation of the causal transformer);
- 20488 80GB GPUs, over 21 days.

Briefly fine-tuning on instructions data leads to rapid improvements.

Self-instruct: aligning language model with self-generated instructions
Y. Wang et al.

To fine-tune a large language model (LLM) on instruction data, you do not need a lot of data:

- Start with a small seed set of manually written instructions (175 instruction-input-output triplets);
- Ask the model itself to generate new instructions; prune low-quality or duplicated ones;
- Fine-tune the model using those instructions.

Alpaca applies self-instruct to llama.

Training compute-optimal large language models
J. Hoffmann et al. (2022)

For compute-optimal training, model size and training tokens should be scaled equally.

$$\begin{aligned}\#\text{parameters} &\propto \text{FLOP}^{1/2} \\ \#\text{tokens} &\propto \text{FLOP}^{1/2} \\ \#\text{tokens}/\#\text{parameters} &= 20\end{aligned}$$

Scaling laws for neural language models
J. Kaplan et al. (2020)

Larger language models make more effective use of training data; the number of parameters should increase faster than the number of tokens.

$$\begin{aligned}\#\text{tokens} &\propto \text{FLOP}^{1/4} \\ \#\text{parameters} &\propto \text{FLOP}^{1/3}\end{aligned}$$

BloombergGPT: a large language model for finance
S. Wu et al. (2023)

Bloom-like model, trained on 50% public (non-financial) data, and 50% Bloomberg data.

- 50B parameters, for 700B tokens, in line with the Chinchilla scaling laws

$$\begin{aligned}\#\text{parameters} &= \text{FLOP}^{1/2}/10 \\ \#\text{tokens} &= \text{FLOP}^{1/2}\end{aligned}$$

- L MSA layers with hidden dimension $D = e^{5+0.06L}$;
- GELU activations, $x \mapsto x\Phi(x)$;
- ALiBi positional encodings;
- Embedding layer normalization;
- AdamW
- Model sharding over 128 GPUs (ZeRO);
- Hierarchical communication and 2-hop gradient updates to reduce communication (MiCS);
- Checkpointing (recompute the activations in the backward pass to reduce memory consumption);
- Mixed precision: FP32 and BF16 (FP32 with truncated mantissa – FP16 truncates both mantissa and exponent);
- Tweak batch size, learning rate, dropout as needed.

BLOOM: a 176B-parameter openaccess multilingual language model
T. Le Scao et al.

Publically available model, trained on 500 multilingual Huggingface datasets (ROOTS corpus), with:

- ALiBi positional encoding (instead of learned or rotary embeddings);
- LayerNorm after the embeddings;
- bfloat16 instead of float16 (which is responsible for some LLM training instabilities);
- Learned multilingual subword tokenizer (BPE) with 250k tokens;
- Distributed learning.

Several models are available, finetuned (BLOOMZ) or not (BLOOM), with 560M, 1.1B, 1.7B, 3B, 7.1B, 176B parameters.

Pythia: a suite for analyzing large language models across training and scaling
S. Biderman et al.

Family of LLMs, with the same structure as GPT-Neo or OPT, from 70m to 12b parameters, each with 154 checkpoints, to study scaling laws.

LoRa: low-rank adaptation of large language models
E. Hu et al.

To efficiently fine-tune large models, replace big weight matrices W with $W + B'A$, freezing W and only fine-tuning the low-rank matrix $B'A$ (initialize them as $A \sim N(0, \sigma^2)$, $B = 0$).

OPT: open pre-trained transformer language models
S. Zhang et al.

GPT3-like model, with 175B parameters (only smaller variants are available, 125B to 66B).

OPT-IML: scaling language model instruction meta learning through the lens of generalization
S. Iyer et al.

Instruction fine-tuning of OPT on 2000 NLP tasks (30B and 175B parameters).

GLM: general language model pretraining with autoregressive blank infilling
Z. Du et al.

LLMs tend to fall in one of three categories: encoder-only (BERT), encoder-decoder (T5), autoregressive (GPT). They can be combined:

- Start with a sentence, $x_1x_2x_3x_4x_5x_6$;
- Mask a few spans (hide the sizes): $x_1x_2[M]x_3[M]$;
- Ask the model to recover them, in an autoregressive way $x_1x_2[M]x_4[M][S]x_5x_6[S]x_3$.

Models available for English and Chinese, with a restrictive license (do not offend the Chinese government).

***Causal reasoning and large language models:
opening a new frontier for causality***
E. Kıcıman et al. (2023)

Causal inference addresses different questions (existence and direction of a causal relation; strength of that relation; full causal graph; attribution: sufficient cause, necessary cause, social norm violation; counterfactual reasoning). On several (small) benchmarks, LLMs perform those tasks better than data-based approaches: *knowledge-based causal inference* answers those questions, by looking, not at the data, but at the metadata (the column names).

To check if the model has seen and memorized the benchmark dataset, provide it with half the column names, or half the questions, and ask for the other half.

To measure the importance of each word in the prompt, remove a few words, and check if the output changes.

***A comprehensive survey
on pretrained foundation models:
a history from BERT to ChatGPT***
C. Zhou et al.

List of models for text, images, or graphs.

***Community detection via semi-synchronous
label propagation algorithms***
G. Cordasco and L. gargano

Label propagation (LPA) computes communities on a graph, by starting to put each node in its own community and then assigning each node to the majority community of its neighbours (breaking ties at random), until convergence. The synchronous version of the algorithm can exhibit cyclic oscillations; the asynchronous version can wrongly produce a giant community.

For bipartite graphs, alternately updating all the nodes of one of the partitions is more stable. This semi-asynchronous algorithm can be generalized to arbitrary graphs, by choosing a node colouring such that adjacent nodes have different colours.

Peirce's tutorial on existential graphs
J.F. Sowa

In MS514, Peirce presents a graphical language for first order logic (FOL).

A *line of identity* represents an existential classifier.

— $\exists x$

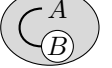

It can be connected to one or several predicates.

— A	$\exists x A(x)$
A — B	$\exists x A(x) \wedge B(x)$
A $\begin{array}{c} \diagup \quad \diagdown \\ B \\ \\ C \end{array}$	$\exists x A(x) \wedge B(x) \wedge C(x)$
S — V — O	$\exists x, y S(x) \wedge O(y) \wedge V(x, y)$

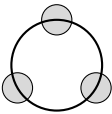

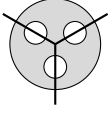

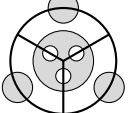

Conjunction is implicit.

— A — B $\exists x \exists y A(x) \wedge B(y)$

Shaded ellipses represent negations.

	$\neg \exists x A(x)$
	$\exists x \neg A(x)$
	$\forall x A(x)$
	$\forall x A(x) \Rightarrow B(x)$
p q	$p \wedge q$
	$p \vee q$
	$p \Rightarrow q$
	$\forall x A(x) \Rightarrow B(x), i.e., A \subset B$
	$p \Rightarrow (q \wedge r \wedge s)$

Lines can be replaced with explicit equalities

—	$\exists x$
— is —	$\exists x \exists y x = y$
— is —	$\exists x \exists y x \neq y$
—  —	$\exists x \exists y x \neq y$
A —  — A	$\exists x \exists y x \neq y \wedge A(x) \wedge A(y)$
	at most one A
	exactly one A
	at least 3
	at most 3
	exactly 3

There are 3 rules of inference:

1. You can erase anything in the unshaded areas (e.g., cut lines); you can add anything in the shaded areas

2. Lines can be extended into any enclosed area; lines can be retracted from any enclosed areas; anything can be copied inwards; anything can be deleted outwards;
3. You can add or remove vacant ring-shaped areas (double negations).

Deep learning on graphs

Y. Ma and J. Tang

4. Graph embedding models look for (graph or node) representations preserving some information about the graph or node,

e.g., random-walk-based co-occurrence (DeepWalk is word2vec on random walks) or structural similarity (struc2vec)

$$g_0(v_1, v_2) = 0$$

$$g_k(v_1, v_2) = g_{k-1}(v_1, v_2) + d(sN_k(v_1), sN_k(v_2))$$

where

v_1, v_2 are nodes

$N_k(v)$ is the set of k -hop neighbours of v

$s(N)$ is the degree distribution of the nodes in N

d is the DTW distance

or neighbourhood similarity

$$s_{ij} = \frac{A_i A'_j}{\|A_i\| \|A_j\|}$$

or community membership, or the adjacency matrix

$$A_{ij} \sim \text{Bernoulli}(\sigma(u'_i u_j)).$$

5. GNNs combine filtering layers (which change the features but not the graph structure) and pooling layers (which coarsen the graph).

Filtering layers include

- Spectral filters $f \mapsto U\gamma(\Lambda)U'f$, where

$$L = D - A \text{ or } D^{-1/2}(D - A)D^{-1/2}$$

$$L = U\Lambda U'$$

$$\gamma(\lambda) = (1 + c\lambda)^{-1} \text{ (low pass filter)}$$

or γ is a (learned) Chebychev polynomial;

- Aggregation of the neighbouring values (mean, sum, max, or even LSTM for some (possibly arbitrary) order of the neighbours);
- Attention, *i.e.*, weighted average of the neighbouring values, with data-dependent weights;

- Mixture models (MoNet) are a type of attention where the weights are computed from the degrees

$$c_{ij} = \begin{bmatrix} \sqrt{d_i} \\ \sqrt{d_j} \end{bmatrix}$$

$$\alpha_{ij} = \exp -\frac{1}{2} \|c_{ij}\|_{(\mu, \Sigma)}^2$$

$$\|c\|_{(\mu, \Sigma)}^2 = (c - \mu)' \Sigma^{-1} (c - \mu)$$

μ, Σ : learnable parameters

- GRU and LSTM cells (considering that the aggregated current value of the neighbours is the previous state).

Flat graph pooling contracts the graph to a single node, by aggregating the node features with mean or max, or with a gating mechanism.

Hierarchical pooling progressively shrinks the graph,

- by selecting the most “important” nodes, where the importance is computed from the node features, directly (gPool) or with a GCN (SAGPool),
- or by collapsing nodes into “supernodes”, computed with spectral clustering (EigenPool) or with a GCN to get cluster membership probabilities (diffpool)

$$A \leftarrow S'AS$$

$$F \leftarrow S'F$$

6. GNNs can be the target of attacks (credit scoring, spam, etc.). *Evasion attacks* target a trained network; *poisoning attacks* corrupt the training data. The goal can be targeted (change the classification of a few nodes) or not (reduce the model performance). The attacker may alter the node features, add or delete nodes or edges; the attacker may have access to the model weights, or to the training data (greybox attack: they train a surrogate model and attack it), or just a black box.

White box attacks often use min-max (or bilevel) optimization, or meta-learning; black-box attacks can use reinforcement learning.

To defend against those attacks:

- Use adversarial samples during training;
- Clean the graph (“purification”), removing edges whose ends have low feature similarity, or reducing the rank of the adjacency matrix;
- Downweight suspicious nodes (replace the hidden representations with Gaussian distributions, and the the variance as a suspiciousness gauge) or penalize suspicious edges (with attention weights, trained on a clean graph to which you apply an adversarial attack, so that you know which edges are adversarial);
- Jointly learn the purification (a new adjacency matrix, S , close to the original one A , low rank, with smooth features), and train a GNN.

7. To train GNNs on large networks, GraphSAGE samples the neighbours. Instead of sampling the neighbours for each node separately, sample a set of nodes N (you need to define the probability distribution) and use $\mathcal{N}_i \cap N$ instead of \mathcal{N}_i , for a whole layer (or for all layers).

Edge-based node samplers sample pairs of nodes with high influence on one another.

Random-walk-based samplers improve the connectivity.

9. LSTMs can be generalized to trees or arbitrary graphs (Tree-LSTM, Graph-LSTM): just aggregate the inputs before feeding them to the LSTM cell.

To generate graphs (AE, VAE, GAN), simply generate the adjacency matrix.

10. For many NLP tasks, first process the sentence with a BiLSTM; then use a GNN on the parse tree.

Node embeddings of knowledge graphs help various downstream tasks, and knowledge graph completion.

14. To limit oversmoothing, add jump-layer connections,

randomly drop edges, or add regularization terms to force the representations of distant nodes to be distinct.

Self-supervised learning on graphs can predict:

- Node properties (degree, centrality, clustering coefficient, features);
- Pairwise similarity or ranking of node properties;
- Edge presence (if some were removed before training);
- Pairwise distances;
- Context (word2vec).

A fast and high quality multilevel scheme for partitioning irregular graphs
G. Karypis and V. Kumar (1998)

Multilevel partitioning (Metis):

- First reduces the size of the graph (coarsening) by collapsing some edges;
- Then partitions (clusters) it, using an algorithm of your choice;
- Finally refines the solution back to the original graph (Kernigham-Lin).

A fast kernel-based multilevel algorithm for graph clustering
I. Dhillon et al. (2005)

To cluster the nodes of a graph, use (weighted) k -means with kernel matrix $\sigma I + A$, $\sigma I - D + A$ or $\sigma D^{-1} + D^{-1}AD^{-1}$ (and $w = 1$ or $w = \text{degree}$).

To coarsen a graph (prior to clustering), visit the vertices in a random order:

- If x is marked, continue;
- If x is unmarked and all its neighbours are marked, mark it and continue;
- Otherwise, merge x with the vertex y maximizing

$$\frac{e_{xy}}{w_x} + \frac{e_{xy}}{w_y}$$

and mark both x and y .

This can also be used to order the nodes, when plotting the adjacency matrix.

Weighted graph cuts without eigenvectors: a multilevel approach
I.S. Shillon et al. (2007)

More details on the `gracclus` algorithm.

Simplifying graph convolutional networks
F. Wu et al. (2019)

Remove the nonlinearities and collapse the weight matrices between consecutive layers:

$$Y = \text{softmax}(S^k X W)$$

$$S = D^{-1/2}(A + I)D^{-1/2}$$

Knowledge graphs: a guided tour
A. Hogan

General $E(2)$ -equivariant steerable CNNs
M. Weiler and G. Cesa (2019)

Consider a Euclidean graph $G \leq E(2) = (\mathbf{R}, +) \rtimes O(2)$. A *steerable feature field* is defined by a feature field and its type

$$f : \mathbf{R}^2 \rightarrow \mathbf{R}^c \quad \text{feature field}$$

$$\rho : G \rightarrow \text{GL}(\mathbf{R}^c) \quad \text{representation.}$$

For instance, for scalar fields, or RGB fields, $\rho = 1$ (trivial representation), but for vector fields, $\rho(t, g) = g$ is another meaningful choice.

Equivariant maps are convolutions with a *steerable* kernel $k : \mathbf{R}^2 \rightarrow \mathbf{R}^{c_{\text{out}} \times c_{\text{in}}}$

$$\forall g \in G \forall x \in \mathbf{R}^2 \quad k(gx) = \rho_{\text{out}}(g)k(x)\rho_{\text{in}}(g^{-1}).$$

(To solve those constraints, first decompose ρ_{out} and ρ_{in} into irreducible components.)

You cannot use arbitrary nonlinearities (they have to be equivariant as well):

- For unitary representations, nonlinearities acting only on the norm $x \mapsto \sigma(x) \cdot x/\|x\|$ are equivariant:
 - NormReLU, $\sigma(u) = \text{ReLU}(u - b)$
 - Squashing, $\sigma(u) = u^2/(u^2 + 1)$
 - Gating $\sigma(u) = u/(1 + e^{-s(x)})$, where s is a scalar field;

- For regular representations (representations on $\mathbf{R}^{|G|}$, permuting the axes), or quotient representations (regular representations of G/H), coordinatewise nonlinearities are equivariant.

Implementation in `e2cnn`.

**Overcoming oversmoothness
in graph convolutional networks
via hybrid scattering networks**
F. Wenkel et al.

The *lazy random walk matrix* (the random walk matrix is WD^{-1}) $P = \frac{1}{2}(I + WD^{-1})$

$$(PX)_i = \frac{1}{2}X_i + \sum_{j \sim i} \frac{X_j}{d_j}$$

defines wavelets

$$\begin{aligned}\Psi_0 &= I = P \\ \Psi_k &= P^{2^{k-1}} - P^{2^k}\end{aligned}$$

and the *geometric scattering transform*

$$U : x \mapsto (\Psi_{k_m} \circ \sigma \circ \dots \circ \Psi_{k_2} \circ \sigma \circ \Psi_{k_1})(x).$$

Combine low-pass layers $X \mapsto \sigma(AX\Theta + B)$, band-pass layers $X \mapsto \sigma(U(X\Theta) + B)$, aggregation (or concatenation, or attention) and *graph residual convolution*

$$X \mapsto [(1 - \lambda)I + \lambda WD^{-1}]X\Theta + B$$

to limit oversmoothing and underreaching in GNNs.

**Scattering GCN: overcoming oversmoothness
in graph convolution networks**
Y. Min et al. (2020)

**Can hybrid geometric scattering networks help
solve the maximum clique problem?**
Y. Min et al. (2022)

Use a scattering GCN to predict which nodes are in the maximum clique, using eccentricity, clustering coefficient, and logarithm of degree as node features, and

$$L(p) = -p'Wp + \beta p'\bar{W}p$$

as loss, where \bar{W} is the adjacency matrix of the complement of G (same node, non-edges as edges).

Neural processes
M. Garnelo et al. (2018)

Neural networks can replace Gaussian processes.

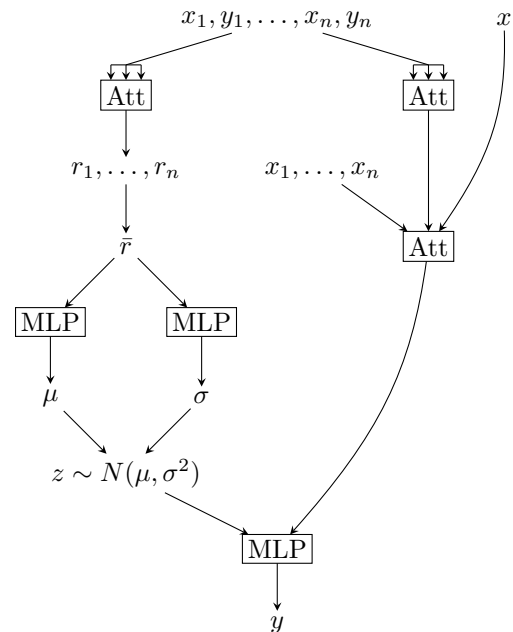

Conditional neural processes
M. Garnelo et al.

Neural process without sampling (a form of meta learning), with applications to image completion.

Attention neural processes
H. Kim et al.

Neural processes underfit the training data, because the average of the latent, representations gives the same weight to all context points. Try with multihead attention blocks.

**Causal inference using invariant prediction:
identification and confidence intervals**
J. Peters et al.

To distinguish between causal and non-causal models (to explain a variable Y), remember that causal models are robust to interventions: they should remain the same when estimated in different settings (interventions, regimes); we do not need to know which variables are intervened on.

An introduction to g methods
A.I. Naimi et al. (2016)

G methods (G-formula, marginal structural models, and structural nested models) compute

$$E[Y | \text{do}(A_0 = A_1 = 1)] - E[Y | \text{do}(A_0 = A_1 = 0)]$$

in the following situation

If we only wanted $\text{do}(A_1)$, we would condition on the confounder Z_1 , but if we also want $\text{do}(A_0)$, we cannot condition on Z_1 because it is a collider. The *G-formula* is obtained by writing down the joint probability.

$$P(y, a_1, z_1, a_0) = P(y | a_1, z_1, a_0) P(a_1 | z_1, a_0) P(z_1 | a_0) P(a_0)$$

$$E[Y] = \sum_{a_1, z_1, a_0} E[Y | a_1, z_1, a_0] P(a_1 | z_1, a_0) P(z_1 | a_0) P(a_0)$$

$$E[Y | \text{do}(a_0, a_1)] = \sum_{z_1} E[Y | a_1, z_1, a_0] P(z_1 | a_0)$$

Marginal structural models use inverse probability weighting to fit the regression $y \sim a_1 + a_2$.

$$P[a_0, a_1 | z_1] = P[a_0 | a_1, z_1] P[a_1 | z_1]$$

$$= P[a_0] P[a_1 | z_1]$$

$$= \frac{1}{2} P[a_1 | z_1]$$

$$P[a_1, a_2] = \frac{1}{2} P[a_1]$$

$$w_{a_0, a_1, z_1} = \frac{P[a_0, a_1]}{P[a_1, a_1 | z_1]}$$

**Estimation of the causal effects
of time-varying exposures**
K.M. Robins and M.A. Hernán

More details on *G*-methods.

**A causal analysis of market contagion:
a double machine learning approach**
J. Simonian

Double machine learning

$$\text{lm}(\text{res}(Y \sim W) \sim \text{res}(T \sim W))$$

(do the inner and outer regressions on different datasets) for

- Treatment: S&P 500 weekly returns
- Outcome: some non-US market weekly returns (for the same or next week)
- Confounders: weekly returns of other non-US markets.

**Unsuitability of NOTEARS
for causal graph discovery**
M. Kaiser and M. Sipos (2021)

NOTEARS $h(w) = \text{trace}(e^{W \odot W}) - d$ is not scale-invariant (for weighted adjacency matrices). GOLEM has the same problem.

**DAGMA: learning DAGs via M-matrices
and a log-determinant acyclic characterization**
K. Bello et al. (2022)

The NOTEARS condition, $\text{Tr}(e^{W \odot W}) = d$, for an adjacency matrix W to be that of a DAG, or

$$\text{Tr} \left(I + \frac{1}{d} W \odot W \right)^d = d,$$

can be replaced with $h(W) = 0$ or, equivalently, $\nabla h(W) = 0$, where

$$h(W) = -\log \det(sI - W \odot W) + d \log s,$$

for $s > 0$. In addition, $h(W) \geq 0$,

$$\nabla h(W) = 2(sI - W \odot W)^{-\top} \odot W.$$

Contrary to NOTEARS (where the contribution of large cycles vanishes quickly), it can detect large cycles.

**On the role of sparsity and DAG constraints
for learning linear DAGs**
I. Ng et al. (2020)

The NOTEARS hard constraint $h(B) = \text{tr}(e^{B \odot B}) - d = 0$ can be replaced with a soft constraint (GOLEM)

$$\text{Minimize}_B \mathcal{L}(B, x) + \lambda_1 \|B\|_1 + \lambda_2 h(B)$$

where the log-likelihood is

$$\mathcal{L}(B, x) = \frac{1}{2} \sum_i \log \sum_k (x_{ki} - B'_i x_k)^2 - \log |\det(I - B)|$$

(but it is not an exact characterization).

**DAG-GNN: DAG structure learning
with graph neural networks**
Y. Yu et al. (2019)

Given the adjacency matrix of a DAG, a SEM (structural equation model) is of the form $X = A'X + Z$, $Z \sim \text{noise}$, i.e., $X = (I - A')^{-1}Z$. It can be made non-linear, and the model can be extended to a VAE.

$$Z \xrightleftharpoons[f_4]{f_1} \cdot \xrightleftharpoons[(I - A')^{-1}]{(I - A')^{-1}} \cdot \xrightleftharpoons[f_3]{f_2} X$$

$$X = f_2[(I - A')^{-1}f_1(Z)]$$

$$Z = f_4[(I - A')^{-1}f_3(X)]$$

To ensure acyclicity: $\text{tr}(I + \alpha A \odot A)^d = d$.

**Learning optimal Bayesian networks:
a shortest path perspective**
C. Yuan and B. Malone (2013)

To find the best Bayesian network for a given dataset, it suffices to find the best leaf (childless variable) and use dynamic programming. The resulting order is a path in the *Hasse diagram* of subsets of variables. Use A^* to restrict the search to promising paths

**Improving causal discovery
by optimal Bayesian network learning**
N.Y. Lu et al. (2021)

Triplet A^* speeds up A^* -based causal discovery by restricting the search for $\text{Pa}(x)$ to subsets of neighbours of $y-x-z$ (given a PC-based initial guess of parents and children of each node).

**Domain-knowledge
in A^* -based causal discovery**
S. Kleinegesse et al.

Add domain knowledge ($x \in \text{Pa}(y)$ or $x \notin \text{Pa}(y)$) to A^* score-based causal discovery.

**Reliable causal discovery
with improved exact search
and weaker assumptions**
I. Ng et al. (2021)

Speed up A^* -based causal discovery by limiting the size of the parent graphs (A^* superstructure) and/or limiting the search to the 2-hop neighbourhood of each variable in its graphical lasso graph (local A^*).

**A neural network based model
for multi-dimensional nonlinear
Hawkes processes**
S. Joseph and S. Jain

Neural network to estimate (MLE) the kernel of a Hawkes process.

**Feature selection with annealing
for computer vision and big data learning**
A. Barbu et al.

Recursive feature elimination (RFE) alternates between

- Training an SVM model;
- Discarding the features with the smallest coefficients.

Feature selection with annealing (FSA) alternates between

- Gradient descent step;
- Discarding the features with the smallest coefficients.

Also check Boruta.

Quantile-parametrized distributions
T.W. Keelin and B.W. Powley (2011)

A quantile-parametrized distribution (QPD) is defined by

$$F^{-1}(y) = \sum_{i=1}^n a_i g_i(y), \quad y \in (0, 1).$$

For instance, with $n = 4$ and (Q -normal)

$$g_1(y) = 1$$

$$g_2(y) = \Phi^{-1}(y)$$

$$g_3(y) = y\Phi^{-1}(y)$$

$$g_4(y) = y.$$

Then, $f(x) = (\sum a_i g'_i(y))^{-1}$ where $x = F^{-1}(y)$.

Find a from n probability-value pairs $(x_i, y_i)_{1 \leq i \leq n}$ as $a = Y^{-1}x$, $Y_{ij} = g_j(y_i)$, provided Y is invertible and $\forall y \in (0, 1) \sum a_i g'_i(y) > 0$.

***Ontology development 101:
a guide to creating your first ontology***
N.F. Noy and D.L. McGuinness

An *ontology* is a formal specification of the terms used in a domain, their relations, and properties. It consists of:

- Classes (*concepts*),
- Hierarchical relations between those classes,
- *Instances* of those classes,
- Properties (*slots*) of those classes, or of the instances, each with a set of allowable values (*facets*: class, instance, symbol, free text, list, etc.).

***Axiomatic characterization
of pointwise Shapley decompositions***
M.C. Christansen (2023)

The Shapley values decompose a function $F : \{0, 1\}^d \rightarrow \mathbf{R}$ into a sum of contributions of each input variable. It can be generalized to functions with real arguments (*average sequential decomposition*, aka *pointwise Shapley values*) by writing (assuming $F(0) = 0$)

$$\begin{aligned} F(x) &= F(x) - F(0) \\ &= F(x_1, \dots, x_d) - F(x_1, \dots, x_{d-1}, 0) + \\ &\quad F(x_1, \dots, x_{d-1}, 0) - F(x_1, \dots, x_{d-2}, 0, 0) + \\ &\quad \dots \end{aligned}$$

and averaging over all permutations of (x_1, \dots, x_d) .

***Perceptually uniform color space
for image signals including
high dynamic range and wide gamut***
M. Safdar et al. (2017)

$J_z A_z B_z$ is more perceptually uniform than CIELAB (for reflective colours), CIELUV (self-illuminant colours), IPT, CAM16-UCS, $IC_T C_P$; all have 3 coordinates: lightness, red-green, yellow-blue.

***Nonparametric Bayesian deep networks
with local competition***
K.P. Panousis et al. (2019)

To automatically prune a neural network, use a Bayesian neural net, with latent Bernoulli variables indicating which weights should be kept, following an Indian buffet process (IBP)

$$\begin{aligned} u_k &\sim \text{Beta}(\alpha, 1) \\ \pi_k &\sim \prod_{1 \leq i \leq k} u_i \\ z_{ik} &\sim \text{Bernoulli}(\pi_k) \end{aligned}$$

Efficient few-shot learning without prompts
L. Tunstall et al.

Before training a classifier head, fine-tune the model (in a siamese manner, with a triplet loss). Use with MPNet (a sentence transformer, trained with a paraphrase dataset, to recognize semantic similarity).

***Wasserstein-Kelly portfolios:
a robust data-driven solution
to optimize portfolio growth***
J.Y.M. Li (2023)

The Kelly portfolio

$$\begin{aligned} \text{Find} & \quad w \\ \text{To maximize} & \quad \mathbb{E}_R \log(1 + w'R) \\ \text{Such that} & \quad w \geq 0, w'1 = 1 \end{aligned}$$

where R are the asset simple returns, can be made *distributionally robust* by considering the Wasserstein ball of log-returns centered on the empirical log-return distribution (with the *simple* return ball, the optimization problem is unbounded).

$$\begin{aligned} \text{Find} & \quad w \\ \text{To maximize} & \quad \inf_{F \in \mathcal{B}} \mathbb{E}_{r \sim R} \log w'e^r \\ \text{Such that} & \quad w \geq 0, w'1 = 1 \\ \text{Where} & \quad \mathcal{B} = \{F : W_p(F, F_r) \leq \varepsilon\} \end{aligned}$$

This can be solved with `cvxpy`, after reformulation.

***Probabilistic forecasting with factor quantile
regression: application to electricity trading***
L. Maciejowska et al. (2023)

Given several forecasts $\hat{y}_1, \dots, \hat{y}_d$ (different models, or the same model estimated on different windows), forecast quantiles of y with a linear regression $\hat{y}_\alpha \sim \hat{y}_1 + \dots + \hat{y}_d$ or a principal component regression.

***An adaptive volatility method for probability
forecasting and its application to the M6
financial forecasting competition***
J. de Vilmares and N. Werge (2023)

The adaptive volatility model (AdaVol) is a non-stationary GARCH-like model.

$$\begin{aligned} \varepsilon_t &: \text{log-returns} \\ \gamma_t &: \text{sample volatility of } \varepsilon \\ \sigma_t &: \text{target volatility of } \varepsilon \text{ (unobserved)} \\ \eta_t &\sim N(0, 1) \\ \varepsilon_t &= \sigma_t \eta_t \\ \sigma_t^2 - \gamma_{t-1}^2 &= \sum_{i=1}^p \alpha_i (\varepsilon_{t-i}^2 - \gamma_{t-1}^2) + \sum_{j=1}^q \beta_j (\sigma_{t-j}^2 - \gamma_{t-1}^2) \end{aligned}$$

Performance attribution of machine learning methods for stock return prediction
S. Daul et al. (2021)

Decompose the forecasts (and the performance) of a forward-return predicting model (and the corresponding long-short decile portfolio) into:

- Linear marginal,
- Nonlinear marginal,
- Interactions.

The nonlinear marginal part has little predictive power.

Addendum on how many times cointelated pairs cross paths

B. Mahdavi-Damghani and S. Roberts (2020)

The *cointelation* model allows for arbitrary short-term correlation (even $\rho = -1$) and mean reversion ($\rho = +1$ in the long term).

$$\begin{aligned}\frac{dX}{X} &= \mu dt + \sigma dW_1 && \text{leading} \\ dY &= \theta(X - Y)dt + \sigma Y dW_2 && \text{lagging} \\ d\langle W_i, W_2 \rangle &= \rho dt\end{aligned}$$

Exploring the advantages of transformers for high-frequency trading
F. Barez et al. (2023)

Forecast the future (100ms) log-returns with a transformer encoder, linear decoder, spiking activation

$$S(x) = \begin{cases} x & \text{if } x \geq \text{threshold} \\ 0 & \text{otherwise} \end{cases}$$

with `pytorch-spiking` (and PReLU) and quantile loss.

Reinforcement learning for trading systems and portfolios
J. Moody and M. Saffell (1998)

Train your trading/investment strategy end-to-end, maximizing the Sharpe ratio, instead of minimizing the sum of squared residuals.

Macroeconomic forecasting and sovereign risk assessment using deep learning techniques
A. Petropoulos et al.

Predict 9 monthly macroeconomic variables from their 1-year lags and 3 contemporaneous variables, with

- Bayesian model averaging (BMA);
- MLP (5 layers, ReLU, dropout);
- Bayesian neural net;
- Bayesian LWTA (local winner takes all) neural net.

Deep adaptive input normalization for time series forecasting
N. Passalis et al.

Before processing a time series with a neural net, DAIN normalizes it, adaptively.

$$\begin{aligned}a &\leftarrow \text{LSTM}(x) \\ x &\leftarrow x - Wa \\ b &\leftarrow \text{LSTM}(x) \\ x &\leftarrow x \oslash Wb \\ c, d &\leftarrow \text{LSTM}(x) \\ x &\leftarrow x \odot \text{sigm}(Wc + d)\end{aligned}$$

Expectile hidden Markov regression models for analyzing cryptocurrency returns
B. Foroni et al. (2023)

Expectile regression replaces the squares in the loss function with

$$\omega_\tau(u) = \begin{cases} \tau u^2 & \text{if } u \geq 0 \\ (1 - \tau)u^2 & \text{if } u < 0, \end{cases}$$

where $\tau \in (0, 1)$.

$$\underset{\beta}{\text{Minimize}} \mathbb{E}[\omega_\tau(y - X'\beta)]$$

It is often estimated with IRLS (iteratively reweighted least squares).

The *asymmetric normal* distribution has density

$$f(y) \propto \exp -\omega_\tau \left(\frac{y - \mu}{\sigma} \right).$$

The asymmetric normal hidden Markov model (HMM) can be estimated with the expectation-maximization (EM) algorithm.

Frog in the pan: continuous information and momentum
Z. Da et al. (2014)

Investors are inattentive to information arriving continuously in small amounts: combine/replace momentum with/by the “information discreteness”,

$$\text{ID} = \text{sign}(\text{momentum}) \times (\% \text{neg} - \% \text{pos}).$$

Quantum computing: lecture notes
R. de Wolf (2022)

Quantum computing is linear algebra on the Hilbert space $H = (\mathbf{C}^2)^{\otimes n}$. The standard basis of \mathbf{C}^2 is denoted

$$\begin{aligned}|0\rangle &= e_1 = \begin{pmatrix} 1 \\ 0 \end{pmatrix} \\ |1\rangle &= e_2 = \begin{pmatrix} 0 \\ 1 \end{pmatrix}.\end{aligned}$$

The coordinates in that basis are called *amplitudes* (but these are complex numbers). The corresponding row

vectors (conjugate transpose) are denoted $\langle 0|$, $\langle 1|$. Another basis is

$$\begin{aligned}|+\rangle &= (|0\rangle + |1\rangle)/\sqrt{2} \\ |-\rangle &= (|0\rangle - |1\rangle)/\sqrt{2}.\end{aligned}$$

A *classical state* is an element of the standard basis. A pure quantum *state* is a vector of norm 1, up to a scalar multiple; alternatively, it is a 1-dimensional subspace, or a projection onto a 1-dimensional subspace. A quantum state is a *superposition* of classical states, i.e., a linear combination of basis vectors. A *mixed quantum state* is a probability distribution over pure quantum states, $\rho = \sum p_i |\phi_i\rangle \langle \phi_i|$. An *entangled state* in $\mathbf{C}^2 \otimes \mathbf{C}^2$ is a state which is not of the form $u \otimes v$ (elements of $\mathbf{C}^2 \otimes \mathbf{C}^2$ are linear combinations of such *product states*), e.g., the *EPR pair*

$$\frac{|00\rangle + |11\rangle}{\sqrt{2}}.$$

A *measurement* of a quantum state $|\phi\rangle = \sum \alpha_i |i\rangle$ in the standard (or “computational”) basis ($|0\rangle, |1\rangle, \dots, |N-1\rangle$) replaces $|\phi\rangle$ with the classical state $|i\rangle$ with probability $\|\alpha_i\|^2$. A *projective measurement* of $|\phi\rangle$ wrt projections P_1, \dots, P_m such that $\sum P_i = I$ replaces $|\phi\rangle$ with (a state proportional to) $P_i |\phi\rangle$ with probability $\langle \phi | P_i | \phi \rangle = \text{tr } P_i |\phi\rangle \langle \phi|$. A *POVM* (positive operator-valued measurement) wrt positive semi-definite matrices E_1, \dots, E_m such that $\sum E_i = I$ replaces $|\phi\rangle$ with a post-measurement state associated with E_i (not defined) with probability $\text{tr } E_i |\phi\rangle \langle \phi|$.

States can be transformed with unitary matrices U , or *gates*, $|\phi\rangle \mapsto U |\phi\rangle$ (or $\rho \mapsto U \rho U^\dagger$), for instance

$$\begin{aligned}I &= \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix} \\ X &= \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} && \text{bitflip (NOT)} \\ Y &= \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix} \\ Z &= \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix} && \text{phase flip} \\ H &= \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 0 \\ 1 & -1 \end{pmatrix} && \text{Hadamard} \\ R_\phi &= \begin{pmatrix} 1 & 0 \\ 0 & e^{i\phi} \end{pmatrix} && \text{phase gate} \\ T &= R_{\pi/4} \\ \text{CNOT} &= \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix}\end{aligned}$$

The CNOT (controlled NOT) gate applies a bitflip X (NOT) to the second qubit if the first is $|1\rangle$; the Toffoli gate (CCNOT) is similar, but has two control qubits: if they are both 1, the third qubit is flipped. The composition of those gates is often depicted as a quantum circuit.

The *query* for $x \in \{0, 1\}^N$ is the unitary map (a permutation matrix)

$$O_x : \begin{cases} (\mathbf{C}^2)^{\otimes n} \otimes \mathbf{C}^2 & \longrightarrow (\mathbf{C}^2)^{\otimes n} \otimes \mathbf{C}^2 \\ |i, b\rangle & \mapsto |i, b \oplus x_i\rangle \end{cases}$$

where $n = \lceil \log_2 N \rceil$. The *phase query* $O_{x,\pm}$ uses $|i, -\rangle \mapsto (-1)^{x_i} |i, -\rangle$ instead.

The *Deutsch-Jozsa algorithm* tells if $x \in \{0, 1\}^N$ is constant or half 1's and half 0's.

Given $x \in \{0, 1\}^N$ such that $x_i \equiv ia \pmod{2}$, the *Bernstein-Vazirani algorithm* finds a .

Given $x \in \{0, 1\}^N$ such that $x_i = x_j$ iff $i = j$ or $i = j \oplus s$, for some $s \in \{0, 1\}^n$, the *Simon algorithm* finds s .

The *Fourier transform*

$$(F_N)_{jk} = \frac{1}{\sqrt{N}} e^{2\pi i jk/N}$$

generalizes the Hadamard transform $H = F_2$. The Fast Fourier transform (FFT) computes $F_N v$ efficiently by recursively separating even and odd terms. The *Quantum Fourier transform* only requires $O((\log N)^2)$ gates, instead of $O(N \log N)$.

$$F_N |k\rangle = \bigotimes_{\ell=1}^n \frac{1}{\sqrt{2}} \left(|0\rangle + e^{2\pi i k/2^\ell} \right)$$

Shor's *period finding algorithm* is $O((\log N)^2 (\log \log N)^2 \log \log \log N)$.

Grover's search algorithm provides a quadratic speed-up.

$$G = H^{\otimes n} R_0 H^{\otimes n} O_{x,\pm}$$

Unitary operators appearing in quantum mechanics are often of the form $U = e^{-iHt}$, form some Hermitian operator H (the Hamiltonian). If $H = \sum H_j$ (where, for instance, the H_j 's only act on a small number of qubits), we would like to decompose U as a product of simpler (smaller) unitary operators, but $e^{-iHt} \neq \prod e^{-iH_j t}$ in general (if the H_j 's do not commute). The *Lie-Trotter* formula approximates U as

$$e^{-i \sum H_j t} \approx \left(\prod_j e^{i H_j t/r} \right)^r.$$

There are other Hamiltonian approximations (linear combination of unitaries (LCU), block-encoded matrices).

The *HHL algorithm* solves a *quantum* linear system $Ax = b$, *i.e.*, finds a n -qubit state close to

$$|x\rangle = \frac{1}{\|x\|} \sum_{i=0}^{N-1} x_i |i\rangle,$$

Similarly, *quantum machine learning* learns from data encoded as quantum states (the model is a quantum circuit, and the parameters are the gate parameters, *e.g.*, θ for R_θ).

Error correction is more necessary than with classical computing, but possible.

Quantum mechanics for mathematicians A. Alekseev (2019)

1. A finite-dimensional **quantum system** is defined by (\mathcal{H}, H) :

- A1 A Hilbert space over \mathbf{C} , \mathcal{H} ;
- A2 The set of *observables*,

$$\mathcal{A} = \{A \in \text{End } \mathcal{H} : A^* = A\}$$

(note that \mathcal{A} is a Lie algebra);

- A3 The set of *states*

$$\mathcal{S} = \{M \in \text{End } \mathcal{H} : M^* = M, \text{tr } M = 1, M \geq 0\};$$

a *pure state* is a projection in a 1-dimensional subspace; pure spaces form the projective space $\mathbf{P}(\mathcal{H})$;

- A4 A measurement map

$$\begin{cases} \mathcal{A} \times \mathcal{S} & \longrightarrow \{\text{probability measures on } \mathbf{R}\} \\ (A, M) & \longmapsto \mu_A^M \end{cases}$$

defined by

$$\mu_A^M(E) = \text{tr}(PP_A(E)) = \sum_{i: \lambda_i \in E} \text{tr}(MP_i)$$

$$A = \sum \lambda_i P_i$$

P_i : projections on the eigenspaces

$$P_A(E) = \sum_{i: \lambda_i \in E} P_i$$

P_A : projection-valued measure

For a pure state $M = P_u$, $\|u\| = 1$, and 1-dimensional eigenspaces

$$\begin{aligned} \mu_A^M &= \sum_i \text{tr}(MP_i) \delta_{\lambda_i} \\ &= \sum_i |\langle e_i, u \rangle|^2 \delta_{\lambda_i} \\ &= \sum_i p_i \delta_{\lambda_i}; \end{aligned}$$

the $\langle e_i, u \rangle$ are called *probability amplitudes* (without the modulus). The mean and variable of an observable A are

$$\bar{A} = \int_{\mathbf{R}} \lambda d\mu_A^M = \sum \lambda_i p_i$$

$$\text{Var}[A] = \int_{\mathbf{R}} (\lambda - \bar{A})^2 d\mu_A^M = \sum (\lambda_i - \bar{A})^2 p_i.$$

More generally (“functional calculus”), for a function $f : \mathbf{R} \rightarrow \mathbf{R}$, $f(A) = \sum f(\lambda_i) P_i$ is still self-adjoint and

$$\overline{f(A)} = \int_{\mathbf{R}} f(\lambda) d\mu_A^M = \sum f(\lambda_i) p_i.$$

A5 $H \in \mathcal{A}$, the *Hamiltonian* of the system; its eigenvalues are denoted E_1, \dots, E_n ; the evolution of the system is then defined by

$$\frac{dM(t)}{dt} = -\frac{i}{\hbar} [H, M].$$

It is often written for pure states P_u , *i.e.*, projections on 1-dimensional subspaces,

$$\frac{du(t)}{dt} = -\frac{i}{\hbar} H u(t).$$

It can be solved with the (unitary) *evolution operator* $U(t) = \exp(-\frac{i}{\hbar} H t)$ as $u(t) = U(t)u_0$ (for general states, $M_t = U_t M_0 U_t^{-1}$). In the Heisenberg picture, the state is constant and the observables change

$$\frac{dA(t)}{dt} = +\frac{i}{\hbar} [H, A].$$

The Heisenberg uncertainty principle states

$$\sigma_{A_1}^2 \sigma_{A_2}^2 \geq \frac{1}{2} |\text{tr } M([A_1, A_2])|^2.$$

An observable $A \in \mathcal{A}$ is a *conserved quantity*, or a *quantum integral* if $[H, A] = 0$.

The Lie algebra of symmetries is

$$\text{sym } H = \{G \in i\mathcal{A} : [B, H] = 0\} \subset i\mathcal{A}.$$

The group of symmetries is

$$\text{Sym } H = \{g \in U(\mathcal{H}) : g H g^{-1} = H\}$$

A set of observables (H, A_1, \dots, A_m) is a quantum *integrable system* if they commute and their symmetry group $\text{Sym}(H, A_1, \dots, A_m)$ is as small as possible, *i.e.*, $U(1) \times \dots \times U(1)$, *i.e.*, the joint eigenspaces are of dimension 1. Given a basis of common eigenvectors $(e_a)_{1 \leq a \leq n}$,

$$\begin{aligned} H e_a &= E_a e_a \\ A_i e_a &= \alpha_a^i e_a \end{aligned}$$

there is a bijection between the set of *quantum numbers* $\{(E_a, \alpha_a^1, \dots, \alpha_a^m) : 1 \leq a \leq m\}$ and the basis. Examples include:

- The spin $\frac{1}{2}$ particle, $\mathcal{H} = \mathbf{C}^2$, with the Pauli matrices $\sigma_1, \sigma_2, \sigma_3$ as an \mathbf{R} -basis of \mathcal{A} and, for instance,

$$H = \begin{pmatrix} \alpha & 0 \\ 0 & -\alpha \end{pmatrix};$$
- The Heisenberg magnetic chain, $\mathcal{H} = (\mathbf{C}^2)^{\otimes N}$,

$$H = J \sum_{i=1}^N \sum_{a=1}^3 \sigma_a^i \sigma_a^{i+1}$$

where $\sigma_a^i = 1 \otimes \dots \otimes 1 \otimes \sigma_a \otimes 1 \otimes \dots \otimes 1$. Note that $L_a = \sum_i \sigma_a^i$ are conserved quantities, but there are many more.

2. Given a (possibly unbounded) operator on a Hilbert space \mathcal{H}

$$A : \mathcal{H} \supset D(A) \longrightarrow \mathcal{H}$$

with dense domain $D(A)$, its *adjoint* is $A^* : D(A^*) \rightarrow \mathcal{H}$ where

$$D(A^*) = \{v \in \mathcal{H} : u \mapsto \langle u, Au \rangle \text{ is bounded on } D(A)\}$$

and A^* is given by the Riesz representation theorem $\langle v, Au \rangle = \langle A^* v, u \rangle$. The domain $D(A^*)$ need not be dense.

An operator is *closed* if its graph is closed; it is *closable* if it admits a closed extension; it is *symmetric* if $\forall u, v \in D(A), \langle Au, v \rangle = \langle u, Av \rangle$. For a symmetric closable operator, $A \subset \bar{A} \subset A^*$. An operator is *self-adjoint* if $A^* = A$ (in particular, $D(A) = D(A^*)$); it is *essentially self-adjoint* if $\bar{A} = A^*$.

If A is symmetric,

$$A^* = A \text{ iff } \text{Im}(A + i) = \text{Im}(A - i) = \mathcal{H}.$$

If A is symmetric and closed, it admits a self-adjoint extension iff $n_+(A) = n_-(A)$; its self-adjoint extensions are in bijection with unitary operators

$$U : \ker(A^* - i) \rightarrow \ker(A^* + i).$$

Given two self-adjoint operators A, B , with $D(A) \subset D(B)$, if $\forall u \in D(A) \ \|Bu\| \leq \alpha \|Au\| + \beta \|u\|$, for some $\alpha < 1$, then $A + B : D(A) \rightarrow \mathcal{H}$ is self-adjoint (Kato-Rellich).

In ℓ^2 , the operator $Ae_i = a_i e_i$, on

$$D(A) = \{\text{sequences eventually zero}\}$$

is symmetric if the a_i 's are real; its adjoint is defined on

$$D(A^*) = \{v : \sum a_i^1 \|v_i\|^2 < \infty\};$$

it is essentially self-adjoint: $\bar{A} = A^*$.

On $L^2([0, 1])$, the momentum operator

$$A = -i\hbar \frac{d}{dx},$$

defined on $\mathcal{C}_0^1([0, 1], \mathbf{C})$ (continuously differentiable functions u with $u(0) = u(1) = 0$) is symmetric but not essentially self-adjoint: $\bar{A} \subsetneq A^*$, since $\mathcal{C}^1([0, 1]) \subset D(A^*)$. Replacing the boundary conditions with $u(0) = u(1)$ (*i.e.*, replacing $[0, 1]$ with \mathbf{S}^1) fixes the problem.

In $L^2(\mathbf{R}^n)$, multiplication by a measurable function $V = V(x_1, \dots, x_n)$ is a self-adjoint operator \hat{V} on $D(\hat{V}) = \{u \in L^2(\mathbf{R}^n) : \int_{\mathbf{R}^n} V^2 |u|^2 dx < \infty\}$.

Using the Fourier transform and the Schwartz functions $\mathcal{S} = \{u \in \mathcal{C}^\infty : \forall i, j \sup_x |x^i \partial_j u| < \infty\}$ one can build self-adjoint extensions of $-i\partial_i$.

In $L^1(\mathbf{R}^3)$ (not $L^2(\mathbf{R}^n)$ for $n \geq 4$) $A = -\Delta + \hat{V}_1 + \hat{V}_2$, where $V_1 \in L^2, V_2 \in L^\infty$, is self-adjoint on $D(-\Delta)$ and bounded below ($\forall u \ \langle u, Au \rangle \geq C \|u\|^2$).

3. The **spectrum** $\sigma(A)$ of $A : D(A) \rightarrow \mathcal{H}$ is

$$\{x \in \mathbf{C} : A - x \text{ is not invertible}\};$$

it is closed. For instance,

$$\begin{aligned} A &= -i \frac{d}{dx} \\ D(A) &= \mathcal{C}^1(\mathbf{S}^1) \\ \sigma(A) &= \mathbf{Z} \end{aligned}$$

$$\begin{aligned} A &= \hat{x} \\ D(A) &= \left\{ u \in L^2(\mathbf{R}) : \int_{\mathbf{R}} x^2 |u(x)|^2 dx < \infty \right\} \\ \sigma(A) &= \mathbf{R} \end{aligned}$$

If $A : D(A) \rightarrow \mathcal{H}$ is self-adjoint, there is a unique projection-valued measure $E \mapsto P_A(E)$ on \mathbf{R} such that

$$\begin{aligned} D(A) &= \{u \in \mathcal{H} : \int_{\mathbf{R}} \lambda^2 f \langle u, P_A(\lambda) u \rangle < \infty\} \\ Au &= \int_{\mathbf{R}} \lambda d(P_A(\lambda)u) \text{ (Riemann integral)} \\ \langle u, Au \rangle &= \int_{\mathbf{R}} \lambda d \langle u, P_A(\lambda)u \rangle \end{aligned}$$

where $P_A(\lambda) = P_A((-\infty, \lambda))$.

For $f \in \mathcal{C}(\mathbf{R}, \mathbf{C})$, we can define (functional calculus) $f(A)$ as

$$\begin{aligned} D(f(A)) &= \left\{ u \in \mathcal{H} : \int_{\mathbf{R}} |f(\lambda)|^2 d \langle u, P_A(\lambda)u \rangle < \infty \right\} \\ f(A)(u) &= \int_{\mathbf{R}} f(\lambda) d(P(\lambda)u). \end{aligned}$$

In particular, for the Hamiltonian $H : D(H) \rightarrow \mathcal{H}$, we can define the 1-parameter subgroup of unitary evolution operators

$$U(t) = \exp\left(-\frac{i}{\hbar}Ht\right).$$

5. Given two self-adjoint operators A, B , with $D(A) \cap D(B)$ dense, such that $A + B$ be self-adjoint,

$$\forall \psi \quad e^{i(A+B)}\psi - (e^{iA/n}e^{iB/n})^n\psi \longrightarrow 0.$$

If, in addition, A and B are bounded below,

$$\forall \psi \quad e^{-(A+B)}\psi - (e^{-A/n}e^{-B/n})^n\psi \longrightarrow 0.$$

The *Feynman path integral* applies this to $H = A + B$, $A = -(\hbar^2/2m)\Delta$, $B = V(x)$, and conjectures (wrongly) that the resulting limit can be expressed as an integral on a space of paths.

If $A : \mathbf{R}^n \rightarrow \mathbf{R}^n$ is self-adjoint with positive eigenvalues, then the *Gaussian integral* is

$$\int_{\mathbf{R}^n} d^n x e^{-\frac{1}{2}\langle x, Ax \rangle + \langle x, y \rangle} = \frac{(2\pi)^{n/2}}{(\det A)^{1/2}} e^{\frac{1}{2}\langle y, A^{-1}y \rangle}$$

(there is a similar formula for complex exponential).

There are several generalizations of the determinant to infinite dimensions. The *Fredholm determinant* is

$$\det_F(I - \lambda A^{-1}) = \prod \left(1 - \frac{\lambda}{\lambda_k}\right) \quad \text{if } \sum \frac{1}{|\lambda_k|} < \infty$$

(it is a holomorphic function with zeroes at $\lambda = \lambda_k$. If the eigenvalues of A are positive, its zeta function is

$$\zeta_A(s) = \sum \frac{1}{\lambda_k^s}.$$

In finite dimension, $\zeta(0) = n$ and $\zeta'(0) = \log \det A$; in infinite dimension, if ζ admits an analytic continuation to a neighbourhood of 0, we can define the ζ -regularized determinant

$$\det_\zeta(A) = \exp -\zeta'_A(0)$$

and the ζ -regularized dimension $\delta_A = \zeta_A(0)$. In particular, $\det_\zeta(cA) = c^{\delta_A} \det_\zeta(A)$. Those two notions are related:

$$\det_\zeta(A - \lambda) = \det_\zeta(A) \det_F(I - \lambda A^{-1}).$$

***SDDP.jl: a Julia package
for stochastic dual dynamic programming***
O. Dowson and L. Kapelevich

A multistage stochastic optimization problem is of the form

$$\begin{array}{ll} \text{Find} & u \\ \text{To maximize} & \mathbb{E}_{\omega_1} [V_1(x_1, \omega_1)] \\ \text{Where} & x_1 = 0 \quad \text{state} \\ & x_{t+1} = f(x_t, \omega_t, u_t) \\ & \omega_t \sim p_t \quad \text{noise} \\ & V_t(x_t, \omega_t) = \max_u g(x_t, \omega_t, u) + \\ & \quad \mathbb{E}_{\omega_{t+1}} [V_{t+1}(x_{t+1}, \omega_{t+1})] \\ & h(x_{\leq t}, u_{\leq t}, \omega_{\leq t}) = 0 \quad \text{constraints} \end{array}$$

Dynamic low-rank approximation

O. Koch and C. Lubich (2007)

One can compute a low-rank approximation of a smooth path $A : [0, 1] \rightarrow \mathbf{R}^{m \times n}$ as

$$X(t) = \underset{X: \text{rank } X=k}{\text{Argmin}} \|X - A(t)\|_2^2.$$

Alternatively, try

$$\hat{Y}(t) = \underset{X: \text{rank } X=k}{\text{Argmin}} \|X - \dot{A}_t\|_2^2;$$

this gives a *smooth* low-rank approximation.

Sheaf neural networks

J. Hansen and T. Gebhart (2020)

A *cellular sheaf* \mathcal{F} on a graph $G = (V, E)$ is the datum of

- A vector space $\mathcal{F}(v)$ for each node $v \in V$;
- A vector space $\mathcal{F}(e)$ for each edge $e \in E$;
- A linear map $\mathcal{F}_{v \trianglelefteq e} : \mathcal{F}v \rightarrow \mathcal{F}e$ for each incident vertex-edge pair $v \trianglelefteq e$.

A *0-cochain*, resp. *1-cochain*, is an element of

$$C^0(G, \mathcal{F}) = \prod_{v \in V} \mathcal{F}(v)$$

$$\text{resp. } C^1(G, \mathcal{F}) = \prod_{e \in E} \mathcal{F}(e).$$

The *coboundary* map is

$$\delta : \begin{cases} C^0(G, \mathcal{F}) & \longrightarrow & C^1(G, \mathcal{F}) \\ (x_v)_{v \in V} & \longmapsto & (\mathcal{F}_{v \trianglelefteq e} x_v - \mathcal{F}_{u \trianglelefteq e} x_u)_{e \in E} \end{cases}$$

(for an arbitrary orientation of the edges).

The *sheaf Laplacian* is $L_{\mathcal{F}} = \delta^\top \delta$. For the *constant sheaf* $\mathcal{F}v = \mathbf{R}$, $\mathcal{F}e = \mathbf{R}$, $\mathcal{F}_{v \trianglelefteq e} = \text{Id}$, it is the standard Laplacian. With different signs for $\mathcal{F}_{v \trianglelefteq e}$, it can model *signed* graphs and heterophily. The *normalized Laplacian* is $\tilde{L}_{\mathcal{F}} = D^{-1/2} L_{\mathcal{F}} D^{-1/2}$, where $D = \text{diag } L_{\mathcal{F}}$. The corresponding *diffusion operator* is $\tilde{H}_{\mathcal{F}} = I - \tilde{L}_{\mathcal{F}}$. A *sheaf convolution layer* is

$$X \longmapsto \rho[\tilde{H}_{\mathcal{F}}((I_{|V|} \otimes B)XA)]$$

where ρ is an elementwise nonlinearity.

**Sheaf neural networks
with connection Laplacians
F. Barbero et al. (2022)**

GNNs work poorly on heterophilic data (homophily is an inductive bias) and suffer from oversmoothing. Replacing the Laplacian with a sheaf Laplacian can address those problems. Instead of choosing the sheaf manually using domain knowledge, or learning it end-to-end,

$$\mathcal{F}_{v \triangleleft (v,u)} = \Phi(x_v, x_u) \in \mathbf{R}^{d \times d},$$

compute it at preprocessing time, using local PCA:

$$\begin{aligned} i, j &: \text{ nodes} \\ \hat{X}_i &: \text{ features of the neighbours of } i \\ \hat{X}_i &= U_i \Sigma_i V_i' \text{ (SVD)} \\ O_i &= U_i[:, : d] \\ O_i' O_j &= U \Sigma V' \text{ (SVD)} \\ O_{ij} &= UV' \\ O_{ij} &= \mathcal{F}_{j \triangleleft e}^\top \mathcal{F}_{i \triangleleft e}. \end{aligned}$$

This is the parallel transport: it gives the entries of $L_{\mathcal{F}}$, up to sign for the off-diagonal blocks.

**Neural sheaf diffusion:
a topological perspective on heterophily
and oversmoothing in GNNs
C. Bodnar et al. (2022)**

A *discrete $O(d)$ -bundle* is a cellular sheaf with orthogonal maps $\mathcal{F}_{v \triangleleft e} \in O(d)$. If the *transports*

$$P_{\gamma: v_1 \rightarrow \dots \rightarrow v_n} = (\mathcal{F}_{v_{n-1} \triangleleft e}^\top \mathcal{F}_{v_n \triangleleft e}) \cdots (\mathcal{F}_{v_1 \triangleleft e}^\top \mathcal{F}_{v_2 \triangleleft e})$$

are path-independent, then there is a nontrivial global section: $H^0 \neq 0$ (in fact, $\dim H^0 = d$). Diffusion, if run long enough, yields a signal constant on each connected component. Diffusion on a well-chosen $O(d)$ -bundle can linearly separate classes, even in presence of heterophily.

Learn the sheaf to use in *neural sheaf diffusion* layers

$$X_{t+1} = X_t - \sigma[\Delta_{\mathcal{F}(t)}(I \otimes W_1^t)X_t W_2^t]$$

as

$$\mathcal{F}_{v \triangleleft (v,u)} = \Phi(x_v, x_u) = \sigma(V[x_v \| x_u]).$$

Parametrize orthogonal matrices with *Householder reflections*.

The sheaf Laplacian is a positive semi-definite block matrix; the diagonal blocks are

$$(L_{\mathcal{F}})_{vv} = \sum_{v \triangleleft e} \mathcal{F}_{v \triangleleft e}^\top \mathcal{F}_{v \triangleleft e}$$

and the off-diagonal blocks are

$$(L_{\mathcal{F}})_{uv} = -\mathcal{F}_{v \triangleleft e}^\top \mathcal{F}_{u \triangleleft e}.$$

**Efficient orthogonal parametrization
of recurrent neural networks
using Householder reflections
Z. Mhammedi et al. (2017)**

All orthogonal matrices in $O(n)$ can be written as $H_n(u_n)H_{n-1}(u_{n-1}) \cdots H_1(u_1)$ where $u_k \in \mathbf{R}^k \setminus \{0\}$, $u_1 \in \{\pm 1\}$,

$$H_k(u) = \begin{pmatrix} I_{n-1} & 0 \\ 0 & I_k - 2 \frac{uu'}{\|u\|^2} \end{pmatrix}, \quad H_1(u) = \begin{pmatrix} I & 0 \\ 0 & u \end{pmatrix}.$$

Use in RNNs to prevent vanishing or exploding gradients.

**Knowledge sheaves: a sheaf-theoretic
framework for knowledge graph embedding
T. Gebhart and J. Hansen**

A *knowledge graph schema* is a directed multigraph with entity types as nodes and relation types as edges. A *knowledge graph* (KG) is a graph morphism to a KG schema $k : G \rightarrow S$. A *knowledge sheaf* is a cellular sheaf \mathcal{F} on a KG schema; it induces a sheaf $k^* \mathcal{F}$ on the KG. A *sheaf embedding* of a KG G is a global section $x \in H^0(G, k^* \mathcal{F}) \subset C^0(G, k^* \mathcal{F})$. It can be learned, together with the sheaf \mathcal{F} , as

$$\underset{x \in C^0(G, k^* \mathcal{F})}{\text{Minimize}} \quad x' L_{k^* \mathcal{F}} x$$

with a penalty (negative examples) to avoid the zero solution (in practice, a margin ranking loss works better). Translational embeddings (TransE) are a special case.

**A brief note for sheaf structures on posets
C.S. Hu (2020)**

A *cellular sheaf* on a poset (P, \leq) is a functor $(P, \leq) \rightarrow \mathbf{Set}$. In the *Alexandrov topology* on a poset (P, \leq) , the open sets are the $U \subset P$ such that

$$\forall x \in U \quad \forall y \in P \quad x \leq y \implies y \in U.$$

The *open stars* $U_x = \{y \in P : x \leq y\}$, $x \in P$, form an open basis. The closure of $x \in P$ is $\bar{x} = \{y \in P : y \leq x\}$. A cellular sheaf \mathcal{F} on (P, \leq) induces a sheaf on P with the Alexandrov topology with $\mathcal{F}(U_x) = \mathcal{F}(x)$.

**Towards a spectral theory of cellular sheaves
J. Hansen and R. Ghrist**

A *cellular sheaf* on a *regular cell complex* is the datum of a vector space $\mathcal{F}(\sigma)$ for each cell σ of X , together with a linear transformation (restriction map) $\mathcal{F}_{\sigma \triangleleft \tau} : \mathcal{F}(\sigma) \rightarrow \mathcal{F}(\tau)$ for each incident cell pair, such that $\mathcal{F}_{\sigma \triangleleft \sigma} = \text{Id}$ and $\mathcal{F}_{\sigma \triangleleft \tau} \circ \mathcal{F}_{\tau \triangleleft \rho} = \mathcal{F}_{\sigma \triangleleft \rho}$. The space of *cochains* is

$$C^k(X, \mathcal{F}) = \bigoplus_{\dim \sigma = k} \mathcal{F}(\sigma)$$

and the coboundary $\delta^k : C^k \rightarrow C^{k+1}$ is

$$\delta^{k+1}|_{\mathcal{F}(\sigma)} = \sum_{\dim \tau = k+1} [\sigma : \tau] \mathcal{F}_{\sigma \triangleleft \tau}$$

where the *signed incidence relation* satisfies

- $\sigma \triangleleft \tau \implies \sum_{\gamma} [\sigma : \gamma][\gamma : \tau] = 0$;
- $[\sigma : \tau] \neq 0$ only if $\sigma \triangleleft \tau$ and there are no cells between σ and τ .

The *Hodge Laplacian* is $\Delta = (\delta + \delta^*) = \delta^* \delta + \delta \delta^*$. Δ^k can be decomposed as $\Delta^k = \Delta_+^k + \Delta_-^k$ with $\Delta_+^k = (\delta^k)^*(\delta^k)$ and $\Delta_-^k = (\delta^{k-1})(\delta^{k-1})^*$. The cohomology is then

$$H^k := \frac{\ker \delta^k}{\text{Im } \delta^{k-1}} = \ker \Delta^k.$$

The degree-zero Laplacian generalizes the graph Laplacian; its diagonal and off-diagonal blocks are

$$\begin{aligned} \Delta_{vv}^0 &= \sum_{v \triangleleft e} \mathcal{F}_{v \triangleleft e}^* \mathcal{F}_{v \triangleleft e} \\ \Delta_{uv}^0 &= -\mathcal{F}_{u \triangleleft e}^* \mathcal{F}_{v \triangleleft e}. \end{aligned}$$

The Laplacian of a *normalized sheaf*

$$\forall x, y \in \mathcal{F}(\sigma) \cap (\ker \delta)^\perp \quad \langle \delta x, \delta y \rangle = \langle x, y \rangle$$

generalizes the normalized graph Laplacian.

Path homologies of deep forward networks **S. Chowdhury et al.**

An *elementary p-path* in a graph (V, E) is a sequence of $p + 1$ nodes (x_0, \dots, x_p) ; it is *allowed* if $\forall i (x_i, x_{i+1}) \in E$. Let $\Lambda_p(V)$ and $A_p(V)$ be the free vector spaces generated by elementary and allowed paths. The boundary of a path is $\partial_p[x_0, \dots, x_p] = \sum (-1)^i [x_0, \dots, \hat{x}_i, \dots, x_p] \in \Lambda_p(V)$. The ∂ -invariant paths $\Omega_p = \{c \in A_p : \partial_p c \in A_{p-1}\}$ form a chain complex

$$\xrightarrow{\partial_3} \Omega_2 \xrightarrow{\partial_2} \Omega_1 \xrightarrow{\partial_1} \Omega_0 \xrightarrow{\partial_0} k \longrightarrow 0$$

defining the *path homology* $H_p^\pm(G) = \ker \partial_p / \text{Im } \partial_p$. The *directed flag complex* (DFC) is defined from sequences (x_0, \dots, x_p) satisfying $\forall i < j (x_i, x_j) \in E$.

Discovering governing equations from data by sparse identification of nonlinear dynamical systems **S.L. Brunton et al.**

To learn a differential equation, *i.e.*, find f in $\dot{x}(t) = f(x(t))$ from trajectories x , SINDy:

- Estimates \dot{x} , with total variation regularization to denoise it;
- Builds a library of nonlinear transformations of the columns of x ;
- Uses a sparse regression.

Learning ODE models with qualitative structure using Gaussian processes **S. Ridderbusch et al.**

To learn a differential equation $\dot{x}(t) = f(x(t))$, model (x, \dot{x}) with a Gaussian process (this gives a less noisy estimate of \dot{x} , with a matrix kernel (uncoupled separable matrix (USM) kernel); to account for symmetries, use group integration matrix (GIM) kernels.

Statistical inference on random dot product graphs: a survey **A. Athreya et al. (2017)**

A *random dot product graph* (RDPG) is an Erdős-Rényi graph with probabilities $p_{ij} = \langle x_i, x_j \rangle$, where $x_i \in \mathbf{R}^d$ is the latent position of node i (try a spectral embedding of the adjacency or Laplacian matrix).

ptype: probabilistic type inference **T. Ceritli et al. (2019)**

Infer data types in CSV files with probabilistic grammars or probabilistic finite state machines (one per type, allowing for missing values, disguised missing values (e.g., -1 or 999) and errors), with their transition probabilities estimated from data.

WarpedGANSpace: finding non-linear RBF paths in GAN latent space **C. Tzelepis et al.**

To find interpretable paths in the latent space of a GAN, without supervision, use the gradient of several sums of RBFs, trained to be easily distinguishable by a discriminator (a non-linear generalization of PCA).

Do vision transformers see like convolutional neural networks? **M. Raghu et al. (2021)**

To compare the information contained in two layers (of the same network, or not), compute the Gram matrices of the activations, $K = XX'$, $L = YY'$ (they measure the similarity of a pair of data points according to the layer) and compute the *centered kernel alignment* (CKA)

$$\text{CKA}(K, L) = \frac{\text{HSIC}(K, L)}{\sqrt{\text{HSIC}(K, K) \text{HSIC}(L, L)}},$$

where HSIC is the scalar product of the centered Gram matrices

$$\begin{aligned} \text{HSIC}(K, L) &= \text{vec } \tilde{K} \cdot \text{vec } \tilde{L} / (m - 1)^2 \\ \tilde{K} &= HKH \\ \tilde{L} &= HLH \\ H &= I + n - \frac{1}{n} \mathbf{1}\mathbf{1}' \end{aligned}$$

Compare the first and last layer of a ViT or of a CNN, the subset of activations of heads focusing on local

(resp. global) information (defined by the average distance between the query patch and the patch attended to): ViTs have more comparable layers.

To measure the importance of skip connections $z_i \mapsto z_i + f(z_i)$, look at $\|z_i\| / \|f(z_i)\|$: ViTs propagate more information through skip connections than CNNs.

Evolution through large models
J. Lehman et al. (2022)

Use a large language model, not to generate programs, but diffs; use those diffs as mutation operators, for genetic programming.

Training data-efficient image transformers and distillation through attention
H. Touvron et al.

More efficient ViT.

Hyperbolic neural networks++
R. Shimizu et al.

Split, concatenation, convolution, attention can be generalized to hyperbolic networks.

Graph-regularized tensor regression: a domain-aware framework for interpretable multi-way financial modelling
Y.L. Xu et al.

Tensor regression is a generalization of linear regression $y = \langle W, X \rangle + b$, for instance

$$y^t = w_{ij\tau} x_{ij\tau}^t + b$$

i : stock
 j : feature
 τ : lag
 t : time

where $x_{ij\tau}^t$ is the value of feature j for stock i at time $t - \tau$. We can make the model more parsimonious with a CP decomposition

$$w_{ij\tau} = \sum_c u_{ic}^1 u_{jc}^2 u_{\tau c}^3.$$

Given a graph on one of the dimensions, e.g., sector membership for the stocks (or a chain graph $\bullet \cdots \bullet$ for the lags, or some a priori relation between the features), with Laplacian L , one can add a penalty $\text{tr}(u_i^{1'} L u_i^1)$ to make the signal smooth.

Quasi-Monte Carlo methods for computing derivatives sensitivities on the GPU
P. Bilokon et al. (2022)

The *pathwise method* computes

$$\frac{\partial}{\partial S_0} \mathbb{E}_{S \sim \text{rw}(\mu, \sigma^2)} [f(S_T)],$$

with Monte Carlo simulations, as

$$\mathbb{E} \left[\frac{\partial f(S_T)}{\partial S_T} \frac{\partial S_T}{\partial S_0} \right]$$

where $\frac{\partial S_T}{\partial S_0} = \frac{S_T}{S_0}$.

Multilevel Monte Carlo and its applications in financial engineering
D. Sinha and S.P. Chakrabarty

Multilevel Monte Carlo (MLMC) uses different resolutions as control variates

$$\mathbb{E}[Y_3] = \mathbb{E}[Y_1] + \mathbb{E}[Y_2 - Y_1] + \mathbb{E}[Y_3 - Y_2]$$

where Y_1 and Y_2 are coarse, fast-to-compute approximations of Y_3 .

Combine with importance sampling.

The pursuit of balance: an overview of covariate-adaptive randomization techniques in clinical trials
Y. Lin et al. (2015)

Simple randomization can lead to accidental bias. Try:

- Block randomization;
- Stratified randomization
- Minimization: allocate the new subject (with high probability, e.g., $p = 0.8$) to produce the smallest total imbalance (variance, standard deviation, range, etc.) over its baseline characteristics;
- Dynamic hierarchical randomization: idem, after putting the baseline characteristics in a tree.

Modifications to a classic BFGS library for use with SIMD-equipped hardware and an AAD library
E. Goncharov and A. Rodrigues

Even if the objective is not parallelizable, some steps in the algorithm are:

- Line search (naive, or with a polynomial regression);
- Partial derivatives.

Liquidity stress testing in asset management
T. Roncalli et al. (2020)

Stress testing includes:

- Redemptions (liability liquidity);
- Market impact (asset liquidity);
- The relation between the two (asset-liability liquidity matching).

Machine learning time series regression with an application to nowcasting
A. Babii et al. (2021)

MIDAS with a sparse group lasso penalty

$$\alpha \|\beta\|_1 + (1 - \alpha) \|\beta\|_{2,1}$$

(i.e., lasso and group lasso), promoting sparsity between and within groups.

Moment sum-of-squares approach for fast risk estimation in uncertain environments

A.M. Jasour et al.

Given $x \in \mathbf{R}^n$ (e.g., robot position), we want to know if $x \in \chi$, where $\chi \subset \mathbf{R}^n$ is a semi-algebraic set. Both x and χ are only known approximately, but we know the moments of their distributions (for χ , the moments of the distributions of the coefficients of the polynomials defining it). The resulting semi-definite program becomes intractable as the size of the problem increases, but one can efficiently compute bounds of the moments.

Randomized geometric tools for anomaly detection in stock markets

C. Bachelard et al.

Uniformly sampling long-only fully-invested portfolios with a prescribed volatility is equivalent to sampling from $K = \mathbf{S}^{n-1} \cap \Delta$ for some simplex Δ . It is not connected, but one can:

- Identify the connected components by looking at how the 1-simplex Δ intersects the sphere \mathbf{S}^{n-1} ;
- Compute the volume of each component.

We can sample, uniformly, from a component K_i , with Monte Carlo, starting from a point p :

- Great cycle walk:
 - Pick a geodesic (great circle) ℓ going through p ;
 - Compute the intersection $\ell \cap K_i$;
 - Pick a point at random on $\ell \cap K_i$;
- Reflective great circle walk:
 - Pick a geodesic;
 - Pick a length, $L = -\tau \log \eta$, $\eta \sim U(0, 1)$;
 - Follow the geodesic for a length L , reflecting on $\partial\Delta$ whenever we reach it.

Interpretable selective learning in credit risk

D. Chen et al.

Fit a logistic regression (for credit scoring); train a neural network for the same task; train another neural network to predict when the neural net is correct and the logistic regression is not [that is a mixture of experts].

Neural variance reduction for stochastic differential equations
P.D. Hinds and M.V. Tretyakov (2022)

Use a neural network to compute control variates to reduce variance when solving SDEs (i.e., computing $E_X[f(X_T)]$).

New financial ratios based on the compositional data methodology
S. Linares-Mustarós et al.

Replace financial ratios of the form a/b , $a/(b+c)$, etc., which are asymmetric, with $\log(a/b)$, $\log(a/\sqrt{bc})$, etc.

Monte Carlo estimation of CoVaR

W. Huang et al.

The CoVaR is defined by

$$P[Y \leq \text{CoVaR}_{\alpha, \beta} \mid X = \text{VaR}_{\alpha} X] = \beta.$$

Its naive Monte Carlo estimation converges in $O(n^{-1/3})$ (we are conditioning on $X = \text{VaR}_{\alpha} X$, which has zero probability, and not on $X \leq \text{VaR}_{\alpha} X$), but it can be brought down to $O(n^{-1/2})$, with importance sampling and a Taylor expansion.

A multimodal embedding-based approach to industry classification in financial markets

R. Dolphin et al. (2022)

Word2Vec-like model, to compute company embeddings, by modeling $P[\text{target}|\text{context}]$, where the context comes from past prices and financial news; turn into a graph by adding an edge whenever cosine similarity is above 0.6.

FinRL-Meta: market environments and benchmarks for data-driven financial reinforcement learning

X.Y. Liu et al. (2022)

Gym-compatible financial market environments for reinforcement learning.

Applying separative non-negative matrix factorization to extra-financial data

P. Fogel et al. (2022)

Nonnegative matrix factorization (NMF) is asymmetric: it pays more attention to high values than low values. Instead, decompose the data as $X = X_0 + X_+ - X_-$, $X_+ \geq 0$, $X_- \geq 0$, for some baseline X_0 (e.g., the column-wise medians) and use a nonnegative tensor factorization for the order-3 tensor $[X_+ | X_-]$.

Python implementation in `nmtf`; application to ESG scores.

Deep differentiable reinforcement learning and optimal trading

T. Jaisson (2022)

Differentiable reinforcement learning (RL), for a single asset ($n = 1$), on simulated data with a 2-scale alpha

$$\begin{aligned} \alpha_t &= \alpha_t^{\text{slow}} + \alpha_t^{\text{fast}} \\ \alpha_t^{\text{slow}} &= \rho^{\text{slow}} \alpha_{t-1}^{\text{slow}} + \text{noise} \\ \alpha_t^{\text{fast}} &= \rho^{\text{fast}} \alpha_{t-1}^{\text{fast}} + \text{noise} \\ \rho^{\text{fast}} &= 0, \quad \rho^{\text{slow}} > 0 \end{aligned}$$

***Distributionally robust
end-to-end portfolio construction***
G. Costa and G.NB. Iyengar (2022)

In the portfolio optimization

$$\begin{aligned} & \text{Minimize Risk}(w) - \gamma w'y, \\ & \quad w \geq 0 \\ & \quad w'1 = 1 \end{aligned}$$

use, as risk, the worst *deviation risk measure*

$$\begin{aligned} \text{Risk}(w) &= \max_{\substack{p \geq 0 \\ p'1=1 \\ D_\phi(p, \text{Unif}) \leq \delta}} f_\varepsilon(w, p) \\ f_\varepsilon(w, p) &= \min_c \sum_j p_j R(w'\varepsilon_j - c) \\ D_\phi: & \phi\text{-divergence} \\ \varepsilon: & \text{past prediction errors} \\ R: & \text{even function} \end{aligned}$$

The minimax problem can be reformulated with convex duality, and solved end-to-end (to maximize the Sharpe ratio), for 20 assets, 15 years, weekly returns, 17 predictors (code available).

Supervised portfolios
G. Chevalier et al. (2022)

Instead of forecasting returns (or uniformized returns, residual returns, volatility-adjusted returns, etc.) forecast the weights of the optimal portfolio (using realized returns as alpha). This adjusts for: factor exposures, volatility, investor preferences (utility, constraints). Example with 25 assets, 14 features.

Alternatives to deep neural networks in finance
A.V. Antonov and V.V. Piterbarg (2022)

To approximate functions $f: \mathbf{R}^k \rightarrow \mathbf{R}$, try

$$\tilde{f}(x) = \sum \alpha_n s(x - z_n).$$

For the Fourier transform, the z_n 's are on a grid, and $\alpha_n = \hat{f}(z_n)$ – but we could use quasi-random points for the z_n 's, estimate the α_n 's with a linear regression, and fine-tune the position of the z_n 's (*stochastic sampling*).

For *image rendering*, s is sinc or its Lanczos generalization

$$s(x) = \frac{\sin(\pi x)}{\pi x} \quad \text{or} \quad s(x) = \frac{\sin(\pi x)}{\pi x} \frac{\sin(\pi x/a)}{\pi x/a} \mathbf{1}_{x \in [-a, a]}.$$

Generalized stochastic sampling uses

$$\tilde{f}(x) = \sum_n \alpha_n \prod_d \phi((x_d - z_{nd})\beta_d)$$

for a fixed activation function ϕ (e.g., sinc), quasi-random z_n 's, and

- $\beta_d = \lambda_d \cdot \eta$, $\lambda_d^2 = \mathbf{E}(\nabla_d f(x))^2$, η optimized;
- or β_d optimized;
- or $\beta_{d,n}$ optimized.

The tensor train decomposition

$$\begin{aligned} A_{i_1, \dots, i_D} &= G_{i_1 k_1}^1 G_{k_1 i_2 k_2}^2 \cdots G_{k_{D-2} i_{D-1} k_{D-1}}^{D-1} G_{k_{D-1} i_D}^D \\ A(i_1, \dots, i_D) &= \underbrace{g_1(i_1)}_{\text{row vector}} \underbrace{g_2(i_2) \cdots g_{D-1}(i_{D-1})}_{\text{matrices}} \underbrace{g_D(i_D)}_{\text{column vector}} \end{aligned}$$

can be made functional (fTT)

$$\tilde{f}(x) = \underbrace{g_1(x_1)}_{\text{row vector}} \underbrace{g_2(x_2) \cdots g_{D-1}(x_{D-1})}_{\text{matrices}} \underbrace{g_D(x_D)}_{\text{column vector}}$$

where the g_d 's are learned (with alternating least squares, from basis functions – note that this depends on the order of the x_d 's).

Classical approaches include:

- Fourier decomposition;
- Chebychev decomposition (up to dimension 7: $7^7 < 10^6$);
- Natural neighbour interpolation (in dimension 2 or 3) or other linear interpolations (barycenters).

***Cryptocurrency bubble detection:
a new stock market dataset, financial task
and hyperbolic models***
R. Sawhney et al.

Identify bubbles in cryptocurrencies (9 exchanges \times 50 currencies, 5 years of daily OHLC prices) with the PSY model, and train a hyperbolic GRU on both text (tweets with currency tickers, e.g., \$DOGE) and prices, to predict the probability that a bubble starts or ends at time t .

In the Poincaré ball:

$$\begin{aligned} g_x &= \frac{2}{1 - \|x\|^2} g_{\text{Euclidean}} \\ x \oplus y &= \frac{(1 + 2\langle x, y \rangle + \|y\|^2)x + (1 - \|x\|^2)y}{1 + 2\langle x, y \rangle + \|x\|^2 \|y\|^2} \\ \exp_x(v) &= x \oplus \left(\tanh\left(\frac{\|v\|}{1 - \|x\|^2}\right) \frac{v}{\|v\|} \right) \\ \log_x(y) &= (1 - \|x\|^2) \tanh^{-1}(\| -x \oplus y \|) \frac{-x \oplus y}{\| -x \oplus y \|} \\ W \otimes x &= \exp_0(W \log_0(x)) \end{aligned}$$

***Testing for multiple bubbles:
historical episodes of exuberance
and collapse in the S&P 500***
P.C.B. Phillips et al. (2015)

To detect a (single) price bubble, try the following test statistics:

$$\begin{aligned} \text{PYW:} \quad \text{SADF}(r_0) &= \sup_{r_0 \leq r_2 \leq 1} \text{ADF}_{[0, r_2]} \\ \text{PSY:} \quad \text{GSADF}(r_0) &= \sup_{\substack{r_0 \leq r_2 \leq 1 \\ 0 \leq r_1 \leq r_2 - r_0}} \text{ADF}_{[r_1, r_2]}. \end{aligned}$$

They can be adapted to the detection of multiple bubbles.

Deep multiple instance learning for forecasting stock trends using financial news
Y. Deng and S.M. Yiu

In *multiple instance learning*, training instances are arranged in bags, and only bags are labeled, not instances.

Forecast the sign of the next day's returns from news:

- Word embedding, pretrained with Glove;
- BiLSTM;
- Instance-level classifiers;
- Aggregation;
- Final classifier.

The RIFT (representation of inter-related time series) model and its applications
A. Sokolov et al. (2022)

Compute a neural representation of financial time series by applying

- A TCN on stock returns;
- A transformer on industry and market returns;
- An industry embedding

in a Siamese network to forecast future correlations. [Instead, forecast reversion or divergence of pairs, or cointegration, or mutual information.]

Decomposing cross-sectional volatility
J. Menchero and A. Morozov (2010)

Given a risk model

$$X_i = \sum_k \beta_{ik} F_k + u_i,$$

the cross-sectional volatility can be decomposed as

$$\sigma(X_i) = \sum_k F_k \sigma(\beta_{ik}) \rho(\beta_{ik}, X_i) + \sigma(u_i) \rho(u_i, X_i).$$

AdaptSPEC: adaptive spectral estimation for nonstationary time series
O. Rosen et al. (2012)

Model (oscillating) non-stationary time series by recursively splitting them and estimating their spectrum on each segment, with reversible jump Markov chain Monte Carlo (RJMCMC).

Statistical indetence of lead-lag at various timescales between asynchronous time series from p-values of transfer entropy
C. Bongiorno and D. Challet (2022)

Asymptotic distribution of the test statistic

$$H_0 : \text{TE}(B \rightarrow A) = \text{TE}(C \rightarrow B)$$

$$H_1 : \text{TE}(B \rightarrow A) > \text{TE}(C \rightarrow B)$$

where the transfer entropy

$$\text{TE}(B \rightarrow A) = H(A^+|A) - H(A^+|A, B)$$

(A^+ denoted the future of A) is a generalization of Granger causality, often approximated by discretizing the data. (If you are patient, you can also compute bootstrap p -values.)

Advances in domain independent linear text segmentation
F.Y.Y. Choi

To segment a text:

- Split it into sentences;
- Remove stopwords, step the words, count the words;
- Compute the matrix of similarities between sentences;
- Replace each value with its rank in a local region;
- Compute s_{ij} , the sum of the values of $\text{sim}_{[i,j] \times [i,j]}$ (start along the diagonal and move outwards);
- Recursively split $[1, N]$, maximizing the density $\sum s_k / \sum a_k$, where a_k is the area of $k \times k$, $k = [i, j]$;
- To decide when to stop, compute the differences $\delta D_n = D_n - D_{n-1}$, smooth them, compute their mean μ and standard deviation σ ; stop when $\delta D > \mu + 1.2\sigma$.

Self-attention between datapoints: going beyond individual input-output pairs in deep learning
J. Kossen et al. (2021)

Do not use attention only between attributes, but also between datapoints (samples – this assumes you put the whole dataset in each minibatch or, at least, a representative part of it). Try on tabular data.

Decision transformer: reinforcement learning via sequence modeling
L. Chen et al.

To learn, offline, from suboptimal trajectories, train a GPT model to predict the next token in a sequence of return-to-go, state, action. For instance, one can find shortest paths on a graph by training on random walks.

```
t = embed_t(t) # Positional embedding
s = embed_s(s)
a = embed_a(a)
R = embed_R(R)
return transformer( s+t, a+t, R+t ).action
```

CrossViT: cross-attention multi-scale vision transformer for image classification
C.F. Chen et al.

Process both small and large image patches with a ViT; to combine them, use *cross-attention*, i.e., attention between the CLS token for one patch size and the image patch tokens for the other size – the CLS tokens can be seen as “inducing points” (or tokens): the computations only require linear time.

Efficient and modular implicit differentiation

M. Blondel et al. (2022)

Implicit differentiation (computing the gradient of the solution of an optimization problem) in JAX (for optimization layers, or bilevel problems: hyperparameter optimization, meta-learning): separately specify the optimality conditions and implement the optimization.

Evaluating robustness of neural networks with mixed integer programming

V. Tjeng et al. (2019)

Neural networks can be verified (their robustness to adversarial examples can be measured) efficiently, up to 100,000 ReLU, with mixed integer programming (MIPVerify.jp).

Random dot product graph models for social networks

S.J. Young and E.R. Scheinerman

The dot product random graph model generates graphs by sampling a vector X_u (from some probability distribution) and adding an edge $u-v$ with probability $\langle X_u, X_v \rangle$. For directed graphs, use two distributions $p(u-v) = \langle X_u, Y_v \rangle$. Other random graph models include:

- Configuration model (prescribed degree distribution);
- Preferred attachment (Barabási-Albert);
- Copying model.

Duplication models for biological networks

F. Chung et al. (2003)

The degree distribution of biological graphs follows a power law with exponent $\beta \in (1, 2)$, in contrast with non-biological networks, for which $\beta \in (2, 4)$. This can be modeled by a duplication process:

- Start with a graph G_0 ;
- Pick a node at random;
- Duplicate it, keeping each edge with probability p ;
- Iterate.

Asymptotically, the power law exponent β satisfies $p(\beta - 1) = 1 - p^{\beta-1}$; in particular, if $p \in (\frac{1}{2}, 1)$, then $\beta < 2$.

Modernizing PHCpack through phcpy

J. Verschelde (2014)

PHCpack is an (old, file and menu-based) package to solve systems of polynomial equations (over \mathbf{C}^n) $f(x) = 0$ using a system with known solutions $g(x) = 0$ by keeping track of the solutions of $h_t(x) = 0$ where

$$h_t(x) = \gamma(1-t)g(x) + tf(x), \quad t \in (0, 1)$$

and $\gamma \in \mathbf{C}$ is random.

Multivariate backtests and copulas for risk evaluation

B. David and G. Zumbach (2022)

Fit a bivariate Student copula to LM-GARCH innovations (to remove heteroskedasticity), in-sample; then apply the *Rosenblatt transform* to out-of-sample

$$\begin{cases} \text{Student copula} & \longrightarrow & \text{Uniform copula} \\ (u_1, u_2) & \longmapsto & (u_1, P[U_2 \leq u_2 \mid U_1 = u_1]) \end{cases}$$

and test if the result is indeed uniform.

Polynomial voting rules

W. Tang and D.D. Yao (2022)

In a proof of stake (PoS) system, agents have a voting power proportional to

- Their stake;
- The square root of their stake;
- Their randomly fluctuating stake: each bidder receives a new stake with probability proportional to some power of its current stake.

On finding the community with maximum persistence probability

A. Avellone et al.

The persistence probability of a subgraph $C \subset V$ of a graph $G = (V, E)$ is

$$\alpha = \frac{\sum_{i,j \in C} a_{ij}}{\sum_{i \in C, j \in V} a_{ij}}.$$

For small graphs, it can be computed with a mixed integer program (MIP); for larger graphs, heuristics are available.

Compromise-free Bayesian neural networks

K. Javid et al.

The *Bayesian evidence* (aka *marginal likelihood*) is the average of the likelihood function over the parameter space, weighted by the prior distribution. It is often a proxy for the out-of-sample performance.

Randomized Nyström preconditioning

Z. Frangella et al.

To solve $(A + \mu I)x = b$, with A positive semi-definite, $\mu \geq 0$, consider a randomized Nyström approximation

$$\Omega \sim N(0_{n \times \ell} I)$$

$$\hat{A} = (A\Omega)(\Omega' A \Omega)^\dagger (A\Omega)',$$

compute its eigendecomposition $\hat{A} = U\Lambda U'$ and use the preconditioner

$$P = \frac{U(\Lambda + \mu I)U'}{\lambda_\ell + \mu} + (I - UU')$$

i.e., replace $(A + \mu I)$ with $P^{-1}(A + \mu I)$ (it is easy to solve $Py = 0$).

Binarsity: a penalization for one-hot encoded features in linear supervised learning
M.Z. Alaya et al. (2019)

Discretize (binarize) continuous variables into b bins and fit a linear model with a fused lasso (total variation) penalty to make the transformation locally constant, and a constraint to have the sum of the weights sum to zero for each predictor.

To total variation proximal operator can be computed efficiently, and applied separately from the constraint.

Quantifying the impact of ecological memory on the dynamics of interacting communities
M. Khalighi et al. (2021)

To add memory to the Lotka-Volterra model, replace d/dt with the fractional derivative \mathfrak{D}^μ , where $\mu \in (0, 1)$ measures the memory.

$$\mathfrak{D}^\mu g(t) = \frac{1}{\Gamma(1-\mu)} \int_{t_0}^t \frac{g'(\tau) d\tau}{(t-\tau)^\mu}$$

Three-species Lotka-Volterra model with respect to Caputo and Caputo-Fabrizio fractional operators
M. Khalighi et al. (2021)

The fractional derivative is not unique; popular definitions include (Caputo, Caputo-Fabrizio)

$$\begin{aligned}\mathfrak{D}^\alpha f(t) &= \frac{1}{\Gamma(1-\alpha)} \int_0^t \frac{f'(\tau) d\tau}{(t-\tau)^\alpha} \\ \mathfrak{D}^\alpha f(t) &= \frac{1}{1-\alpha} \int_0^t \exp\left[-\frac{\alpha(t-\tau)}{1-\alpha}\right] f'(\tau) d\tau.\end{aligned}$$

Conic optimization via operator splitting and homogeneous self-dual embedding
B. O'Donoghue et al. (2016)

The pair of primal and dual problems

$$\begin{array}{ll}\text{Find} & x, s \\ \text{To minimize} & c'x \\ \text{Such that} & Ax + s = b \\ & x \in \mathbf{R}^n \\ & s \in K\end{array} \quad \begin{array}{ll}\text{Find} & y, r \\ \text{To maximize} & -b'y \\ \text{Such that} & -A'y + r = c \\ & r = 0 \\ & y \in K^*\end{array}$$

can be converted into a feasibility problem

$$\begin{pmatrix} r \\ s \\ \kappa \end{pmatrix} = \begin{pmatrix} 0 & A' & c \\ -A & 0 & b \\ c' & b' & 0 \end{pmatrix} \begin{pmatrix} x \\ y \\ \tau \end{pmatrix} \quad \begin{array}{l} \text{dual constraint} \\ \text{primal constraint} \\ \text{duality gap} \end{array}$$

or, after introducing scaling factors $\tau, \kappa \geq 0$ to detect primal or dual infeasibility (*homogeneous self-dual embedding*)

$$\begin{pmatrix} r \\ s \\ \kappa \end{pmatrix} = \begin{pmatrix} 0 & A' & c \\ -A & 0 & b \\ -c' & -b' & 0 \end{pmatrix} \begin{pmatrix} x \\ y \\ \tau \end{pmatrix}.$$

This problem is self-dual:

$$\begin{array}{ll}\text{Find} & u, v \\ \text{Such that} & v = Qu \\ & (u, v) \in C \times C^*.\end{array}$$

It can be solved with the ADMM algorithm.

$$\begin{array}{ll}\text{Find} & u, v, \tilde{u}, \tilde{v} \\ \text{To minimize} & I_{C \times C^*}(u, v) + I_{Q_{u=v}}(\tilde{u}, \tilde{v}) \\ \text{Such that} & (u, v) = (\tilde{u}, \tilde{v})\end{array}$$

An agent-based model with realistic financial time series: a method for agent-based models validation
L.G. de Faria

Long list of stylized facts, for log-returns

- Fat tails, which disappear at lower frequencies;
- Heavy tails (tail index), even after correction for volatility (GARCH);
- Equity premium: $E[r] > E[r_{\text{rf}}]$;
- Excess volatility: $\sigma(\text{returns}) > \sigma(\text{fundamentals})$;
- Leverage: $\text{Cor}(r_{\text{past}}, \sigma_{\text{future}}) < 0$;
- No autocorrelation;
- Long memory: $\text{Cor}(|r_t|, |r_s|)$;
- Power law of returns ("inverse cubic law") and of volatility;
- Volatility clustering: $\text{Cor}(\sigma_t, \sigma_{t+1})$;
- $\text{Cor}(\sigma, \text{volume}) > 0$

volume:

- Power law;
- Long memory

inter-trade duration:

- Clustering;
- Long memory;
- Over-dispersion

transaction size:

- Power law

spreads:

- $\text{Cor}(\text{spread}, \sigma) > 0$;
- $\text{Cor}(\text{spread}, \text{volume}) < 0$.

Improving graph neural network expressivity via subgraph isomorphism counting
G. Bouritsas et al.

Graph neural nets (GNN) are blind to structural properties, such as triangles and larger cycles. Add node and edge features counting small subgraphs containing a given node or edge.

***Weisfeiler and Leman go sparse:
towards scalable higher-order graph embeddings***
C. Morris et al. (2020)

Generalize the Weisfeiler-Lehman (WL) graph isomorphism algorithm by considering k -tuples of nodes, two tuples being neighbours if they differ by only one node, and if those nodes are neighbours.

***A theoretical comparison
of graph neural network extensions***
P.A. Papp and R. Wattenhofer (2022)

To increase the expressiveness of GNNs:

- Add node features, e.g., the number of cycles of length k (or some other motif) containing that node;
- Add, as node features, the isomorphism class of the k -hop neighbourhoods;
- Drop k nodes at random, and consider the resulting collection of graphs;
- Mark k nodes at random, and consider the resulting collection of graphs.

***SpeqNets: sparsity-aware
permutation-equivariant graph networks***
C. Morris et al. (2022)

The k -dimensional Weisfeiler-Lehman algorithm (k -WL) generalizes the WL algorithm (1-WL) by considering all k -tuples of nodes (there are exponentially many). The (k, s) -LWL algorithm considers a subset of all k -tuples, viz those whose induced graph has at most s components.

***Spectre: spectral conditioning
helps to overcome the expressivity limits
of one-shot graph generators***
K. Martinkus et al. (2022)

Generate graphs, with a GAN, by conditioning on the first eigenvalues and eigenvectors of the Laplacian matrix (which encode global properties):

- First, generate eigenvalues;
- Then, generate the eigenvectors, conditioned on the eigenvalues, starting with a bank of orthogonal matrices, and multiplying them, on both sides, by orthogonal matrices (exponentials of skew-symmetric matrices, computed by a PointNetST); note that not all eigenvalues and eigenvectors come from valid Laplacians;
- Use a PPGN (provably powerful graph network) to refine the approximate Laplacian, $L = U \text{diag}(\Lambda) U'$, and convert it to an adjacency matrix;
- Use a discriminator for each step; the last one ensures the adjacency matrix is consistent with the eigenvalues and eigenvectors.

Provably powerful graph networks
H. Maron et al. (2019)

Adding a matrix multiplication layer to GNNs increases their expressiveness to 3-WL.

$$X \in \mathbf{R}^{h \times n \times n}$$

$$M_1 = \text{MLP}_1(X) \in \mathbf{R}^{h \times n \times n}$$

$$M_2 = \text{MLP}_2(X)$$

$$M^i = M_1^i M_2^i \in \mathbf{R}^{n \times n}$$

$$M \in \mathbf{R}^{n \times n}$$

$$Y = \text{MLP}_3(X \parallel M) \in \mathbf{R}^{h \times n \times n}$$

repeat n times, with skip-connections

Local augmentation for graph neural networks
S. Liu et al. (2022)

To augment data, find similar nodes and look at their neighbourhoods.

***Janossy pooling:
learning deep permutation-invariant
functions for variable-size inputs***
R.L. Murphy et al. (2019)

Arbitrary permutation-invariant functions can be defined as averages (of permutation-sensitive functions f) over all orderings.

$$\text{Mean}_{\sigma \in \mathfrak{S}_n} f(x_\sigma)$$

They can be approximated using:

- Canonical orderings;
- Functions f using only their first k arguments, $f(x_1, \dots, x_n) = f(x_1, \dots, x_k)$, $k \ll n$, i.e., accounting for order- k interactions at most;
- Random orderings (and stochastic optimization).

The permutation-sensitive function f could be an LSTM.

***G-Mixup: graph data augmentation
for graph classification***
X. Han et al.

To apply Mixup to graphs, estimate a graphon for each class, and sample from a convex combination of them.

To estimate a graph from a set of graphs, first align them by sorting their nodes by degree, estimate a step function graphon for each graph, and average them – this assumes the marginal $\int W(x, y) dx = W(y)$ is very different from a constant function.

**GenLabel: Mixup relabeling
using generative models**
J.Y. Sohn et al. (2022)

Mixup can suffer from *manifold intrusion*: mixing two classes may intrude into the manifold of another one.

Additionally, the linear labeling is suboptimal for softmax regression. Replacing

$$y_{\text{mix}} = \lambda e_1 + (1 - \lambda) e_2$$

with

$$y_{\text{gen}} \propto \sum_i \hat{p}_i(x_{\text{mix}}) e_i,$$

where $\hat{p} = p(x|y)$ is a generative model, addresses both issues.

**Large-scale representation learning on graph
via bootstrapping**
S. Thakoor et al.

For self-supervised training on graph data, consider two augmentations, g_1 , g_2 of a graph, and train two encoders, e_1 such that $e_1(g_1) \approx e_2(g_2)$, and set $e_2 = \text{EMA}(e_1)$.

**Structure-aware transformer
for graph representation learning**
D. Chen et al. (2022)

Transformers augment the data with a positional embedding. For graphs, node distances are not enough: also add structural information.

**Interpretable and generalizable graph learning
via stochastic attention mechanism**
S. Miao et al. (2022)

Add noise *inside* the network (in the attention mechanism); this also helps identify task-relevant subgraphs.

**Mention memory: incorporating textual
knowledge into transformers
through entity mention attention**
M. de Jong (2022)

Combine language model and knowledge base (entity mention embeddings) with an attention mechanism.

**Logical rule induction and theory learning
using neural theorem proving**
A. Campero et al.

Use a dense representation of facts as (V, S, O, belief) and rules as

$$\begin{matrix} (V_0 S_0 O_0 & V_1 S_1 O_1 & V_2 S_2 O_2) \\ \text{conclusion} & \text{premise} & \end{matrix}$$

and define the belief of a conclusion as

$$\langle v, V_0 \rangle \langle s, S_0 \rangle \langle o, O_0 \rangle \langle v_1, V_1 \rangle \langle s_1, S_1 \rangle \langle o_1, O_1 \rangle \langle v_2, V_2 \rangle \langle s_2, S_2 \rangle \langle o_2, O_2 \rangle$$

and use forward chaining for derive new facts.

**Learning hierarchy-aware knowledge graph
embeddings for link prediction**
Z. Zhang et al. (2020)

Use polar coordinates to find an embedding of entities (head, tail) and relations accounting for hierarchy.

$$\text{score} = -\|h_m \odot r_m - t_m\|_2 - \lambda \|\sin(h_p + r_p - t_p)\|_1$$

There are many other score functions: TransE, RotatE, ComplEx, etc.

**Translating embeddings
for modeling multi-relational data**
A. Bordes et al.

TransE embeds entities as vectors and relations as translations (as in the semantic interpretation of word2vec: king-man+woman).

**RotatE: knowledge graph embedding
by relational rotation in complex space**
Z. Sun et al.

**3D Infomax improves GNNs
for molecular property prediction**
H. Stärk et al. (2022)

E(n) equivariant graph neural network
V.G. Satorras et al. (2021)

Replace the GNN layer with

$$m_{ij} = \phi_2(h_i^\ell, h_j^\ell, a_{ij})$$

$$m_i = \sum_{j \in N(i)} m_{ij}$$

$$h_i^{\ell+1} = \phi_h(h_i^\ell, m_i)$$

with

$$m_{ij} = \phi_2(h_i^\ell, h_j^\ell, \|x_i^\ell - x_j^\ell\|^2, a_{ij})$$

$$x_i^{\ell+1} = x_i^\ell + \text{Mean}_{j \neq i}(x_i^\ell - x_j^\ell) \phi_x(m_{ij})$$

$$m_i = \text{unchanged}$$

$$h_i^{\ell+1} = \text{unchanged}$$

**Vector neurons: a general framework
for $SO(3)$ -equivariant networks**
C. Deng et al.

Replace 1-dimensional (scalar) neurons with 3-dimensional ones: linear transformations

$$f_W : \begin{cases} \mathbf{R}^{c \times 3} \longrightarrow \mathbf{R}^{c' \times 3} \\ V \longmapsto WV \end{cases}$$

are naturally equivariant, $f_W(V)R = (WV)R = W(VR) = f_W(VR)$, but the non-linearities have to be changed, e.g., to $V \mapsto V'$, where

$$\begin{aligned} V &= (v_1, \dots, v_c) \in \mathbf{R}^{c \times 3} \\ W_c, U_c &\in \mathbf{R}^{1 \times C} \text{ for each } c \in \llbracket 1, C \rrbracket \\ q_c &= W_c V, \quad k_c = U_c V \in \mathbf{R}^{1 \times 3} \\ v' &= \begin{cases} q_c & \text{if } \langle q_c, k_c \rangle = 0 \\ q_c - \left\langle q_c, \frac{k_c}{\|k_c\|} \right\rangle \frac{k_c}{\|k_c\|} & \text{otherwise.} \end{cases} \end{aligned}$$

(The normalization layers are easy to make equivariant.)

**On the equivalence between temporal and static
equivariant graph representations**
J. Gao et B. Ribeiro (2022)

Instead of time-and-graph representations (compute node embeddings for each graph G_t in the sequence, and then model the evolution of those embeddings), try time-then-graph: compute representations of the time series of node features (e.g., with an LSTM), and then embed them.

**Inductive representation learning
on temporal graphs**
D. Xu et al. (2020)

Dynamic graphs can be seen as graphs with another type of edge, for the time evolution; temporal graph attention (TGAT) layers use the attention mechanism in the time dimension (in the space dimension, use a GCN, GAT, etc.)

**Temporal graph networks
for deep learning on dynamic graphs**
E. Rossi et al.

To process dynamic graphs (in discrete or continuous time, *i.e.*, sequences of graphs, or time-stamped lists of graph events), replace the node (or edge) features with time series (LSTM, attention, etc.).

**Cycle representation learning
for inductive relation prediction**
Z. Yan et al. (2022)

Given a graph (V, E) , its incidence matrix $\partial \in \mathbf{F}_2^{|V| \times |E|}$ defines a map $\partial : \mathbf{F}_2^{|E|} \rightarrow \mathbf{F}_2^{|V|}$; its kernel is the set of cycles, Z .

To get a basis of Z , pick a node p and build its shortest path tree T_p : the edges not in T_p define cycles, which form a basis of Z , with $\beta_1 = |E| - |V| + 1$ elements.

(To have shorter cycles, repeat for several points, e.g., the cluster centers from spectral clustering.)

The cycle incidence matrix of this basis is $C_{T_p} \in \mathbf{F}_2^{|E| \times \beta_1}$.

Use a bidirectional LSTM to compute cycle features.

Build a new graph, with cycles as nodes, and edge weights equal to the number of edges the cycles have in common.

To test if an edge should be in the graph, add it to the graph, and use a GNN on the cycle graph to compute its “confidence”.

**GNNRank: learning global rankings
from pairwise comparisons
via directed graph neural networks**
Y. He et al. (2022)

Given a set of pairwise comparisons between n elements as the (weighted) adjacency matrix A of a directed graph, *serial rank* computes the binary comparison matrix $C_{ij} = \text{sign}(A_{ij} - A_{ji})$, then the similarity matrix $S = \frac{1}{2}(n\mathbf{1}\mathbf{1}' + CC')$, and finally its Fiedler vector (eigenvector for the second largest eigenvalue – the first one is $\mathbf{1}$), whose coordinate define the desired order.

GNNRank replaces the computation of the similarity matrix $A \mapsto S$ with a GNN, and the computation of the Fiedler vector with a few proximal gradient steps for the constrained optimization problem

$$\begin{aligned} \text{Find} \quad & x \\ \text{To minimize} \quad & x' S x \\ \text{Such that} \quad & \|x\|_2 = 1 \\ & x' \mathbf{1} = 1 \end{aligned}$$

**G^2 CN: graph Gaussian convolution networks
with concentrated graph filters**
M. Li et al.

The action of a GNN on node features can be written as $x \mapsto g(L)x$, where L is the normalized Laplacian. Look at the maximum response, the center, and the bandwidth.

$$\begin{aligned} R &= \max_{\lambda \in [0, 2]} g(\lambda) \\ b &= \text{Argmax}_{\lambda \in [0, 2]} g(\lambda) \\ \text{bw} &= \int_0^2 \mathbf{1}(g(\lambda) \geq R/\sqrt{2}) d\lambda \end{aligned}$$

Try $g(\lambda) = e^{-T(\lambda-b)^2}$.

**Molecular representation learning
via heterogeneous motif graph neural networks**
Z. Yu and H. Gao (2022)

Molecules and motifs (, C-C, C-OH, etc.) for a bipartite graph, similar to the document-word bipartite graph in NLP: TF-IDF features can complement graph neural nets.

**Topology-aware network pruning
using multi-stage graph embedding
and reinforcement learning**
S. Yu et al. (2022)

Use reinforcement learning (RL) to find a good pruning strategy, with a reward function defined from accuracy and pruning ratio, after encoding the neural network (graph embedding) with a multi-stage GNN (to account for its hierarchical structure).

**Parametrized explainer
for graph neural network**
D. Luo et al.

GNNEExplainer gives an explanation (a subgraph) for the output of a single instance – but this has to be done anew for each sample. PGExplainer trains a GNN to output those explanations

**GNNEExplainer: generating explanations
for graph neural networks**
R. Ying et al. (2019)

To explain the output of a GNN, for a given input, look for a small subgraph, and a subset of features, such that altering those features on that subgraph significantly changes the output – mutual information $H(Y) - H(Y|S)$ measures that.

**PGMEExplainer: probabilistic graphical model
explanations for graph neural networks**
M.N. Vu and M.T. Thai (2020)

Explain the (node prediction) output of a GNN, locally, with a simple Bayesian network (built on a small subgraph (motif) containing the target node).

The CLRS algorithmic reasoning benchmark
P. Veličković et al. (2022)

Benchmarks (30 algorithms from CLRS: sort, search, dynamic programming, graphs, strings, geometry) to test whether neural networks can learn to reproduce them.

**Diffusion-LM
improves controllable text generation**
X.L. Li et al.

Diffusion models can also generate text with a prescribed semantic contents (or length, or sentence structure, etc.)

$$\begin{array}{c} X_T \rightarrow X_{T-1} \rightarrow \dots \rightarrow X_0 \rightarrow \text{text} \\ \text{noise} \qquad \qquad \qquad \text{word} \\ \qquad \qquad \qquad \qquad \qquad \text{vectors} \end{array}$$

**Photorealistic text-to-image diffusion models
with deep language understanding**
C. Saharia et al. (2022)

Contrary to Dall-E, Imagen uses a very large language model (T5-XXL), trained on text only, frozen; it fine-tunes the result with two efficient U-Net steps. It uses dynamic thresholding to avoid fully-saturated pixels.

Drawbench is a benchmark for text-to-image generation (list of prompts, challenging for various reasons).

**GLIDE: Towards photorealistic
image generation and editing
with text-guided diffusion models**
A. Nichol et al.

Diffusion models are trained by progressively adding noise to an image x_0

$$\begin{aligned} x_0 &\sim \text{Data} \\ x_t | x_{t-1} &\sim N(\sqrt{\alpha_t} x_{t-1}, (1 - \alpha_t) I) \end{aligned}$$

and trying to undo that process

$$\begin{aligned} x_T &\sim N(0, I) \\ x_{t-1} | x_t &\sim N(\mu_\theta(x_t), \Sigma_\theta(x_t)) \end{aligned}$$

(with Σ_θ diagonal). If $x_t = x_0 + \varepsilon$, the loss tries to recover ε

$$\text{Loss} = \mathbb{E}_{\substack{t \sim \text{Unif}[1, T] \\ x_0 \sim \text{Data} \\ \varepsilon \sim N(0, 1)}} \|\varepsilon - \varepsilon_\theta(x_t, t)\|^2.$$

Guided diffusion increases the likelihood of a given class y

$$\hat{\mu}_\theta(x_t | y) = \mu_\theta(x_t | y) + s \cdot \Sigma_\theta(x_t | y) \nabla_{x_t} \log p_\phi(y | x_t).$$

Classifier-free guidance also moves the model away from a “null label” \emptyset (e.g., an empty prompt)

$$\hat{\varepsilon}(x_t | y) = \varepsilon_t(x_t | \emptyset) + s(\varepsilon_\theta(x_t | y) - \varepsilon_\theta(x_t | \emptyset)).$$

CLIP-guidance uses a joint representation of images f and text g , encouraging large dot products $f(x) \cdot g(c)$ for matching pairs (contrastive cross-entropy), instead of a classifier

$$\hat{\mu}_\theta(x_t | y) = \mu_\theta(x_t | y) + s \cdot \Sigma_\theta(x_t | y) \nabla_{x_t} f(x_t) \cdot g(c).$$

Denoising diffusion probabilistic models
J. Ho et al.

Initial paper on (unconditional) diffusion models for image generation.

$$\mu_\theta = \frac{1}{\sqrt{\alpha}} \left(x - \frac{\beta}{\sqrt{1 - \alpha}} \varepsilon_\theta \right)$$

**Reverse-time stochastic differential equation
for generative modeling
L. Winkler (2021)**

Given an SDE

$$dX_t = \mu(X_t, t)dt + \sigma(X_t, t)dW,$$

use the Kolmogorov forward equation (KFE)

$$\partial_t p(x_t) = -\partial_{x_t} [\mu(x_t)p(x_t)] + \frac{1}{2}\partial_{x_t}^2 [\sigma^2(x_t)p(x_t)]$$

and the Kolmogorov backward equation ($t \leq s$)

$$-\partial_t p(x_s|x_t) = \mu(x_t)\partial_{x_t} p(x_s|x_t) + \frac{1}{2}\sigma^2(x_t)\partial_{x_t}^2 p(x_s|x_t)$$

to derive a PDE for $p(x_s, x_t) = p(x_s|x_t)p(x_t)$:

$$\begin{aligned} -\partial_t p(x_s, x_t) = & \\ & \partial_{x_t} \left[p(x_s, x_t) \left(\mu(x_t) - \frac{\partial_{x_t} [\sigma^2(x_t)p(x_t)]}{p(x_t)} \right) \right] \\ & + \frac{1}{2}\partial_{x_t}^2 [p(x_s, x_t)\sigma^2(x_t)]. \end{aligned}$$

It is the KFE of a SDE. If the noise σ is independent of the input, we can move it outside of the partial derivative, and we recognize the log-derivative of p , the score. The final SDE is

$$d\bar{x}_t = [\mu(x_t) - \sigma_t^2 \partial_{x_t} \log p(x_t)]dt + \sigma_t d\bar{W}_t.$$

**Reverse-time diffusion equation models
B.D.O. Anderson (1980)**

**A primer on monotone operator methods
A.K. Ryu and S. Boyd (2016)**

2. A *relation* (or *operator*, or *correspondance*, or *set-valued function*) on \mathbf{R}^n is a subset $F \subset \mathbf{R}^n \times \mathbf{R}^n$. Its *subdifferential* is

$$\partial f = \{(x, g) : \forall z \ f(z) \geq f(x) + g^T(z - x)\}$$

$$\begin{aligned} (v, u) \in \partial f & \iff (u, v) \in (\partial f)^{-1} \\ & \iff v \in \underset{x}{\operatorname{Argmin}} f(x) - u^T x \\ & \iff f(v) + f^*(u) = v^T u \end{aligned}$$

where $f^*(y) = \sum_x y^T x - f(x)$.

A function $f : \mathbf{R}^n \rightarrow \mathbf{R} \cup \{\infty\}$ is *closed* if its epigraph

$$\operatorname{epi} f = \{(x, t) : x \in \operatorname{dom} f, f(x) \leq t\};$$

it is *proper* if its domain is non-empty. If f is *CCP* (convex, closed, proper), $f^{**} = f$, and $(\partial f)^{-1} = \partial f^*$.

3. A Lipschitz relation with constant L is a function; if $L < 1$, it is a contraction; if $L = 1$, it is *non-expansive*. The set of fixed points of a non-expansive function, $(I - F)^{-1}(0)$, is closed and convex (but possibly empty); for a contraction, it has exactly one point.

An *averaged* operator is of the form $F = (1 - \theta)I + \theta G$, $\theta \in (0, 1)$, G non-expansive; F is still non-expansive, and has the same fixed points as G .

Projections, and *overprojections* (on a compact set C) are non-expansive.

$$\Pi_C(x) = \underset{z \in C}{\operatorname{Argmin}} \|z - x\|$$

$$Q_C = 2\Pi_C - I$$

4. A relation f is *monotone* if

$$\forall x, y \ (fx - fy)^T(x - y) \geq 0;$$

it is *maximal* if there is no larger monotone relation (for the inclusion, on $\mathbf{R}^n \times \mathbf{R}^n$); it is *strongly monotone* if $\forall x, y \ (fx - fy)^T(x - y) \geq m \|x - y\|^2$ ($m > 0$). For a strongly monotone Lipschitz relation,

$$\forall x, y \ m \|x - y\|^2 \leq (fx - fy)^T(x - y) \stackrel{\text{CS}}{\leq} L \|x - y\|^2,$$

the condition number is $\kappa = L/m$.

If F is maximal monotone, then so is F^{-1} .

If F is strongly monotone with parameter m , the F^{-1} is Lipschitz with constant $1/m$ (but if F is Lipschitz, F^{-1} need not be strongly monotone).

If f is CCP, then ∂f is maximal monotone.

A CCP f is strongly convex if $f(x) - m\|x\|^2$ is convex or, equivalently, if ∂f is strongly monotone with parameter m . A CPP f is strongly convex with parameter m iff f^* is strongly smooth with parameter $L = 1/m$.

Continuous monotone functions are maximal.

An affine function $f(x) = Ax + b$ is maximal monotone iff $A + A^T \succeq 0$; it is strongly monotone with parameter $\lambda_{\min}(A + A^T)/2$; it is the subdifferential of a CCP iff $A = A^T$ and $A \succeq 0$. This generalizes to differentiable functions $F : \mathbf{R}^n \rightarrow \mathbf{R}^n$ and their derivative $A = DF(x)$.

Projections are monotone. If $C \subset \mathbf{R}^n$ is closed convex, its *normal cone operator* $N_C = \partial I_C$ is

$$N_C(x) = \begin{cases} \{y : \forall z \in C \ y^T(z - x) \leq 0\} & \text{if } x \in C \\ \emptyset & \text{otherwise} \end{cases}$$

The *saddle subdifferential* of $f : \mathbf{R}^m \times \mathbf{R}^n \rightarrow \mathbf{R} \cup \{\infty\}$ is

$$F(x, y) = \begin{pmatrix} \partial_x f(x, y) \\ -\partial_y f(x, y) \end{pmatrix};$$

if f is convex in x and concave in y , F is often maximal.

For the optimization problem

$$\begin{array}{ll} \text{Find} & x \\ \text{To minimize} & f_0(x) \\ \text{Such that} & \forall i \ f_i(x) \leq 0 \quad \text{CCP} \\ & \forall j \ h_j(x) = 0 \quad \text{affine} \end{array}$$

the KKT operator is

$$T(x, \lambda, \nu) = \begin{pmatrix} \partial_x L(x, \lambda) \\ -F(x) + N_{\lambda \geq 0} \\ -H(x) \end{pmatrix}$$

where $F = (f_1, \dots, f_m)$, $H = (h_1, \dots, h_p)$,

$$L(x, \lambda, \nu) = \begin{cases} f_0(x) + \sum \lambda_i f_i(x) + \sum \nu_j h_j(x) & \text{if } \lambda \geq 0 \\ -\infty & \text{otherwise} \end{cases}$$

it is monotone, and its zero set is the set of optimal primal-dual pairs.

5a. Fixed point iterations of a *contraction* converge, at least geometrically. If f is strongly convex and strongly smppth with parameters m and L , *gradient descent*

$$x_{k+1} = x_k - \alpha \nabla f(x_k) \quad \alpha \in (0, 2L)$$

converges to a minimizer of f . If F is strongly monotone and Lipschitz with parameters m and L , $(I - \alpha F)$ is a contraction for $\alpha \in (0, 2m/L^2)$, and the *forward step method* converges

$$x_{k+1} = x_k - \alpha F(x_k).$$

5b. Iterations of *averaged operators* converge to a solution, if one exists (for non-expansive, but non-averaged operators, they need not converge). If f is convex (not strongly) and Lipschitz, $I - \alpha \nabla f$ is averaged, and gradient descent converges.

5c. The *dual ascent* for

$$\text{Minimize}_x f(x) \text{ such that } Ax = b$$

is gradient ascent on the dual, $\text{Minimize}_y g(y)$ where $g(y) = -(f^*(-A'y) - y'b)$,

$$\begin{aligned} x_{k+1} &= \text{Argmin}_x L(x, y_k) \\ y_{k+1} &= y_k + \alpha(Ax_{k+1} - b) \end{aligned}$$

The *convex feasibility problem* looks for $x \in C \cap D$, where C and D are non-empty, closed, convex.

$$\text{Minimize}_x \theta d^2(x, C) + (1 - \theta) d^2(x, D)$$

The gradient method gives

$$\begin{aligned} x_{k+1}^C &= \Pi_C(x_k) \\ x_{k+1}^D &= \Pi_D(x_k) \\ x_{k+1} &= \theta x_{k+1}^C + (1 - \theta) x_{k+1}^D \end{aligned}$$

6a. The **resolvent** and **Cayley operator** of a relation on \mathbf{R}^n are

$$\begin{aligned} R &= (I + \alpha A)^{-1} \\ C &= 2R - I. \end{aligned}$$

If A is monotone, R and C are non-expansive. If A is maximal monotone, $\text{dom } R = \text{dom } C = \mathbf{R}^n$ (fixed point iterations are always defined); $0 \in A(x)$ iff $x = R_A(x)$ iff $x = C_A(x)$. If A is strongly monotone, then R is Lipschitz with $L = 1/(1 + \alpha m)$. If A is strongly monotone and Lipschitz, then C is a contraction with

$$L = \left(1 - \frac{4\alpha m}{(1 + \alpha L)^2}\right)^{1/2}.$$

If A is maximal and single-valued, $C = (I - \alpha A)(I + \alpha A)^{-1}$.

If A is a symmetric matrix with positive eigenvalues, R has eigenvalues in $(0, 1]$, C in $(-1, 1]$.

The resolvent of the subdifferential of a convex function f is the *proximal operator*

$$R(x) = (I + \alpha \partial f)^{-1}(x) = \underset{u}{\text{Argmin}} f(u) + \frac{1}{2\alpha} \|u - x\|^2.$$

For the normal cone operator $N_C(x) = \partial I_C(x)$,

$$\begin{aligned} R &= (I + \alpha N_C)^{-1} = \Pi_C && \text{projection} \\ C &= 2\Pi_C - I - Q_C && \text{overprojection.} \end{aligned}$$

To solve $0 \in A(x)$, where A is maximal monotone, the *Cayley* and *proximal point* methods iterate

$$\begin{aligned} x_{k+1} &= C(x_k) && (\text{may not converge}) \\ x_{k+1} &= R(x_k) && (\text{converges: } R \text{ is averaged}). \end{aligned}$$

6b. To solve $\text{Minimize}_x f(x)$ s.t. $Ax = b$, where f is CCP, the *method of multipliers* looks for a dual variable y such that $0 \in -\nabla g$ with the *proximal point method*, $y \leftarrow R_{-\nabla g}(y)$.

$$\begin{aligned} x_{k+1} &= \text{Argmin}_x L_\alpha(x, y_k) \\ y_{k+1} &= y_k + \alpha(Ax_{k+1} - b). \end{aligned}$$

The *proximal method of multipliers* uses the KKT operator T instead, $(x, y) \leftarrow R_T(x, y)$:

$$\begin{aligned} x_{k+1} &= \text{Argmin}_x L_{\alpha_1}(x, y_k) + \frac{\alpha_2}{2} \|x - x_k\|^2 \\ y_{k+1} &= y_k + \alpha_1(Ax_{k+1} - b). \end{aligned}$$

To find a zero of $F(x) = Ax - b$, where $A + A^T \succ 0$, so that F is maximal monotone, the proximal point method with $R_F = (I + \varepsilon^{-1}F)^{-1}$ gives the *iterative refinement*

$$\begin{aligned} r_k &= Ax_k - b \\ x_{k+1} &= x_k - (A + \varepsilon I)^{-1} r_k \end{aligned}$$

$(A + \varepsilon I)$ is often better conditioned than A).

If F is maximal monotone, then so is $L^{-1}TFL^{-1}$; the corresponding proximal point method (*generalized proximal point method*) is $x_{k+1} = (A + \alpha F)^{-1}Ax_k$, where $A = L^T L \succ 0$.

7a. To solve $0 \in (A + B)(x)$, where A and B are maximal monotone, *forward-backward operator splitting* uses the fixed point iteration $x = (I + \alpha B)^{-1}(I - \alpha A)(x)$, i.e. $x_{k+1} = R_B(x_k - \alpha Ax_k)$; for $\alpha \in (0, 2/L)$ (if A is L -Lipshitz) or $\alpha \in (0, 2m/L^2)$; it is averaged.

The *proximal gradient method* solves $\text{Minimize}_x f(x) + g(x)$, f, g CCP, by applying forward-backward splitting to $0 \in (\partial f + \partial g)(x)$, assuming f is differentiable,

$$x_{k+1} = \underset{x}{\text{Argmin}} f(x_k) + \nabla f(x_k)^T(x - x_k) + g(x) + \frac{1}{2\alpha} \|x - x_k\|^2$$

Forward-backward-forward splitting writes $0 \in (A + B)(x)$ as

$$x = ((I - \alpha A)R_B(I - \alpha A) + \alpha A)(x), \quad \alpha \in (0, 1/L),$$

which gives

$$\begin{aligned} x_{k+\frac{1}{2}} &= R_B(x_k - \alpha Ax_k) \\ x_{k+1} &= x_{k+\frac{1}{2}} - \alpha(Ax_{k+\frac{1}{2}} - Ax_k) \end{aligned}$$

For $B = 0$, this is the *extra gradient* method

$$\begin{aligned} x_{k+\frac{1}{2}} &= x_k - \alpha Ax_k \\ x_{k+1} &= x_k - \alpha Ax_{k+\frac{1}{2}}. \end{aligned}$$

The *Combettes-Pesquet* method solves $0 \in (A + B + C)(x)$ with forward-backward-forward splitting by writing it as

$$0 \in \begin{pmatrix} Ax \\ B^{-1}u \end{pmatrix} + \begin{pmatrix} u + Cx \\ -x \end{pmatrix}.$$

Peaceman-Rachford splitting solves $0 \in (A + B)(x)$ using $C_A C_B(z) = z$, $x = R_B(z)$.

$$\begin{aligned} x_{k+\frac{1}{2}} &= R_B z_k \\ z_{k+\frac{1}{2}} &= 2x_{k+\frac{1}{2}} - z_k \\ x_{k+1} &= R_A(z_{k+\frac{1}{2}}) \\ z_{k+1} &= 2z_{k+\frac{1}{2}} - z_{k+\frac{1}{2}} \end{aligned}$$

Douglas-Rachford splitting uses $(\frac{1}{2}I + \frac{1}{2}C_A C_B)(z) = z$, $x = R_B(z)$, i.e.,

$$\begin{aligned} x_{k+\frac{1}{2}} &= R_B(x_k) \\ z_{k+\frac{1}{2}} &= 2x_{k+\frac{1}{2}} - z_k \\ x_{k+1} &= R_A(z_{k+\frac{1}{2}}) \\ z_{k+1} &= z_k + x_{k+1} - x_{k+\frac{1}{2}}. \end{aligned}$$

For instance, to solve $\text{Minimize}_x \sum f_i(x)$, rewrite it as

$$\text{Minimize}_{x_1, \dots, x_n} \sum f_i(x_i) \text{ s.t. } x_1 = x_2 = \dots = x_n,$$

then, as

$$0 \in \begin{pmatrix} \partial f_1(x_1) \\ \vdots \\ \partial f_n(x_n) \end{pmatrix} + N_{[x_1 = \dots = x_n]}(x_1, \dots, x_n),$$

which gives

$$\begin{aligned} x_i &\leftarrow \underset{x}{\text{Argmin}} f_i(x) + \frac{1}{2\alpha} \|x - z_i\|^2 \\ z_1 &\leftarrow z_i + 2\bar{x} - \bar{z} - x_i. \end{aligned}$$

Davis-Yin 3-operator splitting solves $0 \in (A + B + C)(x)$, where A, B, C are maximal monotone, by writing it as $Tz = z$, $x = R_B(z)$, where $T = C_A(C_B - \alpha C)R_B - \alpha CR_B$; the iteration is

$$\begin{aligned} x_{k+\frac{1}{2}} &= R_B(z_k) \\ z_{k+\frac{1}{2}} &= 2x_{k+\frac{1}{2}} - z_k \\ x_{k+1} &= R_A(z_{k+\frac{1}{2}} - \alpha Cx_{k+\frac{1}{2}}) \\ z_{k+1} &= z_k + x_{k+1} - x_{k+\frac{1}{2}} \end{aligned}$$

7b. The proximal gradient solves $\text{Minimize}_x f(x) + \lambda \|x\|_1$, where f is CCP, as (*iterative shrinkage thresholding algorithm*, ISTA)

$$\begin{aligned} x &\leftarrow S_{\alpha\lambda}(x - \alpha \nabla f(x)) \\ S_k(x)_i &= \text{sign}(x_i)(|x_i| - \kappa)_+. \end{aligned}$$

The proximal gradient solves $\text{Minimize}_{x \in C} f(x)$, f CCP, C convex, as (*projected gradient*)

$$x \leftarrow \Pi_C(x - \alpha \nabla f(x)).$$

The proximal gradient solves the convex feasibility problem $x \in C \cap D$, i.e., $\text{Minimize}_{x \in C} d(x, D)^2$, as (*alternating projections*)

$$x \leftarrow \Pi_C \Pi_D x.$$

Douglas-Rachford splitting solves it as $0 \in (N_C + N_D)(x)$

$$\begin{aligned} x_{k+\frac{1}{2}} &= \Pi_D(z_k) \\ x_{k+1} &= \Pi_C(2x_{k+\frac{1}{2}} - z_k) \\ z_{k+1} &= z_k + x_{k+1} - x_{k+\frac{1}{2}}. \end{aligned}$$

Chambolle-Pock solves $\text{Minimize}_x f(x) + g(Mx)$ by rewriting it as

$$0 \in \begin{pmatrix} \partial f(x) \\ \partial g^*(u) \end{pmatrix} + \begin{pmatrix} 0 & M^T \\ -M & 0 \end{pmatrix} \begin{pmatrix} x \\ u \end{pmatrix}$$

and applying the generalized proximal point method with $A = \begin{pmatrix} I & -\alpha M^T \\ -\alpha M & I \end{pmatrix}$

$$\begin{aligned} x_{k+1} &= R_{\partial f}(x_k - \alpha M^T u_k) \\ u_{k+1} &= R_{\partial g^*}(u_k + \alpha M(2x_{k+1} - x_k)) \end{aligned}$$

(if R_{g^*} is easier to compute than $R_P M^T \partial g M$).

The linear program $\text{Minimize}_{x \geq 0} c^T x$ s.t. $Ax = b$ can be written as $0 \in (T_1 + T_2)(x, \nu, \lambda)$, where

$$T_1(x, \nu, \lambda) = \begin{pmatrix} x + A^T \nu - \lambda \\ -(Ax - b) \\ x \end{pmatrix} \quad T_2(x, \nu, \lambda) = \begin{pmatrix} 0 \\ 0 \\ N_{[\lambda \geq 0]} \end{pmatrix}$$

and solved with forward-backward-forward splitting.

The convex-concave game $\text{Maximize}_y \text{Minimize}_x f(x, y)$ can be written $0 \in F(x, y)$, where

$$F(x, y) = \begin{pmatrix} \partial_x f(x, y) \\ \partial_y - f(x, y) \end{pmatrix}$$

and solved with forward-backward-forward splitting (*extra gradient*)

$$\begin{aligned} x_{k+\frac{1}{2}} &= x_k - \alpha \nabla_x f(x_k, y_k) \\ y_{k+\frac{1}{2}} &= y_k + \alpha \nabla_y f(x_k, y_k) \\ x_{k+1} &= x_k - \alpha \nabla_x f(x_{k+\frac{1}{2}}, y_{k+\frac{1}{2}}) \\ y_{k+1} &= y_k + \alpha \nabla_y f(x_{k+\frac{1}{2}}, y_{k+\frac{1}{2}}) \end{aligned}$$

The *complementarity problem*

$$\begin{aligned} \text{Find} \quad & x \in K \\ \text{Such that} \quad & F(x) \in K^* \\ & x \perp F(x) \end{aligned}$$

(with F maximal monotone and Lipschitz) can be written as $0 \in (F + N_K)(x)$ and solved with forward-backward-forward splitting

$$\begin{aligned} x_{k+\frac{1}{2}} &= \Pi_K(x_k - \alpha F x_k) \\ x_k &= x_{k+\frac{1}{2}} - \alpha(F x_{k+\frac{1}{2}} - F x_k). \end{aligned}$$

Quasidefinite systems

$$Kx = b, \quad K = \begin{pmatrix} -A & C \\ C^T & B \end{pmatrix}, \quad A, B \succ 0$$

can be written as

$$F(x) = 0, \quad F(x) = J(Kx - b), \quad J = \begin{pmatrix} -I & 0 \\ 0 & I \end{pmatrix},$$

split using

$$K_1 = \begin{pmatrix} -A & 0 \\ 0 & B \end{pmatrix}, \quad K_2 = \begin{pmatrix} 0 & C \\ C^T & 0 \end{pmatrix},$$

and solved with Peaceman-Rachford.

ADMM solves

$$\begin{aligned} \text{Find} \quad & x, z \\ \text{To minimize} \quad & f(x) + g(z) \\ \text{Such that} \quad & Ax + Bz = c \end{aligned}$$

by applying Douglas-Rachford to the dual problem

$$\text{Maximize}_{\nu} -f^*(-A^T \nu) - g^*(-B^T \nu) + c^T \nu$$

(there are other derivations of ADMM).

Parameter selection and pre-conditioning for a graph form solver C. Fougner and S. Boyd (2015)

The *graph form* optimization problem

$$\begin{aligned} \text{Find} \quad & x, y \\ \text{To minimize} \quad & f(y) + g(x) \\ \text{Such that} \quad & y = Ax \end{aligned}$$

can be solved with ADMM

$$\begin{aligned} (x', y') &= \text{prox}_g(x - \tilde{x}), \text{prox}_f(y - \tilde{y}) \\ (x, y) &= \Pi(x' + \tilde{x}, y' + \tilde{y}) \\ (\tilde{x}, \tilde{y}) &= (\tilde{x} - (x - x'), \tilde{y} - (y - y')). \end{aligned}$$

This can be sped up with

- Over-relaxation: replace x' with $\alpha x' + (1 - \alpha)x$, $\alpha \in (1.5, 1.8)$;
- Approximate projection
- Preconditioning: replace y , x and A with Dy , $E^{-1}x$ and DAE respectively, such that the singular values of DAE be close to 1

$$\text{cond}(DAE) \approx 1, \quad \|DAE\|_2 \approx 1;$$

- Adaptive proximal penalty ρ ,

$$\text{prox}_f v = \underset{z}{\text{Argmin}} f(z) + \frac{\rho}{2} \|x - v\|_2^2$$

(start with a large ρ , which encourages primal feasibility, then, when the primal variables (x, y) converge, decrease it; when the dual variables (\tilde{x}, \tilde{y}) converge, increase it again).

Applications include portfolio optimization: $w' \mu - \lambda w'(FF' + D)w$ becomes

$$\begin{aligned} g(x) &= x' \mu - \lambda x' D x + I(x \geq 0) \\ f(y) &= \lambda y' y + I(y_{m+1} = 1) \\ y &= \begin{pmatrix} F' \\ \mathbf{1}' \end{pmatrix} x. \end{aligned}$$

C++ implementation: `pogs`.

Pretrained transformers for text ranking: BERT and beyond J. Lin at al. (2021)

Information retrieval is often done in two steps: first identify a set of documents “close” to the query, with a bag-of-words approach such as BM25 (lucene)

$$\text{BM}_{25}(q, d) = \sum_{t \in q \cap d} \log \frac{N - \text{df}_t + .5}{\text{df}_t + .5} \cdot \frac{\text{df}_{d,t}(k+1)}{\text{tf}_{d,t} + k \cdot (1 - n + b \ell_d / L)}$$

(where ℓ_d is the length of document d and L the average document length), second, rerank those documents, e.g., using

- Cosine similarity between query and document embeddings

- An **interaction model**, *i.e.*, a neural network exploiting the histogram of similarities between query terms and document terms

(You can stack several rerankers.)

3. BERT is a transformer-based encoder-only network (GPT is decoder-only; the original transformer is a sequence-to-sequence model) providing *contextual embeddings*.

MonoBERT uses BERT to predict if a document is relevant to a query

$$P[\text{relevant} \mid [\text{CLS}] q [\text{SEP}] d [\text{SEP}]]$$

from the contextual embedding of the [CLS] token.

To overcome the input length limit:

- Birch trains BERT on short passages (e.g., tweets), and uses aggregated sentence scores;
- VERT-MaxP trans BERT on overlapping passages, assuming that they are all relevant (or irrelevant) if the document is, and uses aggregated (max) passage relevance at inference time;
- CEDR feeds BERT embeddings to an interaction model;
- Parade uses BERT to compute a vector representation of each sentence, then another BERT to turn that sequence of sentence embeddings into a document embedding.

The Reformer (LSH attention) and the Longformer (sparse attention) also deal with long documents,

DuoBERT compares the relevance of two documents.

4. The vocabulary used in a query may not match that in the document (e.g., “car”, vs “automobile”):

- The query can be expanded:
 - First, retrieve documents with the query words;
 - Assume the first results are relevant;
 - Add words from those documents to the query;
 - Retrieve more documents;

Those words can be chose by training a model

$$P[\text{term} \mid \text{query}, \text{document}]$$

measuring how relevant a term is (CEQE);

- The query can be reformulated to make it more human-like (BERT works better with those);
- The document themselves can be turned into queries (doc2query, trained on MS MARCO);
- The query terms can be re-weighted, by modeling

$$\text{representation of document } d \text{ term } t \mapsto \frac{\# \text{ queries relevant for } d \text{ with } t}{\# \text{ queries relevant for } d}$$

- Expansion and reweighting can be combined.

5. Document retrieval, with approximate neighbour (ANN) search, from pretrained dense representations, is worse than retrieval from average pooling of GloVe embeddings – fine-tuning is necessary, and careful selection of negative samples improves performance.

InPars: data augmentation for information retrieval using large language models
L. Bonifacio et al.

Given a (small) set of (query, document) pairs, generate plausible queries for all the documents (few shot learning, with GPT3 and the MS MARCO dataset, providing triplets text / good question / bad question); keep the highest probability pairs, and use them for reranking (T5, after pyserini).

Pyserini: a Python toolkit for reproducible information retrieval research with sparse and dense representations
J. Lin et al.

ToxiGen: a large-scale machine-generated dataset for adversarial and implicit hate speech detection
T. Hartvigsen et al.

Toxic language detection systems often incorrectly flag texts merely because they mention some minority group (often targeted by online hate): use a language to generate subtly toxic and benign text about those minorities.

Zero-shot neural passage retrieval via domain-targeted synthetic question generation
J. Ma et al.

Synthetic question generation, to compute question embeddings (instead of document embeddings), for first stage information retrieval (nearest neighbour).

SwinIR: image restoration using Swin transformer
J. Liang et al.

Transformers for image restoration (upsampling, denoising, artefact removal):

- Start with a 3×3 convolution, to extract shallow features;
- Apply 6 residual swin transformer blocks (RSTB), followed by a convolution;

- Each RSTB has 6 swin transformer layers (STL), followed by a convolution;
- Each STL has a LayerNorm, a multihead self-attention (MSA) on non-overlapping $M \times M$ windows, another LayerNorm, an MLP;
- The network ends with a convolution, to reconstruct the image from the shallow and deep features (there are skip-connections everywhere).

Generalized cross-entropy loss for training deep neural networks with noisy labels
Z. Zhang and M.R. Sabuncu

To increase robustness to noisy labels, try the negative Box-Cox transformation $\text{loss}(j, p) = (1 - p_j^q)/q$, $q \in (0, 1)$, where j is the label (y) and p the probabilities output by the model (\hat{y}). The cross-entropy $\ell = \log p_j$ and the MAE $\ell = \|e_j - p\|_1 = 2 - 2p_j$ are limiting cases, for $q \rightarrow 0$ or 1. Truncate by replacing p_j with $\text{Min}(p_j, k)$.

Modeling tabular data using conditional GAN
L. Xu et al. (2019)

To account for multimodal continuous columns, estimate the number of modes with a *variational Gaussian mixture* (VGM) and fit a Gaussian mixture; then, separately sample the mixture component and the value within that component. To account for the imbalance in discrete columns,

- Learn conditional generators, conditioned on the value of one of the discrete columns,
- Sample the discrete values according to the log-frequency of each category.

Opacus: user-friendly differential privacy library in pytorch
A. Yousefpour et al. (2021)

DP-SGD (differentially private stochastic gradient descent) makes SGD differentially private (intuitively, removing one sample from the batch does not change the update) by computing the per-sample gradients, clipping them, aggregating them, and adding noise.

Supervised contrastive learning
P. Khosla et al. (2020)

The *triplet loss* uses one positive sample (augmentation) and one negative sample, but requires negative mining. *Contrastive learning* uses one positive sample and many negative samples

$$\text{loss} = \sum_i -\log \frac{\exp(z_i \cdot z_{j(i)}/\tau)}{\sum_{a \in N(i)} \exp(z_i \cdot z_a/\tau)}$$

i : samples

$j(i)$: positive sample

$N(i)$: negative samples

$z_i \in \mathbf{S}^{d-1}$: features.

Supervised contrastive learning uses many positives (augmentations and samples from the same class) and many negative samples

$$\text{loss} = \sum_i -\text{Mean}_{p \in P(i)} \log \frac{\exp(z_i \cdot z_p/\tau)}{\sum_{a \in N(i)} \exp(z_i \cdot z_a/\tau)}$$

(putting the mean outside the log rather than inside works better).

Generate features in 2048 dimensions, normalize them, reduce the dimension to 128 (MLP), and normalize again; use scalar products instead of Euclidean distance.

Energy-latency attacks via sponge poisoning
A.E. Cinà (2022)

Mount a DoS attack on a deep learning model, running on sparsity-based ASIC accelerators adopting zero-skipping strategies to avoid multiplications when the input is zero, by adding a penalty (ℓ_0 relaxation)

$$\hat{\ell}_0(x) = \sum \frac{x_i^2}{x_i^2 + \varepsilon}$$

for non-zero activations.

A new correlation coefficient between categorical, ordinal and interval variables with Pearson characteristics
M. Baak et al. (2019)

The ϕ_k correlation coefficient (implementation in **phik**) is the correlation for which a Gaussian variable would have the same χ^2 (after binning the quantitative variables into 10 bins).

The *global correlation coefficient* is the highest possible correlation between variable k and a linear combination of the other variables.

$$g_k = \sqrt{1 - [V_{kk} \cdot (V^{-1})_{kk}]^{-1}}$$

Decision tree learning with spatial modal logics
G. Pagliarini and G. Sciacicco

Modal logic extends propositional logic with

$$\begin{array}{ll} \Diamond P & \text{possibly } P \\ \Box P & \text{necessarily } P. \end{array}$$

It is less expressive than first order logic (FOL, which allows quantifiers, \forall, \exists).

Allen's interval algebra

can be generalized to hyperrectangles, or replaced with the *region connection calculus* (RCC8)

Modal decision trees, for temporal or spatial data, allows rules like

$$\begin{aligned} \exists[a, b] \ T_{[a, b]} \geq 39 & \quad \exists R_1 \ \text{Red}(R_1) \geq a \\ \exists[c, d] \ \text{HR}_{[c, d]} \geq 140 & \quad \text{or} \quad \exists R_2 \ \text{Green}(R_2) \leq b \\ [a, b] \cap [c, d] \neq \emptyset & \quad R_2 \subset R_1. \end{aligned}$$

They are more expressive (and sparser) than decision trees, but more interpretable than ILP models (inductive logic programming, *i.e.*, FOL rules).

**Bayesian streaming
sparse Tucker decomposition**
S. Fang et al. (2021)

The CP decomposition is a Tucker decomposition with a diagonal core – instead, add a sparsifying penalty (with a Bayesian spike-and-slab prior).

**CoSTCo: a neural tensor completion model
for sparse tensors**
H. Liu et al. (2019)

The Tucker decomposition

$$T_{i_1, \dots, i_N} = \sum_{j_1, \dots, j_N} G_{j_1, \dots, j_N} U_{j_1 i_1}^1 U_{j_2 i_2}^2 \dots U_{j_N i_N}^N$$

can be made nonlinear $T_{i_1, \dots, i_N} = f_\theta(i_1, \dots, i_N)$:

- Use the 1-hot encoding $e \in \mathbf{R}^{\sum d_i}$ of the index tuple (i_1, \dots, i_N) ;
- Compute an embedding

$$\begin{pmatrix} U^1 & & 0 \\ & \ddots & \\ 0 & & U^N \end{pmatrix} e \in \mathbf{R}^{r \times N};$$

- Apply CNNs with filter sizes $(r, 1)$ and $(1, N)$;
- Finish with a fully-connected layer.

**How many bins should be put
in a regular histogram**
L. Birgé and Y. Rozenholc (2005)

Choose the number of bins D to partition $[0, 1]$ by maximizing

$$\begin{aligned} L(D) &= \sum_{1 \leq j \leq D} N_j \log \frac{DN_j}{n} - \text{pen}(D) \\ \text{pen}(D) &= D - 1 + (\log D)^{2.5}. \end{aligned}$$

Test with $N(0, 1)$, $\frac{1}{4}N(0, 1) + \frac{3}{4}N(2, \frac{1}{16})$, $\frac{3}{4}N(0, 1) + \frac{1}{4}N(3, \frac{1}{9})$, $\text{Exp}(1)$, $T(3)$, $U(0, 1)$.

**Cone-constrained monotone mean-variance
portfolio selection under diffusion models**
Y. Shen and B. Zou (2022)

The mean-variance preference

$$J(X) = \mathbb{E}_{\mathbf{P}}[X] - \lambda \text{Var}_{\mathbf{P}}[X]$$

is not monotonic: we can have $X \geq X'$ a.s., but $J(X) < J(X')$ (for instance $X = \bullet\bullet\bullet\bullet\bullet$, $X' = \bullet\bullet\bullet\bullet\bullet$, $\lambda = 1$)

Replace it with the monotone mean variance preference

$$J(X) = \inf_{\mathbf{Q} \ll \mathbf{P}} \mathbb{E}_{\mathbf{Q}} \left[X + \lambda^{-1} \left(\frac{d\mathbf{Q}}{d\mathbf{P}} - 1 \right) \right].$$

**Portfolio selection with monotone
mean-variance preferences**
F. Maccheroni et al. (2009)

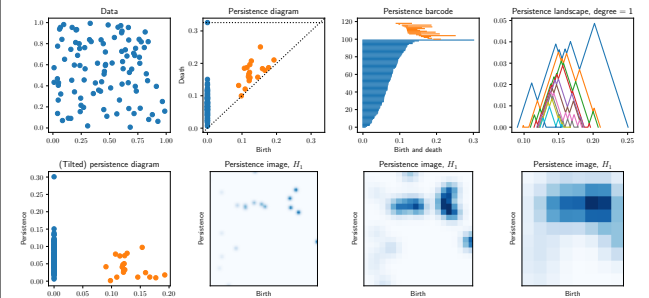

The MMV preference coincides with the mean-variance preference on its domain of monotonicity (the subset of L^2 where the Gâteaux derivative of $U(f) = \mathbb{E}[f] - \frac{1}{2}\lambda \text{Var}[f]$ is positive), and is the best monotone approximation outside.

The unconstrained optimal portfolio is still of the form $\alpha^* = \lambda^{-1}V^{-1}\mu$, but V and μ are now *lower* moments of X (for some threshold).

**Persistence images: a stable vector
representation of persistent homology**
H. Adams et al. (2017)

Persistence diagrams can be fed directly to distance-based machine learning algorithms (with the bottleneck distance, or the Wasserstein distance), but not to arbitrary machine learning algorithms (which often require coordinates). The *persistence image* is a vector representation for a persistence diagram (PD) obtained by:

- Rotating the (birth, death) PD into (birth, persistence), where persistence = death – birth;
- Replacing each point with a Gaussian distribution (you need to choose its variance);
- Considering a weighted sum of those distributions, with weights increasing with persistence (it should be zero on the diagonal) \lhd
- Rasterising the data (for H_0 , the birth coordinate is always zero: it is a 1-dimensional image).

**Persistence diagrams
with linear machine learning models**
I. Obayashi and Y. Hiraoka

Linear models built on the *persistence image* are interpretable: large positive or negative coefficients correspond to desired or undesirable regions of the persistence diagram.

Add a regularization term to smooth the weights for higher resolution persistence images.

***Persistence weighted Gaussian kernel
for topological data analysis***
G. Kusano et al.

Map persistence diagrams D to functions

$$D \mapsto \sum_{x \in D} w(x)k(x, \cdot)$$

where k is a kernel and w a weight function decreasing with persistence.

***Persistent entropy for separating topological
features from noise in Vietoris-Rips complexes***
N. Atienza et al. (2017)

Given a persistence diagram $(b_i, d_i)_i$, the *persistent entropy* is the entropy H of the persistences $p_i \propto d_i - b_i$; it can help prune non-significant barcodes (intuitively, $\exp H$ is the number of significant barcodes).

***Tropical coordinates
on the space of persistence barcodes***
S. Kališnik

The *tropical semiring* is $(\bar{\mathbf{R}}, \text{Min}, +, \infty, 0)$; the *arctic semiring* is $(\mathbf{R} \cup \{-\infty\}, \text{Max}, +, -\infty, 0)$. Max-plus polynomials up to functional equivalence (identify polynomials if they always take the same values) form a semiring $\text{MaxPlus}[x_1, \dots, x_n]$. Similarly, Min-plus polynomials, and rationals tropical functions, form semirings.

Symmetric tropical rational functions can be used as coordinates on the barcode space.

***The ring of algebraic functions
on persistence barcodes***
A. Adcock et al. (2013)

We could use symmetric polynomials as coordinates on the space of barcodes: $k[x_1, y_1, \dots, x_n, y_n]^{\mathfrak{S}_n}$ is complicated (there are non-trivial relations between the symmetric polynomials – syzygies), but $\varinjlim k[x_1, y_1, \dots, x_n, y_n]^{\mathfrak{S}_n}$ is freely generated. However, we do not only want $(x_1, y_1, \dots, x_n, y_n) \sim (x_1, y_1, \dots, x_n, y_n, 0, 0)$, but $(x_1, y_1, \dots, x_n, y_n) \sim (x_1, y_1, \dots, x_n, y_n, x_{n+1}, x_{n+1})$: the corresponding subring of $k[x_1, y_1, \dots, x_n, y_n]^{\mathfrak{S}_n}$ is that of polynomials f such that

$$\left(\frac{\partial}{\partial x_i} + \frac{\partial}{\partial y_i} \right) f \in (y_i - x_i)$$

and the limit of those subrings is freely generated by the

$$\sum_i x_i^{a+1} y_i^b - x_i^a y_i^{b+1}.$$

(Those coordinates are not Lipschitz wrt the bottleneck or Wasserstein distance.)

***Stable topological signatures
for points on 3D shapes***
M. Carrière et al.

To identify a point on a surface, consider their persistence diagram, *i.e.*, the 1-holes of the geodesic balls centered on this point.

To get a vector embedding, compute the pairwise distances between the points in the persistence diagram, sort them, and pad them with zeroes,

$$m(x, y) = \text{Min}\{d(x, y), d(x, \text{diag}), d(y, \text{diag})\}.$$

***A stable multi-scale kernel
for topological machine learning***
J. Reininghaus et al.

Define a feature map $\Phi_\sigma : \text{PD} \rightarrow L^2$ on the space of persistence diagrams by replacing each point p with a Gaussian density and subtracting another Gaussian \bar{p} on the other side of the diagonal.

$$\begin{aligned} \Phi_\sigma(D) : x &\mapsto \sum_{p \in D} \phi_\sigma(\|x - p\|) - \phi_\sigma(\|x - \bar{p}\|) \\ \phi_\sigma(t) &= e^{-t^2/\sigma^2} \end{aligned}$$

The corresponding kernel is

$$k_\sigma(F, G) = \sum_{\substack{p \in F \\ q \in G}} \phi_\sigma(\|p - q\|) - \phi_\sigma(\|p - \bar{q}\|).$$

***Statistical analysis
of persistence intensity functions***
Y.C. Chen et al.

Replace persistence diagrams with weighted sums of Gaussians, one for each point, with weights proportional to the persistence, $w = \text{death} - \text{birth}$: you can then easily average them, cluster them, etc.

A topology layer for machine learning
R. Brüel-Gabrielsson et al. (2020)

Persistence diagrams as a layer: you can use

$$\xi(p, q, i_0, \text{PD}_k) = \sum_{i \geq i_0} |d_i - b_i|^p \left(\frac{b_i + d_i}{2} \right)^q$$

in the loss, *i.e.*, increase or decrease $\beta_0, \beta_1, (\beta_0 - 1)_+, (\beta_1 - 1)_+$, etc.

Use as a regularizer (image reconstruction) or a prior (generative models).

The Bayesian learning rule
M.E. Khan and H. Rue

Empirical risk minimization

$$\text{Minimize}_{\theta} \sum_i \ell(y_i, f_{\theta}(x_i)) + R(\theta)$$

can be generalized to probability distributions

$$\text{Minimize}_q \mathbb{E}_{\theta \sim q} \left[\sum_i \ell(y_i, f_{\theta}(x_i)) \right] + \text{KL}(q(\theta) \parallel p(\theta))$$

$$p(\theta) \propto \exp -R(\theta).$$

The *Bayesian learning rule* looks for a probability distribution in an exponential family

$$q(\theta) = h(\theta) \exp[\langle \lambda, T(\theta) \rangle - A(\lambda)]$$

λ : natural parameters
 A : log-partition (cummulant) function
 $T(\theta)$: sufficient statistics
 h : base measure
 $\mu = \mathbb{E}_{\theta \sim q} [T(\theta)]$ expectation parameters

by iterating

$$\lambda_{t+1} \leftarrow \lambda_t - \rho_t \tilde{\nabla}_t \left[\mathbb{E}_{\theta \sim q_t} \bar{\ell}(\theta) - H(q_t) \right]$$

where

$$\bar{\ell}(\theta) = \sum_i \ell(y_i, f_{\theta}(x_i))$$

$$H(q_t) = \mathbb{E}_{\theta \sim q_t} [-\log q_t(\theta)] \text{ entropy}$$

$$\tilde{\nabla}_t \mathbb{E}_{\theta \sim q_t} [\cdot] = F(\lambda_t)^{-1} \nabla_t \mathbb{E}_{\theta \sim q_t} [\cdot] \text{ natural gradient}$$

$$= \nabla_{\mu} \mathbb{E}_{\theta \sim q_t} [\cdot] \Big|_{\mu = \nabla_{\lambda} A(\lambda_t)}$$

$$F(\lambda) = \nabla_{\lambda}^2 A(\lambda) \text{ Fisher information matrix.}$$

For instance, the exponential families $N(m, I)$ (unknown mean, known variance) and $N(m, S^{-1})$ (unknown mean and variance) give gradient descent and Newton's method.

Do t -statistic hurdles need to be raised?
A.Y. Chen (2022)

Calls to lower the 5% significance rate for publications account for false positives but ignores (unobserved) false negatives.

MDD aggregated two-sample test
A. Schrab et al. (2021)

To test if two samples come from the same distribution (non-parametrically, not only in dimension 1, contrary to the Kolmogorov-Smirnov test) use the maximum mean discrepancy (MMD) test (an integral probability metric)

$$\text{MMD}_k(p, q) = \sup_{f \in \mathcal{H}} \left| \mathbb{E}_{X \sim p} f(X) - \mathbb{E}_{Y \sim q} f(Y) \right|$$

$$\|f\|_{\mathcal{H}_k} \leq 1$$

where \mathcal{H}_k is the RKHS associated to a kernel k

$$\widehat{\text{MMD}}_a = \text{Mean}_{i, i'} k(x_i, x_{i'}) + \text{Mean}_{j, j'} k(x_j, x_{j'})$$

$$- 2 \text{Mean}_{ij} k(x_i, x_j)$$

or

$$\widehat{\text{MMD}}_b = \text{Mean}_{i, j} h(X_i, X_j, Y_i Y_j)$$

$$h(x, x', y, y') = k(x, x') + k(y, y') - k(x, y') - k(x', y)$$

JKONet: proximal optimal transport modeling of population dynamics
C. Bunne et al. (2021)

The *JKO flow* is an analogue of proximal descent for probability distributions

$$\rho_{t+1} = \underset{\rho}{\text{Argmin}} J(\rho) + \lambda W^2(\rho_t, \rho)$$

where ρ_t is a probability distribution and W the 2-Wasserstein distance.

The optimal transport map is the gradient of a convex function (if ρ_t has a density – Brenier's theorem), which can be modeled with an *input-convex neural net* (ICNN).

$$T = \nabla \psi_{\theta}$$

$$\rho_{t+1} = (\nabla \psi_{\theta^*})_{\#} \rho_t$$

$$\theta^* = \underset{\theta}{\text{Argmin}} J((\nabla \psi_{\theta})_{\#} \rho_t) + \lambda \int \|x - \nabla \psi_{\theta}(x)\|^2 d\rho_t(x)$$

We want to find J such that the JKO flow describes the evolution of a cloud of points

$$J_{\xi}(\rho) = \int_{\xi} \mathbb{E}(x) d\rho(x).$$

Implementation in JAX, with `ott`.

Fully parallel hyperparameter search: reshaped space-filling
M.L. Cauwet et al.

Transform low discrepancy sequences in $[0, 1]^d$ as $x \mapsto \Phi(\lambda \cdot \Phi^{-1}(x))$ or $x \mapsto \Phi(\lambda \cdot \Phi_{\text{Cauchy}}^{-1}(x))$ (remove the outer Φ if the parameters are unbounded).

The *Hammersley sequence* is the same as the Halton sequence, except for the first dimension, in which the points are equidistant (the Halton and Hammersley sequences have a “scrambled” version, with better discrepancy guarantees).

Evolution under strong noise: a self-adaptive evolution strategy can reach the lower performance bound – the pcCMSA-ES

M. Hellwig and H.G. Beyer

Adaptively change the population size in CMSA-ES, increasing it if the optimization stalls because of noise.

Covariance matrix adaptation revisited: the CMSA evolution strategy
H.G. Beyer and B. Sendhoff

CMSA-ES is a simplification of the CMA-ES optimization algorithm with fewer hyperparameters, scaling to larger populations.

Parametric estimate of intensity inhomogeneities applied to MRI
M. Styner et al. (2000)

In “(1+1) evolution strategy”, both the population size and the number of children are equal to 1.

Portfolio performance attribution via Shapley value
N. Moehle et al. (2021)

The Shapley attribution can be defined as

$$a = \frac{1}{n!} \sum_{\pi \in \mathfrak{S}_n} a_\pi$$

where

$$a_{\pi,i} = f(e_{\pi(1)} + \dots + e_{\pi(i)}) - f(e_{\pi(1)} + \dots + e_{\pi(i-1)})$$

and approximated by sampling permutations $\pi \in \mathfrak{S}_n$ (with replacement) but we end up evaluating the same $f(x)$ many times. Instead, use

$$a_i = \sum_{x: x_i=0} \frac{(\mathbf{1}'x)!(n - \mathbf{1}'x - 1)}{n!} (f(x + e_i) - f(x))$$

(where we assume, wlg, $f(0) = 0$) and approximate it

$$a_i = \mathbb{E}_{x \sim p} [f(x + e_i) - f(x)]$$

$$p(x) = \frac{(\mathbf{1}'x)!(n - \mathbf{1}'x - 1)}{n!}$$

by sampling the number of active features $\mathbf{1}'x$ from a multinomial distribution

$$p_k = \frac{k!(n - k - 1)!}{n!}$$

and then sampling $\mathbf{1}'x$ features at random.

Does non-linear factorization of financial returns help build better and stabler portfolios?
B. Spilak and W.K. Härdle (2022)

Statistical factor portfolios can be computed with a low rank factorization

$$X \approx WF$$

X : asset returns

F : factor returns.

Convex non-negative matrix factorization adds constraints

$$W \geq 0, \quad F = H'X, \quad H \geq 0$$

(the assets are non-negative linear combinations of the factors, and conversely).

Non-linear statistical factors can be computed with an autoencoder

$$x \mapsto z = Hx + b \mapsto W\sigma(z) + \varepsilon$$

with constraints $H \geq 0$, $W \geq 0$ and penalties $\|W'W - I\|_2^2$ and $\|\Sigma_z \odot (1 - I)\|^2$.

Use risk parity, hierarchical risk parity, etc. to combine the factor portfolios.

Fast high-dimensional integration using tensor networks
S. Cassel

The tensor train decomposition generalizes the approximation

$$f(x, y) \approx \frac{f(x, \bar{y})f(\bar{x}, y)}{f(\bar{x}, \bar{y})};$$

it interpolates a function from its restrictions on a few 1-dimensional axis-aligned subspaces

$$f(x, y) \approx \sum_{ij} f(x, b_j)(Q^{-1})_{ij} f(a_{ij}, y)$$

$$Q_{k\ell} = f(a_k, b_\ell)$$

In dimension n :

$$f(x_1, \dots, x_q) = F(x_1)Q_{12}^{-1}F_2(x_2) \cdots Q_{d-1,d}^{-1}F_d(x_d).$$

Application include high-dimensional integration; it can be combined with Aitken extrapolation.

Given a sequence $(\psi_n)_n$, Aitken extrapolation writes it as a telescopic series.

$$\psi_n = \psi_0 + \sum_{i=0}^{n-1} (\psi_{i+1} - \psi_i) \quad \text{telescopic series}$$

$$= \psi_0 + \sum_{i=0}^{n-1} (g(\psi_i) - \psi_i)$$

$$g(\psi_\infty) = \psi_\infty \quad \text{fixed point}$$

$$\frac{g(\psi_i)}{\psi_i - \psi_\infty} \approx g'(\psi_i) \quad \text{secant method}$$

$$\psi_\infty \approx \psi_i - \frac{g(\psi_i)}{g'(\psi_i)}$$

Reciprocity in machine learning
M. Sundararajan and W. Krichene (2022)

Compare the average over i and the average over j of the influence of observation i on prediction j (the latter is Cook's distance): they tend to be similar.

Bridging level- k to Nash equilibrium

D. Levin and L. Zhang (2022)

Nash equilibrium assumes that each player is equally sophisticated. A level 0 player plays at random; a level $n + 1$ player plays the best strategy assuming the opponent is level n . An NLK₁ player plays the optimal strategy assuming the opponent is level 0 with probability λ and NLK₁ with probability $1 - \lambda$.

Generative art using neural visual grammars and dual encoders

C. Fernando et al. (2021)

Given a text prompt, generate an image with a hierarchical neural L -system and evaluate them with an image/text dual encoder.

Planting undetectable backdoors in machine learning models

S. Goldwasser et al.

Given a natural training algorithm

$\text{train} : \text{data} \mapsto \text{classifier},$

a *backdoor* is a pair of algorithms

Backdoor : $\text{data} \mapsto \text{classifier, key}$

Activate : $\text{input, key} \mapsto \text{new input}$

such that

- The classifier is indistinguishable from the natural one
- The new input is close to the old, but ends up in the other class.

Undetectable backdoors exist, for dimension reasons (the same arguments proves the existence of adversarial examples) and can easily be built, e.g., for models using random Fourier features.

Manipulating SGD with data ordering attacks

I. Shumailov et al. (2021)

You can poison a model by tampering with the order of the samples used to train it (rank the samples with a surrogate loss).

A generalist agent

S. Reed et al. (2022)

Compress (behaviour cloning) 600 reinforcement learning, language and image models into a single model, with a transformer: convert all the data into discrete sentences (break down images into 16×16 patches, in raster order; mu-law encode

$$F(x) = \text{sign}(x) \frac{\log(1 + \mu |x|)}{\log(1 + \mu M)}$$

continuous values into $[-1, 1]$, and discretize them into 24 bins).

Model cards for model reporting

M. Mitchell et al.

The *model card* should include: data, model type, model architecture, training algorithm, loss, intended use, out-of-scope use, performance metrics, performance across different factors or subpopulations.

Deep signature models for financial equity time series prediction

M. Noguer i Alonso et al. (2022)

Forecast time series (daily returns, for 10 US stocks, from 14 days of data), by stacking *signets*.

Deep signature transforms

P. Bonnier et al. (2019)

Prior to the truncated signature transform, augment the time series to keep the information that would otherwise be discarded by the truncation

$$x \mapsto \begin{pmatrix} x \\ \phi(x) \end{pmatrix} \mapsto \text{Sig}^N \begin{pmatrix} x \\ \phi(x) \end{pmatrix}.$$

This may be very similar to wavelet or Fourier features.

Nonstationary temporal matrix factorization for multivariate time series forecasting

X. Chen et al.

Temporal matrix factorization reconstructs a multivariate time series from (contemporaneous) latent factors, with a penalty to make them close to VAR.

$$\begin{aligned} \text{Find} \quad & W, X, A_1, \dots, A_d \\ \text{To minimize} \quad & \frac{1}{2} \|P_\Omega(Y - W'X)\|_F^2 \\ & + \frac{1}{2} \rho(\|W\|_F^2 + \|X\|_F^2) \\ & + \frac{1}{2} \lambda \sum_t \|x_t - \sum_k A_k x_{t-k}\|_2^2 \end{aligned}$$

If the time series are not stationary, differentiate them first.

**LDE-Net: Lévy induced
stochastic differential equation
equipped with neural network
for time series forecasting**
L. Yang et al.

Model time series as

$$\begin{aligned} X_{k+1} &= X_k + f(X_k)\Delta t + g(X_k)(\Delta t)^{1/\alpha} L_k \\ L_k &\sim \text{Stable}(\alpha) \\ f, g &: \text{neural nets.} \end{aligned}$$

Combine with an embedding and an attention layer.

**On Hawkes processes
with infinite mean intensity**
C. Aubrun et al. (2022)

The linear Hawkes process has intensity

$$\lambda_t = \lambda_\infty + \int_{-\infty}^t \phi(t-u) dN_u.$$

It can be generalized to

$$\begin{aligned} \lambda_t &= \lambda_\infty + \int_{-\infty}^t \phi(t-u) dN_u + \\ &\int_{-\infty}^t \int_{-\infty}^t Q(t-s, t-u) \varepsilon_u \varepsilon_s dN_u dN_s \end{aligned}$$

(with $\varepsilon_t = \pm 1$). For instance, the ZHawkes model uses

$$Q(s, u) = \phi(s)\delta(s-u) + z(s)z(u).$$

**Distributionally robust risk evaluation with
causality constraint and structural information**
B. Han (2022)

Optimal transport (OT) computes the Wasserstein distance

$$W(\mu, \nu) = \inf_{\pi \in \Pi(\mu, \nu)} \int_{X \times Y} c(x, y) \pi(dx, dy).$$

For distributions on time series, *causal optimal transport* (COT) only considers causal transport plans: $\pi(y_t|x_{1:T}) = \pi(y_t|x_{1:t})$ (it can be formulated as a linear constraint). A risk measure ρ can be made distributionally robust by taking the worst case in a Wasserstein ball around the empirical distribution

$$\max_{W(\mu, \hat{\mu}) \leq \varepsilon} \rho(\mu).$$

**What affects the relationship
between oil prices and the US stock market?**
A mixed-data sampling copula approach

The *copula-Midas-X* model models a high-frequency (daily) bivariate time series (u, v) using low frequency (monthly) time series X_s .

$$\begin{aligned} (u_t, v_t) &\sim C(\lambda_t) && \text{copula} \\ \lambda_t &= \lambda_\tau + \alpha \Phi^{-1}(u_t) \Phi^{-1}(v_t) + \beta \lambda_{t-1} && \text{daily} \\ \lambda_\tau &= \sum_s \gamma_s \sum_k \phi_k(w_s) X_{s, \tau-k} && \text{monthly} \end{aligned}$$

γ_s : weight of predictor s

$\phi_k(w_s)$: weight decay of predictor s

$$\phi_k(w) \propto \left(1 - \frac{k}{K}\right)^{w-1}, \quad \phi_k(w) = 1$$

Try with the symmetrized Joe-Clayton (SJC) copula.

**Structural clustering of volatility regimes
for dynamic trading strategies**
A. Prakash et al. (2021)

To determine the number of volatility regimes (in a return time series):

- Partition the time series into stationary segments (Mood test, in R's `cpm` package to detect changes in variance)
- Compute the Wasserstein distance matrix

$$D_{ij} = W_p(F_i, F_j) = \left(\int |F_1 - F_j|^p \right)^{1/p}$$

- Use spectral clustering, with affinity matrix

$$A_{ij} = \exp - \frac{D_{ij}^2}{\sigma_i \sigma_j},$$

where σ_i is the distance between i and its $\lceil \sqrt{m} \rceil$ th nearest neighbour, where m is the number of segments.

The resulting strategy could be: buy the S&P when volatility is low, switch to gold when it is high.

To compare (x_i, \dots, x_s) and (x_1, \dots, x_t) , replace the observations by their ranks and compare $\langle (x_i - \bar{x})^2 \rangle$ in each segment.

**High-frequency-based volatility model
with network structure**
H. Yuan et al.

The HEAVY volatility model combines high and low frequency data.

$$\begin{aligned} r_t &: \text{daily returns} \\ \text{RM}_y &: \text{daily realized volatility} \\ h_t &= \text{Var}_{t-1}[r_t] \\ \mu_t &= \text{E}_{t-1}[\text{RM}_t] \\ h_t &\sim h_{t-1} + \text{RM}_{t-1} \\ \mu_t &\sim \mu_{t-1} + \text{RM}_{t-1} \end{aligned}$$

It can be generalized to N assets ($N = 18$, in the example), linked through an adjacency matrix A (e.g., industry membership).

$$h_{i,t} \sim h_{i,t-1} + \text{RM}_{i,t-1} + \frac{1}{d_i} \sum_j a_{ij} \text{RM}_{j,t-1}$$

$$\mu_{i,t} \sim \mu_{i,t-1} + \text{RM}_{i,t-1} + \frac{1}{d_i} \sum_j a_{ij} \text{RM}_{j,t-1}$$

***Learning probability distributions
in macroeconomics and finance***
J. Baruník and L. Hanus (2022)

Forecast the h -period ahead distribution of GDP growth, inflation, unemployment from 60 years of 200 macroeconomic variables (FREQ-QD), with a multi-output neural net (MLP, RNN, LSTM) forecasting the binary variables $[y_{t+h} \geq q_t^\alpha]$, where q_t^α is the α -quantile of y on $[0, t]$, for 20 values of α (0.01 to 0.99), with a penalty to ensure the quantiles are in the correct order.

Implementation in Julia (Flux.jl): DistrNN.jl.

***Complexity and persistence of price time
series of the European electricity spot market***
C. Han et al.

To look at the tails of a distribution, plot its (kernel) density with a logarithmic vertical scale and fit a symmetric Lévy α -stable distribution

$$L(x) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \phi(t) e^{-ixt} dt$$

$$\phi(t) = \exp[it\mu - |ct|^\alpha] \quad \alpha < 2$$

or a q -Gaussian distribution

$$G(x) \propto e_q(-c(x - \mu)^2)$$

$$e_q(x) = [1 - (1 - q)]^{1/(1-q)} \quad q > 1$$

using $\text{KL}(\text{data}||p)$.

To show multifractality, plot the return variance versus the window size: if the Hurst exponent is constant, it is a straight line.

***Machine learning forecast disagreement
and equity returns***
T.G. Bali et al. (2022)

Dispersion between ML models trained on the same inputs have some predictive power on future returns.

***Gamma and vega hedging using
deep distributional reinforcement learning***
J. Cao et al. (2022)

Assuming that Δ -hedging (of an option portfolio) can be done without cost, use D3PG to learn a gamma and vega hedging strategy using options, where the state is

(asset price, portfolio gamma, portfolio vega), the action is the number of options to hold, and the reward is

change in portfolio value – option cost.

***Always safe: reinforcement learning without
safety constraint violations during training***
T.D. Simão et al. (2021)

Factored constrained Markov decision processes (CMDP) use a small subset of the features to describe the dynamics relevant to the safety constraints: the safety dynamics are easier to learn, and the model can be deployed, safely, to continue learning.

***Constrained optimal stopping time
under a regime-switching model***
T. Arai and M. Takenaka (2022)

The optimal stopping time

$$\text{Argmax}_{\tau} \mathbb{E}[e^{-r\tau} \pi(X_{\tau}) \mid X_0 = x]$$

$$\pi(x) = \mathbb{E}\left[\int_t^{\infty} e^{-r(t-s)} X_s ds - I \mid X_t = x\right]$$

is sometimes of *threshold type*

$$\tau^* = \inf\{t > 0 : X_t \geq x^*\}$$

(X_t is a regime switching geometric Brownian motion, and the stopping time is constrained to exogenous random times (Poisson) and regime 1).

***textnets: a Python package
for text analysis with networks***
J.D. Boy

Community detection, on a term-document bipartite graph, is an alternative to LDA topic models.

***Combining natural language processing
and network analysis to examine
how advocacy organizations stimulate
conversation on social media***
C.A. Bail

To get more reactions, on social media, blend unrelated topics (e.g., autism and vaccines): advocacy organization with a high *betweenness centrality* (in a graph built from term co-occurrences), *i.e.*, “cultural bridges”, lead to more reactions.

***Landscape of academic finance
with the structural topic model***
D. Ardia et al. (2022)

The *structural topic model* (STM) extends the latent Dirichlet allocation (LDA) and correlated topic models (CTM) by allowing for document covariates (e.g.,

time).

d : document
 k : topic
 n : word
 X_d : covariates
 θ_d : distribution of topics in document d
 $\theta_d | X_d \sim \text{LogisticNormal}$
 β_k : distribution of words in topic k
 $\beta_k \propto \exp(m + \kappa_k)$
 $z_{d,n} | \theta_d \sim \text{Multinomial}$ topic of word n
 $w_{d,n} | \beta_{z_{d,n}} \sim \text{Multinomial}$ word n

***Do word embeddings really understand
Loughran-McDonald polarities?***
M. Li and C.A. Lehalle (2021)

Word embeddings are bad at sentiment extraction: antonyms tend to be used in the same context (“this was a good film”, “this was a bad film”) – they are frequentist synonyms.

***Heterogeneous
information network based default analysis
on banking micro and small enterprise users***
Z. Zhang et al.

Build a network of industries, small enterprises and persons accounting for:

- Fund transfer between companies
- Person/company controlling/investing in a company
- Industry membership; up/down-stream industries

***Stock embeddings: learning distributed
representations for financial assets***
R. Dolphin et al.

Use word2vec to compute stock embeddings, linking a stock to a context (the k stocks with the closest returns on a random n -day window, $k = 3$, $n = 1$)

Understanding the quintile portfolio
R. Zhou and D.P. Palomar (2020)

The long-only quintile portfolio (more generally, the top $k\%$ portfolio) is the solution of the robust optimization problem

$$\begin{aligned}
 &\text{Find} && w \\
 &\text{To maximize} && \text{Min}_{\mu: \|\mu - \mu_0\|_1 \leq \varepsilon} w' \mu \\
 &\text{Such that} && w \geq 0 \\
 &&& w' \mathbf{1} = 1
 \end{aligned}$$

(for some value of ε); for larger values of ε , it is the $1/N$ portfolio.

For the long-short quintile portfolio, replace the constraints with $\|w\|_1 = 1$, $w' \mathbf{1} = 0$.

For inverse-volatility weights, replace the uncertainty set with $\{\mu_0 + e : \|e \oslash \sigma\|_1 \leq \varepsilon\}$ where \oslash is the elementwise division.

The results generalize to market exposure $w' \beta = 0$ or sector exposures.

***QuantNet: transferring learning
across trading strategies***
A. Koshiyama et al.

Train 60 country-specific models, with a shared central layer, to output a trading signal in $[-1, 1]$ (weights), maximizing the Sharpe ratio; encoder and decoder are LSTMs.

***The virtue of complexity
in machine learning portfolios***
B. Kelly et al. (2021)

Financial models exhibit the double descent phenomenon.

***Dynamic portfolio optimization
with inverse covariance clustering***
Y. Wang and T. Aste (2022)

Define market states by clustering stock returns, using:

- The Euclidean distance;
- Or the Gaussian or Student log-likelihood, computed using a *sparse* estimate of the inverse covariance matrix.

A factor model for option returns
M. Büchner and B. Kelly

Instrumented PCA allows the loadings to depend on exogenous variables (e.g., moneyness, time to maturity, implied volatility, embedded leverage, Greeks).

$$\begin{aligned}
 r_{it} &: \text{asset returns} \\
 z_{it} &: \text{exogenous variables} \\
 \beta_{it} &= z'_{it} \Gamma + \text{noise} \\
 r_{i,t+1} &= \beta_{it} f_{t+1} + \text{noise} \\
 f_t &: \text{factor returns}
 \end{aligned}$$

For options on the S&P 500 (monthly holding period, delta-hedged daily), 3 factors are needed; they can be interpreted as volatility surface level, term structure slope of the volatility surface, moneyness skew of the volatility surface.

Drawdown beta and portfolio optimization

R. Ding and S. Uryasev (2021)

The *drawdown at risk* (DaR) is the α quantile of the distribution of drawdowns, The *conditional drawdown at risk* (CDaR) is the average of the drawdowns beyond the DaR. The *expected regret of drawdown* (ERoD) is the average of the drawdowns beyond some fixed threshold (instead of a quantile). The *CDaR beta* (resp., ERoD beta) is the average asset return, divided by the market CDaR (resp. ERoD), with the averages in the numerator and denominator are computed over matching periods.

You want to invest in stocks with $\beta \approx 0$ but $\beta_{\text{CDaR}} < 0$.

Capital asset pricing model (CAPM) with drawdown measure

M. Zabarankin et al. (2013)

In the CAPM, replace the 1-period returns with returns over market drawdown periods.

Sensitivity to large losses and ρ -arbitrage for convex risk measures

M. Herdegen and N. Khan (2022)

A risk measure ρ is susceptible to ρ -arbitrage if it is possible to have arbitrary high returns with arbitrarily low risk. If ρ is

- Monotone: $X \leq Y$ a.s. $\implies \rho(X) \geq \rho(Y)$,
- Normalized: $\rho(0) = 0$,
- Star-shaped: $\forall X \forall \lambda \geq 1 \rho(\lambda X) \geq \lambda \rho(X)$,
- Sensitive to large losses:

$$P[X < 0] > 0 \implies \exists \lambda > 0 \rho(\lambda X) > 0,$$

there is no ρ -arbitrage.

Universal approximation of credit portfolio losses using restricted Boltzmann machines

G. Genovese et al. (2022)

Probability equivalent level of value at risk and higher order expected shortfalls

M. Barczy et al.

The *probability equivalent level of VaR and ES*, $\text{PELVE}_\alpha X$ is the $c \geq 1$ such that $\text{VaR}_{1-\alpha} X = \text{ES}_{1-c\alpha} X$. It is motivated by the Basel move from $\text{VaR}_{.99}$ to $\text{ES}_{.975}$ ($c=2.5$). The PELVE can be generalized from (VaR, ES) to $(\rho, \tilde{\rho})$, for families of risk measures $(\rho_p)_p$ and

$$\tilde{\rho}_p = \frac{1}{1-p} \int_p^1 \rho_s(X) ds.$$

The n th order expected shortfall is

$$\text{ES}_{p,n} = \frac{n}{1-p} \int_p^1 \left(\frac{s-p}{1-p} \right)^{n-1} \text{VaR}_s(X) ds.$$

A simple method for measuring inequality

T. Sitthiyot and K. Holasut (2020)

Instead of using only the Gini index, look at several measures:

- Gini index;
- Income share held by the top 10%: T_{10} ;
- Income share held by the bottom 10%: B_{10} (or their ratio, B_{10}/T_{10});
- Entropy H of the income distribution.

Combine those measures as

$$\sqrt{\frac{\text{Gini}^2 + H^2}{2}} \text{ or } \sqrt{\frac{\text{Gini}^2 + \sqrt{1 - \frac{B_{10}}{T_{10}}}}{2}}$$

since $H \approx (1 - B_{10}/T_{10})^{1/4}$.

Missing financial data

S. Bryzgalova et al.

To fill in missing data in panel data $C_{it\ell}$

i : asset
 ℓ : feature
 t : time

estimate a cross-sectional factor model (PCA with missing values, for each t , but with $\Lambda_t = \Lambda$ constant)

$$C_t = F_t \Lambda + \text{noise}$$

$I \times L \quad I \times K \quad K \times L$

and use it in a time series model

$$C_{it} \leftarrow \text{coalesce}(C_{it}, f(C_{i,t-1}, F_{it}))$$

(or $f(C_{i,t-1}, C_{i,t+1}, F_{it})$ if you are willing to use future data) where f is linear.

Vulnerability-CoVaR: investigating the crypto market

M. Waltz et al. (2022)

There are many generalizations of value at risk (VaR) to several assets:

- $\text{CoVaR}^{j|i}$: α quantile of X_j conditioned on X_i being below its α quantile;
- MCoVaR^j : α quantile of X_j conditioned on all the X_i being below their α quantile;
- VCVaR^j : α quantile of X_j conditioned on at least one X_i being below its α quantile;
- $\text{SCoVaR}^{j|i}$: α quantile of X_j conditioned on $\sum_{i \neq j} X_i$ being below its α quantile;
- Vulnerability index (VI): probability that X_j is below its α quantile given that at least one X_i is below its α quantile;
- ΔCoVaR : difference between $\text{CoVaR}^{j|i}$ and the α quantile of X_i being at its 50% quantile.

Evolutionary correlation, regime switching, spectral dynamics and optimal trading strategies for cryptocurrencies and equities
N. James (2022)

Compute the correlation matrix between 45 cryptocurrencies, between 100 equities, and within each sector (for cryptocurrencies, use the `coinmarketcap.com` classification: centralized exchanges, collectibles (NFT), decentralized finance, platform, smart contracts, store of value, wallet – some are in several categories), apply random matrix theory, and plot, over time:

- The number of non-random eigenvalues;
- The largest eigenvalue;
- The proportion of variance explained by the first eigenvalue.

Common risk factors in cryptocurrency
Y. Liu et al. (2019)

Among Fama-French-like factors for crypto currencies (capitalization, age, volume, β , β^2 , volatility, idiosyncratic volatility, skewness, maximum return in the previous week, momentum for various lookback periods, Amihud), market, size and momentum explain cross-sectional returns.

Sequence-based target coin prediction for cryptocurrency pump-and-dump
S. Hu et al.

Detect pump and dump announcements from 1000 Telegram channels (start on PumpOlymp and follow the invitation links; use tf-idf vectors) and try to predict the target coin.

A word is worth a thousand dollars: adversarial attacks on Tweet fools stock prediction
Y. Xie et al.

Retweet semantically similar adversarial tweets (replace a single word) to attack Stocknet, FinGRU and FinLSTM.

NFT appraisal prediction: utilizing search trends, public market data, linear regression and recurrent neural networks
S. Jain et al.

Forecast NFT prices using:

- The degree and PageRank centrality of buyers and sellers; user activity on Twitter and OpenSea;
- The first 5 principal components of AlexNet embeddings of the NFT;
- Price history (in the NFT collection, using the `covalent` API); gas (ETH transaction fee);
- BTC, ETH, Gold, S&P 500, Nasdaq 100, FAANG;
- Google search volume (`pytrends`); news sentiment.

Constructing and NFT index and applications
H. Schnoering and H. Inzirillo

Build an NFT index from 60 collections:

$$\log(\text{price}_{ijt}) \sim \text{collection}_j + \text{scarcity}_{ij} + \log(\text{index}_t) + \text{noise}_{it}$$

where scarcity_{ij} measures the scarcity of the traits of NFT i in collection j .

Algorithms for optimization
M.J. Kochenderfer and T.A. Wheeler (2019)

3. Given a univariate function f , three points $a < b < c$ are said to **bracket** a minimum if $f(b) < f(a)$ and $f(b) < f(c)$. *Fibonacci search* splits an interval in an optimal way (to obtain the smallest bracket after n iterations); it is often approximated with a *golden section search*. *Quadratic fit search* (often faster) improves a bracket by approximating the function with a quadratic and taking its minimum.

For a Lipschitz continuous function, the *Schubert-Piyavskii method* keeps track of a lower bound on the function and progressively improves it.

If the derivative of the objective f is known, the bisection method can solve $f'(x) = 0$.

4. *Line search* starts with a point x , a direction d , and solves the 1-dimensional problem

$$\underset{\alpha}{\text{Minimize}} f(x + \alpha d).$$

Approximate line search looks for a step size providing a “sufficient decrease” (Armijo condition)

$$f(x + \alpha d) \leq f(x) + \beta \alpha \nabla_d f(x) \quad \beta = 10^{-4}.$$

The Wolfe conditions also include

$$\nabla_d f(x + \alpha d) \geq \sigma \nabla_d f(x).$$

Trust region methods forbid excessively large step sizes

$$\underset{x}{\text{Minimize}} \hat{f}(x) \text{ such that } \|x - x_0\| \leq \delta;$$

the radius δ can be adjusted by looking at the local model performance

$$\eta = \frac{\text{actual improvement}}{\text{predicted improvement}} = \frac{f(x) - f(x_0)}{\hat{f}(x) - f(x_0)}.$$

5. Gradient descent can perform poorly in narrow valleys. *Conjugate gradient* minimizes a quadratic function $f(x) = \frac{1}{2}x'Ax + b'x + c$ in n mutually conjugate

steps $\forall i \neq j \ d'_i A d_j = 0$.

$$d_k = -g_k + \beta_k d_{k-1}$$

$$\beta_k = \frac{g'_k A d_{k-1}}{d'_{k-1} A d_{k-1}}$$

We do not know A , but we can use approximations.

$$\beta_k = \frac{g'_k g_k}{g'_{k-1} g_{k-1}} \text{ or } \beta_k = \frac{g'_k (g_k - g_{k-1})}{g'_{k-1} g_{k-1}}$$

Gradient descent can be improved with:

- Momentum
- Nesterov momentum (momentum at the next point)
- An adaptive learning rate for each coordinate, using $\sum_k g_{ki}^2$ (AdaGrad, but the learning rate decreases too much) or an exponential moving average of the g_{ki}^2 (RMSProp, which has inconsistent units, or AdaDelta);
- Adam, which combines momentum and adaptive learning rate.

Hypergradient descent also optimizes the learning rate.

6. *Newton's method* approximates the objective function with a quadratic function, $x \leftarrow x - H^{-1}g$; it can fail (oscillations, overshoot, or $f'' < 0$). The *secant method* uses an approximation of the second derivative with the first (in dimension 1). *Quasi-Newton methods* use an approximation of the Hessian (DFP, BFGS, L-BFGS).

7. *Coordinate descent* (aka cyclic coordinate search) optimizes one coordinate at a time. *Powell's method* is similar, but progressively changes the directions, replacing the last one with $x_{n+1} - x_1$ (occasionally reset the search direction lest they become colinear).

The *Hooke-Jeeves* method evaluates $f(x)$ and $f(x \pm \alpha e_i)$. *Generalized pattern search* is similar but evaluates $f(x)$ and $f(x + \alpha d)$, $d \in \mathcal{D}$, where \mathcal{D} is a *positive spanning set*, which can have as few as $n + 1$ elements.

The *Nelder-Mead method* uses a simplex to explore the space.

The *divided rectangle* (DIRECT) method uses Lipschitz bounds, but without specifying the Lipschitz constant (it considers all possible values), and dividing the search space recursively, into rectangles (otherwise, the Lipschitz lower bound is a (rather complex) intersection of cones); rectangles for which there is a Lipschitz constant for which their lower bound would be a minimum are split into thirds along their largest dimension.

8. To avoid plateaus and saddle points, try noisy descent (adding Gaussian noise to the gradient), *mesh adaptive direct search* (random positive spanning directions)

or, even, simulated annealing.

The *cross-entropy method* does not follow a point but a distribution; at each step, it samples from that distribution, and fits a distribution to the best samples.

Natural evolution strategies also solve

$$\underset{\theta}{\text{Minimize}} \quad \mathbb{E}_{x \sim p_\theta} [f(x)]$$

but uses gradient descent and the log-derivative trick.

CMA-ES differs from CEM:

- After estimating μ, σ , it samples from $N(\mu, \sigma^2 \Sigma)$;
- Instead of selecting the best samples, it weighs them (some weights are negative)

$$w_i = \log \frac{m+1}{2} - \log i \quad i \in \llbracket 1, m \rrbracket;$$

- The step size is updated (in a complicated way).

9. Initialize population methods with a uniform, Gaussian or Cauchy: genetic algorithms (cross-over and mutations), *differential evolution*

$$x = x_i + w(x_j - x_k),$$

particle swarm optimization (momentum), firefly algorithm (the attractive power of each particle depends on its fitness), etc. – there is an excessive proliferation of nature-inspired methods.

Hybrid methods combine population search with local search.

10. Transforming a constrained optimization problem can sometimes help remove constraints.

Lagrange multipliers deal with equality constraints

$$\underset{x}{\text{Minimize}} \quad f(x) \text{ such that } h(x) = 0.$$

The first-order conditions

$$h(x) = 0$$

$$\nabla f(x) = \lambda \nabla h(x)$$

can be written with the Lagrangian

$$\mathcal{L}(x, \lambda) = f(x) - \lambda h(x)$$

$$\nabla_x \mathcal{L} = 0$$

$$\nabla_\lambda \mathcal{L} = 0.$$

With inequality constraints,

$$\begin{array}{ll} \text{Find} & x \\ \text{To minimize} & f(x) \\ \text{Such that} & g(x) \leq 0 \\ & h(x) = 0 \end{array}$$

things are more complicated. The *KKT conditions* are

$$\begin{aligned} g &\leq 0 \\ h &= 0 \\ \mu &\geq 0 \\ \mu \odot g &= 0 \\ \nabla f + \mu' \nabla g + \lambda' h(x) &= 0. \end{aligned}$$

With the generalized Lagrangian

$$\mathcal{L}(x, \mu, \lambda) = f(x) + \mu' g(x) + \lambda' h(x),$$

the primal and dual problems are

$$\begin{aligned} \text{primal} \quad & \text{Minimize} \text{Max}_{x, \mu \geq 0, \lambda} \mathcal{L}(x, \mu, \lambda) \\ \text{dual} \quad & \text{Maximize} \text{Min}_{x, \mu \geq 0, \lambda} \mathcal{L}(x, \mu, \lambda). \end{aligned}$$

The max-min inequality is

$$\text{Max}_a \text{Min}_b f(a, b) \leq \text{Min}_b \text{Max}_a f(a, b).$$

To solve constrained optimization problems, try adding a quadratic penalty

$$\sum_i \text{Max}(g_i(x), 0)^2 + \sum_j h_j(x)^2.$$

For equality-constrained problems, the *augmented Lagrange method* uses both a quadratic and a linear penalty

$$\begin{aligned} p(x) &= \frac{1}{2} \rho \|h(x)\|^2 - \lambda' h(x) \\ \lambda_{k+1} &= \lambda_k - \rho h(x). \end{aligned}$$

Interior point methods use a *barrier penalty* (infinite for infeasible points), e.g.,

$$p(x) = -\sum \frac{1}{g_i(x)} \text{ or } p(x) = -\sum \log(-g_i(x)) \mathbf{1}_{g_i(x) \geq -1}$$

(to find a feasible point, use a quadratic penalty).

11. The *simplex algorithm* moves from vertex to vertex of the feasible set.

To find a feasible solution of

$$\text{Minimize}_{x, z} c'x \text{ such that } Ax = b, x \geq 0,$$

add extra variables z and try to zero them out

$$\begin{aligned} \text{Find} \quad & x, z \\ \text{To minimize} \quad & \begin{pmatrix} 0 \\ 1 \end{pmatrix}' \begin{pmatrix} x \\ z \end{pmatrix} \\ \text{Such that} \quad & (A \quad Z) \begin{pmatrix} x \\ z \end{pmatrix} = b \\ & x, z \geq 0 \end{aligned}$$

where $Z = \text{diag}(\text{sign}(b))$.

12. To solve multiobjective optimization problems:

- Constrain all but one of the objectives;
- Rank the objectives, and maximize them one by one, adding constraints to fix the previous ones;

or combine the objectives:

- $w' f(x)$
- $\|f(x) - y_{\text{goal}}\|_p$ (goal programming)
- $\sum w_i (f_i(x) - y_i^{\text{goal}})^p$
- $\text{Max}_i w_i (f_i(x) - y_i^{\text{goal}})^p$
- $\sum (e^{pw_i} - 1) e^{pf_i(x)}$.

NSGA-II is a population method keeping track of the level of the individuals (level-1 are non-dominated, level $k+1$ are non-dominated after removing levels 1 to k). To preserve diversity, reinject good points into the population, or penalize points with the density of their neighbourhood.

To choose w in the weighted model $w' f(x)$, ask experts if they prefer a or b , and pick w such that $w'a < w'b$; repeat with other pairs; prefer the w that best separates $w'a$ and $w'b$. Choose a and b to cut the feasible space \mathcal{W} into two equal parts (Q-eval).

Robust optimization does not choose one $w \in \mathcal{W}$:

$$\text{Minimize}_x \text{Max}_{w \in \mathcal{W}} w' f(x).$$

The *minimax regret* approach solves

$$\text{Minimize}_x \text{Max}_{w \in \mathcal{W}} \text{Max}_y w' f(x) - w' f(y).$$

13. Grid search (full factorial design) does not scale to high dimensions: try random sampling. A *uniform projection plan* is a sampling plan over a grid with uniform margins (latin hypercube sampling).

To measure how space-filling a sampling plan is, look

$$\text{discrepancy}(X) = \sup_{H \text{ hyperrectangle}} \left| \frac{\#X \cap H}{\#X} - \text{vol}(H) \right|$$

$$d(X) = \text{Min}_{i \neq j} d(x_i, x_j)$$

$$\Phi_q(X) = \left(\sum_{i \neq j} d(x_i, x_j)^{-q} \right)^{1/q}$$

$$\Phi(X) = \text{Max}_{q \in \{1, 2, 5, 10, 20, 50, 100\}} \Phi_q(X)$$

Quasi-Monte Carlo (with quasi-random sequences, such as additive recurrences, Halton or Sobol sequences) has an error $O(1/m)$ instead of $O(1/\sqrt{m})$.

14. One can build a *surrogate model* with basis functions (sines, polynomials, radial basis functions) and assess it with cross-validation or *0.632 bootstrap* (linear combination of leave-out-one bootstrap and bootstrap, to avoid bias).

15. Gaussian processes (GP) are probabilistic surrogate models.

16. To choose where next to evaluate the objective function, look at the uncertainty $\hat{\sigma}(x)$, a lower confidence bound $\hat{\mu}(x) - \alpha\hat{\sigma}(x)$, the probability of improvement, or the expected improvement.

To ensure safe exploration, add a “safety score” to the GP model.

17. To deal with noise, e.g., $f(x, z) = f(x) + z$ or $f(x, z) = f(x + z)$, with an uncertainty set, use the minimax

$$\underset{x}{\text{Minimize}} \quad \underset{\|z\| \leq \varepsilon}{\text{Max}} \quad f(x, z)$$

or the information gap

$$\begin{array}{ll} \text{Find} & x, \varepsilon \\ \text{To maximize} & \varepsilon \\ \text{Such that} & \forall z \quad \|z\| \leq \varepsilon \Rightarrow (x, z) \text{ feasible} \\ \text{and} & f(x, z) \leq y_{\max}. \end{array}$$

Probabilistic uncertainty uses distributions over the noise z : look at $\mathbb{E}_z f(x, z)$, $\text{Var}_z f(x, z)$, $\text{VaR}_z^{1-\alpha} f(x, z)$, $\text{CVaR}_z^{1-\alpha} f(x, z)$.

18. Given a distribution $z \sim p$, we can estimate the distribution of $f(z)$ (in particular $\mathbb{E} f(z)$ and $\text{Var} f(z)$) using:

- A Taylor expansion of f ;
- Monte Carlo samples;
- Polynomial chaos: if f is a polynomial (product of orthogonal polynomials), we can easily compute $\mathbb{E} f(z)$ and $\text{Var} f(z)$;
- Gaussian processes: $\mathbb{E}_z f(z) \approx \mathbb{E}_{\hat{f}} \mathbb{E}_z \hat{f}(z) = \mathbb{E}_z \mathbb{E}_{\hat{f}} \hat{f}(z) = \mathbb{E}_z \mu(z)$ (it is a little more complicated for $\text{Var} f(z)$).

19. For an integer program

$$\underset{x}{\text{Minimize}} \quad c'x \text{ such that } Ax = b, \quad x \geq 0$$

with a *totally unimodular* matrix A (the determinant of all submatrices is 0, +1 or −1), the simplex algorithm returns an integer solution.

The *cutting plane* method solves the problem without the integrality constraint, and adds constraints to remove the non-integral parts of the solution. *Branch and bound* recursively splits the problem by adding constraints: $x_i \leq \lfloor x_i^* \rfloor$ and $x_i \geq \lceil x_i^* \rceil$.

20. To explore a search space described by a grammar, try genetic programming (cross-over swaps two random subtrees). A probabilistic grammar, with probabilities progressively updated to focus on derivation rules improving the objective, may help.

21. Multi-disciplinary optimization studies problems of the form

$$\begin{array}{ll} \text{Find} & x \\ \text{To minimize} & f(x) \\ \text{Such that} & \forall i \quad F_i(x) = x \end{array}$$

where F_i only modifies coordinate i of x . Try (cf pro-

jected gradient)

$$\begin{array}{l} x \leftarrow \text{MDA}(x) \\ x \leftarrow \text{improve}(x) \end{array}$$

where MDA returns a compatible assignment.

Algorithms for decision making M.J. Kochenderfer et al. (2022)

1. Decision making algorithms can rely on:

- Explicit programming (hard-coded policies);
- Supervised learning (behavioural cloning);
- Optimization (search in policy space);
- Planning (reduction of the problem to dynamic programming);
- Reinforcement learning (if the model of the environment is not known).

2. Probability distributions on a large number of variables can be represented by Bayesian networks

explaining away: $B \not\perp\!\!\!\perp S \mid E$

3. Inference on Bayesian networks can use:

- Sum-product variable elimination (marginalizing out variables as early as possible);
- Junction tree algorithm (belief propagation on a tree of subsets of variables);
- Loopy belief propagation.

Exact inference is NP-hard: a 3-SAT problem can be converted to a Bayesian network.

Approximate inference can also be done via:

- Direct sampling (use a topological order on the nodes);
- Likelihood-weighted sampling;
- Gibbs sampling.

4. The parameters of a Bayesian network can be learned via

- Maximum likelihood;
- Bayesian methods (with beta or Dirichlet priors);
- Expectation maximization (EM), if some of the data is missing.

5. To learn the structure of a Bayesian network, compute the score (penalized log-likelihood) of candidates, using local search or *K2 search* (iterate over the nodes in a prespecified order, adding parents if this increases the score, with a limit on the number of parents). It may be more efficient to search the space of essential graphs (CPDAG) instead of all DAGs.

6. Under some reasonable assumptions on an agent's preferences, rational decisions are those maximizing the expected utility, for some utility function.

A *decision network* (influence diagram) has

- Chance, decision and utility nodes;
- Conditional, informational and functional nodes (ending in chance, decision, and utility nodes).

The *value of information* is

$$\text{VOI}(O_2|O_1) = \mathbb{E}_{O_2} [\text{EU}(O_1, O_2)] - \text{EU}(O_1)$$

where $\text{EU}(O)$ is the expected utility of an optimal decision given observation O .

7. Many problems require a sequence of decisions; with a Markov assumption, they can be modeled as an MDP.

Policy evaluation computes the value (expected return) of a state (if we follow the policy π) by iterating

$$U(s) \leftarrow R + \gamma \mathbb{E}_{s'} [U(s')].$$

Policy iteration computes an optimal policy by iterating between policy evaluation and policy improvement (replacing the current policy with the greedy policy wrt the value function).

Value iteration computes an optimal policy by iterating Bellman's equation

$$U(s) \leftarrow \text{Max}_a (R(s, a) + \gamma \mathbb{E}_{s'} [U(s')]);$$

the updates can be done asynchronously.

The optimal policy is also solution of the linear program

$$\begin{aligned} &\text{Find} && U \\ &\text{To minimize} && \sum_s U(s) \\ &\text{Such that} && \forall s \ U(s) \geq \text{Max}_a (R(s, a) + \gamma \mathbb{E}_{s'} [U(s')]) \end{aligned}$$

(the minimization turns the inequalities into equalities).

8. If the state space is large (or continuous), approximate the value function: k -nearest neighbour, kernel smoothing, linear interpolation, simplex interpolation (only uses $d + 1$ neighbours in dimension d , instead of 2^d for linear interpolation), linear regression, neural networks. Many of those can be written $U_\theta(s) = \theta' \beta(s)$ for some basis functions $(\beta_i)_{1 \leq i \leq m}$.

9. The reachable state space is often smaller than the full state space: *receding horizon planning* solves a subset of the full MDP by only looking d steps ahead.

- Expand the whole search tree (forward search);
- It may be possible to prune the search tree using a lower bound on the state value function $U(s)$ and an upper bound on the state action value function $Q(s, a)$;
- Sample the next states using a rollout policy and average;
- Monte Carlo tree search (MCTS) not only samples but also updates estimates of the state action value function $Q(s, a)$, often using the UCB1 exploration heuristic

$$\text{UCB1} = Q(s, a) + c \sqrt{\frac{\log N(s)}{N(s, a)}};$$

limit (but progressively increase) the number of actions considered in a state, and the number of states reachable after an action, to $\theta_1 N(s)^{\theta_2}$ and $\theta_3 N(s, a)^{\theta_4}$;

- Heuristic search samples from a greedy policy for value function U , initialized to an upper bound, and progressively refined.

Openloop planning (committing to the next d actions, i.e., not revising the plan when new observations arrive), reduces to an optimization problem; there are robust variants.

10. *Policy search* directly searches the space of policies to maximize the expected discounted return $U(\theta)$, often approximated using m strategy rollouts.

The *Hooke-Jeeves method* is a local search taking steps of size $\pm \alpha$ in each coordinate direction.

Genetic search keeps track of a population of policies, progressively perturbed and pruned.

The *cross-entropy method* (CEM) updates a distribution rather than a set of points

$$\text{Maximize}_{\psi} \mathbb{E}_{\theta \sim p_{\psi}} U(\theta)$$

where $U(\theta)$ is the expected discounted return under policy π_θ ; the expectation is approximated with samples from p_ψ , and the distribution is updated by fitting it to the best samples.

Evolution strategies optimize the same objective function, by using a gradient step, computed with the *log-derivative trick*

$$\nabla_{\psi} \mathbb{E}_{\theta \sim p_\psi} U(\theta) = \dots = \mathbb{E}_{p_\psi} [U(\theta) \nabla_{\psi} \log p_\psi(\theta)].$$

Rank shaping replace the utilities $U(\theta)$ (which are noisy) with their rank, or some transformation thereof.

11. To estimate the gradient $\nabla U(\theta)$, one could use:

- Finite differences;
- Regression, after estimating $U(\theta + \varepsilon)$ for random offsets ε (instead of fixed-size, axis-aligned offsets);
- The log-derivative trick; the variance can be reduced by using the reward-to-go, and by subtracting a baseline.

12. *Gradient ascent* takes a step in the gradient direction; the gradient can be *clipped* (coordinate-wise) or rescaled (to cap its norm). Rescaling the gradient to set its norm (*restricted gradient*) is equivalent to maximizing a linear approximation of the objective inside a ball; the *natural gradient* defines that ball with the Fisher information matrix; the *trust region method* (TRPO) uses a line search in the gradient direction within the Fisher information ball.

13. *Actor-critic* methods jointly optimize the policy (actor) and refine an approximation of the value function (critic): by providing a better baseline, the critic helps lower the variance of the policy gradient.

14. To evaluate the final policy:

- Use importance sampling, to focus on rare events;
- Use robust dynamic programming, or adversarial analysis;
- Compute the Pareto frontier, if there are several competing performance measures.

15. To balance exploration and exploitation, for binary *bandits* (single-state MDP, with binary rewards) one can take random actions once in a while (ε -greedy).

Optimism under uncertainty kept track of an estimate of the (distribution of the) value of each action, and chooses the action (“arm”) with the highest α -quantile, or some other upper confidence bound, e.g.,

$$\text{UCB}_1(a) = \rho_a + c \sqrt{\frac{\log N}{N(a)}}.$$

Dynamic programming on belief states (number of tries, number of wins, for each arm – there are exponentially many beliefs) can be solved efficiently with the *Gittins allocation index* [no details].

16. The MLE of the MDP can be obtained from the counts, and solved at each step; instead of re-solving it each time, a few Bellman updates may be sufficient,

e.g., focusing on states known to lead to the current state. One can bias the estimated MDP to encourage exploration (increasing the reward of insufficiently-visited states).

Bayes-adaptive MDPs extend the state space S to $S \times B$ where B is the set of possible beliefs on the model parameters.

Posterior sampling (Thompson sampling) samples from the posterior model parameters, instead of using the MAP.

17. Model-free methods model the state action value function Q directly, without estimating the MDP.

$$\text{Bellman} \quad Q(s, a) = \mathbb{E}_{r, s'} [r + \gamma \text{Max}_{a'} Q(s', a')]$$

$$\text{Update} \quad Q(s, a) \leftarrow Q(s, a) + \alpha [\text{target} - Q(s, a)]$$

$$\text{Q-learning} \quad \text{target} = r + \gamma \text{Max}_{a'} Q(s', a') \quad \text{off-policy}$$

$$\text{SARSA} \quad \text{target} = r + Q(s', a') \quad \text{on-policy}$$

With sparse rewards, learning can be slow.

Eligibility traces apply the update

$$\begin{aligned} Q(s, a) &\leftarrow Q(s, a) + \alpha \delta \\ \delta &= \text{target} - Q(s, a) \end{aligned}$$

to all state-action pairs, with an exponentially decaying coefficient λ , increased each time the pair is visited

$$Q(s, a) \leftarrow Q(s, a) + \lambda(s, a) \cdot \alpha \cdot \delta$$

(it may not work well with off-policy updates, such as Q-learning).

Experience replay can help avoid *catastrophic forgetting*.

18. *Behavioural cloning* uses supervised learning to reproduce expert decisions, but suffers from cascading errors: small errors compound and eventually lead the agent to regions of the state space never visited by the expert.

Inverse reinforcement learning learns a reward function (not a policy) from trajectories, by matching policy features. The problem is underspecified: also maximize the entropy of the distribution over trajectories.

Generative adversarial imitation learning (GAIL) uses a GAN to generate expert-like trajectories.

19. An MDP is a conditional distribution $r, s' | s, a$. A POMDP is a conditional distribution $r, s', o | s, a$.

The *Kalman filter* progressively updates beliefs about the state, assuming the model is linear and Gaussian.

The *extended Kalman filter* (EKF) linearizes non-linear models (with Gaussian noise).

The *unscented Kalman filter* (UKF) is derivative-free, and uses deterministic sampling (“delta points”) to approximate non-linear functions (“unscented transform”).

$$\mu, \Sigma \mapsto s_i^\pm = \mu \pm \sqrt{\Sigma_i} \mapsto f(s_i^\pm) \mapsto \mu', \Sigma'$$

Particle filters (sequential Monte Carlo, SCM) can deal with nonlinear, non-Gaussian models, but can fail because of *particle deprivation*. *Particle injection* tried to remedy this by occasionally injecting particles from a broad distribution (e.g., uniform), when the mean particle weight becomes too high.

20. A POMDP can be seen as an MDP with beliefs as states; for planning, only use the k -step-ahead sub-MDP.

21. *QMDP* updates a set of *alpha vectors*, one for each action.

$$Q(b, a) = \sum_s Q(s, a) b(s) = \alpha'_a b$$

$$\alpha_a(s) = R(s, a) + \gamma \sum_{s'} T(s'|s, a) \text{Max}_{a'} \alpha_{a'}(s')$$

The *fast informed bound* is similar, but accounts for the observation model. For lower bounds, try best action worst state, or single action forever.

Point-based value iteration uses a set of alpha vectors, associated to different belief points, $U(b) = \text{Max}_{\alpha \in \Gamma} \alpha' b$.

22. MCTS can be extended to POMDPs.

23. A *controller* (finite state controller, FSA) is a policy with an internal state.

24. In a *simple game* (single-state, multi-agent MDP), a *dominant strategy* is a best response against all possible agent policies; a *dominant strategy equilibrium* need not exist.

Games with a finite state space have a Nash equilibrium: each agent follows a best-response strategy. Computing a Nash equilibrium is PPAD-complete.

A *correlated equilibrium* is a joint policy (the agent’s actions need not be independent) in which no agent can change its action to increase its expected utility.

Hierarchical softmax models human agents:

- Level 0 agents play at random;
- Level $k + 1$ agents assume the other players are level k , and select actions with a softmax with precision λ .

25. A *Markov game* (MG) is a multi-agent MDP. Policy evaluation, best response, softmax response

$$\pi_i(a_i|s) \propto \exp \lambda Q(s, a_i),$$

Nash equilibrium can be generalized to MGs. To improve the strategy, try gradient ascent with fictitious play, or Nash Q-learning.

26. A partially-observable Markov game (POMG) is a multi-agent POMDP.

27. In a *decentralized POMDP*, agents share the same reward.

Bayesian optimization R. Garnett (2021)

1. *Sequential optimization* iterates

$$x \leftarrow \text{policy}(\mathcal{D})$$

$$y \leftarrow \text{observe}(x)$$

$$\mathcal{D} \leftarrow \mathcal{D} \cup \{(x, y)\}.$$

The new observation, x , is often selected by maximizing some function (*acquisition* function).

2. *Gaussian processes* are distributions on functions whose restrictions on finite sets are Gaussian – they are “very high-dimensional” Gaussian distributions: $f \sim \text{GP}(\mu, k)$ means (writing ϕ instead of $f(\mathbf{x})$, to simplify the notations)

$$\phi \sim N(\mu, \Sigma)$$

$$\mu = \mathbb{E}[\phi] = \mu(\mathbf{x})$$

$$\Sigma = \text{Cov}[\phi] = k(\mathbf{x}, \mathbf{x}).$$

Values are often observed with noise: $\mathbf{y} \sim N(\mu, \Sigma + N)$.

The posterior is a conditional Gaussian:

$$\mu_{\mathcal{D}} = \mu(a) + k(x, \mathbf{x})(\Sigma + N)^{-1}(\mathbf{y} - \mu)$$

$$k_{\mathcal{D}}(x, x') = k(x, x') - kx(x, \mathbf{x})(\Sigma + N)^{-1}k(\mathbf{x}, x').$$

If L is linear and X Gaussian. then (X, LX) is Gaussian. Since ∇ or $h = \text{vech} \nabla \nabla^\top$ are linear, if f is a GP, then so if $(f, \nabla f, hf)$.

$$(f, \nabla f, hf) \sim \text{GP} \left(\begin{pmatrix} \mu \\ \nabla \mu \\ h\mu \end{pmatrix}, \begin{pmatrix} k & k\nabla^\top & kh^\top \\ \nabla k & \nabla k \nabla^\top & \nabla kh^\top \\ hk & hk \nabla^\top & hkh^\top \end{pmatrix} \right)$$

If $f \sim \text{GP}(\mu \equiv 0, k)$ is sampled from a GP, defined on a compact space X , with $\forall x \neq x' \text{ Var}[\phi - \phi'] = k(x, x') - 2k(x, x') + k(x', x') \neq 0$, then f a.s. has a unique maximum on X .

Adding constraints to a GP, e.g., “ f has a local maximum at x_0 ”, or “ $f'(x_0) = 0, f''(x_0) \leq 0$ ”, can make the process non-Gaussian (with a GP, the distribution of $f''(x_0)$ is unbounded). In this case, use factor graphs.

3. The prior on the mean only affects the extrapolation regime.

For the prior on the mean, use a constant or a linear combination of basis functions, $\mu(x) = \beta' \psi(x)$. *Stationary* covariance functions are of the form $k(x, x') = \kappa(x - x')$; *isotropic* ones of the form $k(x, x') = \kappa(\|x' - x\|)$.

Stationary covariance functions are characterized by their Fourier transform ν (Bochner's theorem)

$$\kappa(\mathbf{x}) = \int \exp(2\pi i \mathbf{x}' \xi) d\nu(\xi)$$

where ν is a finite, positive, symmetric, Borel measure on \mathbf{R}^n (spectral measure).

Common covariance functions include ($d = \|x' - x\|$):

$$\begin{aligned} k_{M^{1/2}} &= \exp(-d) \\ k_{M^{3/2}} &= (1 + \sqrt{3}d) \exp(-\sqrt{3}d) \\ k_{M^{5/2}} &= (1 + \sqrt{5}d + \frac{5}{3}d^2) \exp(-\sqrt{5}d) \\ k_{SE} &= \exp(-\frac{1}{2}d^2) \end{aligned}$$

Their sample paths are a.s. \mathcal{C}^0 , \mathcal{C}^1 , \mathcal{C}^2 , \mathcal{C}^∞ .

The *spectral mixture* covariance is defined by

$$\begin{aligned} k(\xi) &= \sum_i w_i N(\xi; \mu_i, \Sigma_i) \\ \kappa(\xi) &= \frac{1}{2} [k(\xi) + k(-\xi)] \\ K_{SM}(x, x') &= \sum w_i \cdot \exp[-2\pi^2 (x - x')^\top \Sigma_i (x - x')] \\ &\quad \cdot \cos[2\pi (x - x')^\top \mu_i]. \end{aligned}$$

The *linear* covariance function corresponds to

$$\begin{aligned} f(x) &= \beta_0 + \beta^\top \mathbf{x} \\ \beta &\sim N(a, B) \\ k_{LIN}(x, x') &= b^2 + x^\top B x \end{aligned}$$

We can rescale the input and the output of the covariance function: $\lambda^2 k(d/\ell)$.

Automatic relevance determination (ARD) estimates those length and scale parameters from data.

Beta warping transforms the data with

$$\begin{cases} \mathbf{R} \longrightarrow [0, 1] \\ x \longmapsto \text{Beta}(x; a, b) \end{cases}$$

to focus around zero.

Covariance functions can be combined:

$$\begin{aligned} \text{Cov}[f + g] &= k_f + k_g \\ \text{Cov}[fg] &= k_f k_g. \end{aligned}$$

4. To select the GP family, the input and output scales, and the observation noise, use the MAP estimator, or model averaging (hyperparameter marginalization, perhaps via MCMC), or search through a space of covariance structures (e.g., described with a grammar), perhaps with Bayesian optimization.

5. (One-step) *Bayesian decision theory* suggests to select the action maximizing the expected utility

$$\begin{aligned} \mathcal{D} &: \text{observed action} \\ \psi &: \text{unobserved data} \\ a \in \mathcal{A} &: \text{actions} \\ u(a, \psi, \mathcal{D}) &: \text{utility} \\ \text{Maximize}_a \mathbb{E}[u(a, \psi, \mathcal{D}) \mid a, \mathcal{D}] \end{aligned}$$

For $T = 1$, we maximize

$$\alpha_1(x, \mathcal{D}) = \mathbb{E}[u(\mathcal{D}_1) \mid x] - u(\mathcal{D}).$$

For $T = 2$, we would like to maximize

$$\begin{aligned} \alpha_2(x, \mathcal{D}) &= \mathbb{E}[u(\mathcal{D}_2) - u(\mathcal{D}) \mid x_1] \\ &= \mathbb{E}[u(\mathcal{D}_2) - u(\mathcal{D}_1) + u(\mathcal{D}_1) - u(\mathcal{D}) \mid x_1] \\ &= \mathbb{E}[\alpha_1(x_2 \mid \mathcal{D}_1) \mid x_1 = x] + \alpha_1(x, \mathcal{D}) \end{aligned}$$

but we know that, at the next step, we will choose x_2 to maximize α , so

$$\alpha_2(x, \mathcal{D}) = \mathbb{E}[\alpha_1^*(\mathcal{D}_1) \mid x_1 = x] + \alpha_1(x, \mathcal{D}).$$

There is an optimization, α_1^* , parametrized by x_1 , inside an expectation – and, if we increase T , there will be even more nesting.

$$\begin{aligned} \alpha_T &= \alpha_1 + \mathbb{E}[\alpha_{T-1}^*] \\ &= \alpha_1 + \mathbb{E}[\text{Max } \alpha_{T-1}] \\ &= \alpha_1 + \mathbb{E}[\text{Max } \mathbb{E}[\text{Max } \alpha_{T-2}]] \\ &\dots \end{aligned}$$

Instead, we can use an optimal but truncated path ($T = 1$ or 2), or a suboptimal but complete path (using a heuristic to select x_t).

6. For Bayesian optimization, the final action is a bet on the location of the extremum. The action space can be:

- Only the points examined;
- Points close to the points examined;
- All the points in the domain \mathcal{X} of f .

For linear (risk-neutral) utility:

$$\begin{aligned} u(\mathcal{D}) &= \text{Max}_{(x,y) \in \mathcal{D}} \mu_{\mathcal{D}}(x) && \text{single reward} \\ u(\mathcal{D}) &= \text{Max}_{(x,y) \in \mathcal{X}} \mu_{\mathcal{D}}(x) && \text{global reward} \end{aligned}$$

(do not use $\max_{(x,y) \in \mathcal{D}} y$: it includes observation noise).

For risk-averse or risk-seeking behaviour, replace μ with $\mu + \beta\sigma$, $\beta < 0$ or $\beta > 0$.

Optimal control is slightly different: we want each y_i to be large, *i.e.*, we are maximizing $\sum y_i$.

The information gain, $E[\Delta H]$, or $E[\Delta \text{KL}]$, is another utility function.

7. The expected gain utility

$$\alpha(x, \mathcal{D}) = E[u(\mathcal{D}')|x, \mathcal{D}] - u(\mathcal{D})$$

can be used as an activation function.

Utility	Activation
single reward	expected improvement
global reward	knowledge gradient
unit for improving single reward	probability of improvement
information gain	mutual information
cummulated reward	posterior mean

Bayesian optimization is based on either Bayesian decision theory, or multi-arm bandits (infinite-arm bandits), for instance, using an upper bound (e.g., the 99.9% quantile) of $y = f(x)$; it is equivalent to maximizing the probability of improvement beyond some threshold.

Thompson sampling maximizes a random acquisition function, sampled from the posterior.

Two-step lookahead works better.

8. For Gaussian processes, without noise, the acquisition functions without noise are

$$\alpha_{\text{EI}}(x) = (\mu - \phi^*)\Phi\left(\frac{\mu - \phi^*}{\sigma}\right) + \sigma\phi\left(\frac{\mu - \phi^*}{\sigma}\right)$$

$$\alpha_{\text{PI}} = \Phi\left(\frac{\mu - \tau}{\sigma}\right)$$

where

$$\begin{aligned} \mu &= \mu(x) \\ \sigma &= \sigma(x) \\ \phi^* &: \text{best value of } f(x) \text{ so far} \\ \Phi, \phi &: \text{Gaussian cdf and pdf} \\ \tau &: \text{improvement threshold} \end{aligned}$$

9. For the implementation, use the Coolesky decomposition, and update it sequentially.

Given observations z , use *inducing values* v

$$\begin{pmatrix} v \\ z \end{pmatrix} \sim N\left(\begin{pmatrix} \mu \\ m \end{pmatrix}, \begin{pmatrix} \Sigma & k' \\ k & C + N \end{pmatrix}\right)$$

and compute an approximation of their conditional distribution

$$v|z \sim N(\tilde{\mu}, \tilde{\Sigma})$$

and marginalize them

$$p(f|z) = \int p(f|z)q(v|z)dz.$$

11. We assumed that each observation had a constant cost; if it varies, and is known in advance, estimate it (with a GP, jointly).

For optimal batch selection, try an n -dimensional acquisition function.

Multifidelity optimization also uses several surrogates of an expensive objective function (e.g., early stopping – freeze-thaw, hyperband).

For multi-objective optimization, use the volume under an estimate of the Pareto frontier as utility (S -metric) and maximize the expected hypervolume improvement (EHVI).

On the origin of implicit regularization in stochastic gradient descent S.L. Smith et al. (2021)

Full-batch gradient descent with *finite* step size can be described as a modified gradient flow, with a regularizer $\frac{1}{4}\alpha \|\nabla \ell\|^2$, where α is the learning rate. For SGD, the implicit regularization is

$$\frac{\alpha}{4m} \sum \|\nabla \ell_i\|^2.$$

Implicit gradient regularization D.G.T. Barrett and B. Dherin (2021)

The *discrete* steps of gradient descent lead the model away from the steepest descent path on the loss landscape. This path can be described as the steepest descent path on a modified loss landscape. The modified loss uses a gradient penalty $\frac{\alpha}{4} \sum \|\nabla \ell_i\|^2$.

The implicit regularization of stochastic gradient flow for least squares A. Ali et al. (2020)

Gradient descent for least squares

$$\text{Minimize}_{\beta} \frac{1}{2n} \|y - X\beta\|^2$$

with infinitesimal step sizes is described by the *gradient flow*

$$\dot{\beta}_t = \frac{1}{n} X'(y - X\beta_t), \quad \beta_0 = 0.$$

Stochastic gradient descent, with minibatches I of size $|I| = m$, can be described by a SDE

$$d\beta = \frac{1}{n} X'(y - X\beta)dt + \varepsilon Q(\beta)^{1/2} dW$$

$$Q(\beta) = \text{Cov}_I \left[\frac{1}{m} X'_I(y_I - X_I\beta) \right].$$

It is similar to ridge regression with $\lambda = 1/t$.

The benefits of implicit regularization from SGD in least squares problems
Z. Zou et al. (2021)

(Unregularized) *stochastic* gradient descent has a regularizing effect: it generalizes at least as well as ridge regression.

Implicit regularization of discrete gradient dynamics in linear neural networks
G. Gidel et al. (2019)

The optimization of an overparametrized model does not end in any parameter achieving a zero training loss: the choice of optimization algorithm (and of hyperparameters) directs training towards a particular solution; for a deep *linear* model, gradient descent leads to a low-rank solution.

On lazy training in differentiable programming
L. Chizat et al (2019)

Neural nets sometimes converge to zero training loss with their parameters hardly varying: this is due to the scaling of the weights (or, equivalently, of the input), which make the network behave as its linearization around its initialization.

Robust supervised learning with coordinate gradient descent
S. Gaïffas and I. Merad (2022)

Estimating a robust gradient $\nabla_{\theta} \ell$ is time-consuming: instead, use robust estimates of the partial derivatives $E[\partial \ell / \partial \theta_i]$, with coordinate descent. Choose which coordinate to update with importance sampling.

Robust estimators of the mean of x_1, \dots, x_n include the *median-of-means* (MOM) (median of the blockwise means), the *trimmed mean*, and the *Catoni-Holland estimator*: μ such that

$$\sum \psi \left(\frac{x_i - \mu}{\sigma} \right) = 0,$$

where ψ is, e.g., the sigmoid

$$\psi(x) = 2 \operatorname{Arctan}(e^x) - \frac{\pi}{2}$$

and σ satisfies

$$\sum \chi \left(\frac{x_i - \bar{x}}{\sigma} \right) = 0$$

where \bar{x} is the sample mean, and

$$\chi(u) = \frac{u^2}{1 + u^2} - c,$$

where c is such that $E_{Z \sim N(0,1)}[\chi(Z)] = 0$. Both μ and σ can be computed with fixed point iterations:

$$\begin{aligned} \mu &\leftarrow \mu + \frac{\sigma}{\mu} \sum \psi \left(\frac{x_i - \mu}{\sigma} \right) \\ \sigma &\leftarrow \sigma \left(1 - \frac{\chi(0)}{n} \sum \chi \left(\frac{x_i - \bar{x}}{\sigma} \right) \right). \end{aligned}$$

Alternatively, one could use traditional empirical risk minimization (ERM) on disjoint subsets, and aggregate them with a median-of-mean.

A generalized Catoni's M-estimator under finite α th moment assumption with $\alpha \in (1, 2)$
P. Chen et al.

Try M-estimators of location

$$\sum_i \phi(\beta(x_i - \hat{\theta})) = 0$$

with

$$\phi(x) = \begin{cases} \log\left(1 + x + \frac{x^\alpha}{\alpha}\right) & \text{if } x \geq 0 \\ -\log\left(1 - x + \frac{x^\alpha}{\alpha}\right) & \text{if } x < 0 \end{cases}$$

Efficient learning with robust gradient descent
M.J. Holland and K. Ikeda

In gradient descent, replace the average of the gradients with an M-estimator.

Challenging the empirical mean and empirical variance: a deviation study
O. Catoni (2011)

Properties of the M-estimator of the mean

$$\sum \psi(\alpha(y_i - \hat{\theta})) = 0$$

with ψ non-decreasing and

$$-\log\left(1 - x + \frac{x^2}{2}\right) \leq \psi(x) \leq \log\left(1 + x + \frac{x^2}{2}\right).$$

Mean estimation and regression under heavy-tailed distributions – a survey
G. Lugosi and S. Mendelson (2019)

The quality of a (univariate) mean estimator $\hat{\mu}_n$ is often measured with the mean square error $E[(\hat{\mu}_n - \mu)^2]$ but, if the differences $|\hat{\mu}_n - \mu|$ are not sufficiently concentrated, the expectation need not reflect the typical error. Instead, prefer estimators $\hat{\mu}_n$ that are close to μ with high probability

$$|\hat{\mu}_n - \mu| \leq \varepsilon \text{ w.p. } 1 - \delta.$$

For Gaussian data, the sample mean satisfies (L -sub-Gaussian)

$$|\hat{\mu}_n - \mu| \leq \frac{L\sigma\sqrt{\log(2/\delta)}}{\sqrt{n}} \text{ w.p. } 1 - \delta.$$

We want an estimator with a similar inequality, but for fat tail distributions (the estimators will depend on δ , but will only require finite variance; with more assumptions, e.g., finite third moment, they need no longer depend on δ):

- The *median-of-means* estimator splits the data into k groups, computes their means, and the median of those means;
- *Catoni's* estimator generalizes the characterization of the mean as the solution $\hat{\mu}_n$ of $\sum (x_i - \hat{\mu}_n) = 0$ to

$$\sum \psi \left(\frac{x_i - \hat{\mu}_n}{s} \right) = 0$$

for

$$\phi(x) = \begin{cases} \log \left(1 + x + \frac{x^\alpha}{\alpha} \right) & \text{if } x \geq 0 \\ -\log \left(1 - x + \frac{x^\alpha}{\alpha} \right) & \text{if } x < 0 \end{cases},$$

$s = \sqrt{n/2}\sigma$, and some estimator of σ ;

- The *trimmed mean* splits the data in two, uses the first half to compute the quantiles, and the second half (without the observations beyond the quantiles) to compute the mean.

For multivariate sub-Gaussian data,

$$\|\hat{\mu}_n - \mu\| \leq \sqrt{\frac{\text{tr } \Sigma}{n}} + \sqrt{\frac{2\lambda_{\max} \log(1/\delta)}{n}} \text{ w.p. } 1 - \delta$$

$$\mathbb{E} \|\hat{\mu}_n - \mu\|^2 = \frac{\text{tr } \Sigma}{n}$$

Traditional multivariate medians (geometric (spatial), Tukey (half-space), Liu (simplicial), Oja) do not give the desired bounds. Neither do the following medians:

- The point $\hat{\mu}_n$ such that the Euclidean ball centered at $\hat{\mu}_n$ that contains half the data has minimal radius;
- Rescale the x_i 's such that $\|x_i\| \leq 1/\alpha$ (i.e., shrink them towards zero), perhaps after centering the data (use independent batches to estimate the center (mean) and to compute the shrunk mean).

The following (*median of means tournament*) works: let T_a , $a \in \mathbf{R}^n$, be the set of points $x \in \mathbf{R}^n$ at least as close to z_1, \dots, z_k as a , and set $\hat{\mu}_n = \text{Argmin}_a \text{radius}(T_a)$, where z_1, \dots, z_k are block means (a semi-definite relaxation can be computed efficiently).

Robust sparse voting **Y. Allouah et al. (2022)**

The *quadratically regularized weighted median* is

$$\text{QrMed}_W(w, x) = \text{Argmin}_z \frac{1}{2} W z^2 + \sum_i w_i |z - x_i|.$$

Contrary to the median, it is W -Byzantine resilient (an attacker can change the median by choosing to be on one end or the other, and its impact is unbounded).

The *Byzantine resilient mean estimator* is a clipped

mean centered on the QrMed:

$$\text{BrMean}_W(w, x) =$$

$$\text{ClipMean} \left(w, x; \text{QrMed}_{4W}(w, x), \frac{\|w\|_1}{4W} \right)$$

$$\text{ClipMean}(w, x; \mu, \Delta) =$$

$$\frac{1}{\|w\|_1} \sum_i w_i \text{Clip}(x_i, \mu - \Delta, \mu + \Delta).$$

To aggregate complete rankings, use the majority judgement, or the randomized Condorcet voting system.

If the voters only provide sparse scores, on arbitrary scales, the following is sparsely unanimous and W -Byzantine resilient (but not independent of irrelevant alternatives).

n : voter

a : alternative

θ_{na} : scores

w_n : voting rights

$$\theta_a \leftarrow \frac{\theta_a - \text{Min } \theta_{am}}{\text{Max } \theta_{am} - \text{Min } \theta_{am}}$$

$$s_{nm} = \text{Mean}_{a,b} \frac{\theta_{ma} - \theta_{mb}}{\theta_{na} - \theta_{nb}}$$

$$s_n = 1 + \text{BrMean}_m(s_{nm} - 1)$$

$$\tau_{nm} = \text{Mean}_a s_m \theta_{ma} - s_n \theta_{na}$$

$$\tau_m = \text{BrMean}_m \tau_{nm}$$

$$\text{Mehestan}(w, \theta) = \text{QrMed}_n s_n \theta_n + \tau_n$$

(if you do not insist on resilience and scale invariance, the weighted mean is better).

Individually scaling the preferences cannot lead to sparse unanimity.

Algorithmic game theory

T. Kesselheim (2020)

1. In a *network congestion game*, n players have to find a path from their respective start nodes to their target node, on a graph, and incur a cost (delay) for each edge used; the per-user cost depends on the number of users using this edge.

Each player wants to minimize its cost, but society wants to minimize the total cost.

A *congestion game* is the datum of

- A set of players $\llbracket 1, n \rrbracket$;
- A set of resources $R = \llbracket 1, m \rrbracket$;
- A strategy space for each player $\Sigma_i \subset 2^R$;

- A delay function for each resource $d_r : \llbracket 1, n \rrbracket \rightarrow \mathbf{Z}$.

The cost of a state $s = (s_1, \dots, s_n) \in \Sigma_1 \times \dots \times \Sigma_n$ for player i is $c_i(s) = \sum_{r \in S_i} d_r(n_r(s))$, where $n_r(s) = \#\{i : r \in S_i\}$ is the number of players using resource r .

In a congestion game, every sequence of best response improvement steps is finite: there is a pure Nash equilibrium. This can be seen by showing that the *Rosenthal potential*

$$\Phi(s) = \sum_r \sum_{k=1}^{n_r(s)} d_r(k)$$

decreases.

2. This sequence can be exponentially long but, in a *singleton* congestion game ($\forall i \forall R \in S_i \ |R| = 1$), it is at most polynomial.

Pure Nash equilibria are exactly the local minima of the Rosenthal potential.

In symmetric network congestion games (all players have the same source and target nodes), the Nash equilibria can be computed in polynomial time (by reduction to a min-cost flow problem).

3. A (cost-minimization) *normal form game* is defined by

- A set of players $\llbracket 1, n \rrbracket$;
- For each player i , a set of pure strategies S_i ;
- For each player, a cost function

$$c_i : S = \prod_j S_j \rightarrow \mathbf{R}.$$

Bimatrix games are a special case.

	A	B					
A	2	1		L	0		
B	5	1		I	1	6	

4. Pure Nash equilibria do not always exist, but every finite normal form game has a *mixed Nash equilibrium* (a distribution on strategies, for each player); the proof uses Brouwer's fixed point theorem. For bimatrix games, one can find a mixed Nash equilibrium with a simplex-like algorithm.

5. NP is a complexity class for decision problems, but Nash equilibrium is a search problem. A search problem is FP if we can find a solution in polynomial time; it is FNP if we can verify a solution in polynomial time.

Finding a mixed Nash equilibrium in a normal form game is PPAD complete; finding a pure Nash equilibrium in a congestion game is PLS complete.

A local search problem is in PLS (polynomial local search) if there are polynomial algorithms to

- Find a feasible solution;
- Compute the cost of a feasible solution;
- Improve a feasible solution or, if it is already optimal, prove it.

Max-Cut is PLS-complete, and can be reduced to the problem of finding a Nash equilibrium in a congestion game.

6. A *correlated equilibrium* is a probability distribution on states (the players are no longer independent) such that $\forall i \in N \ \forall s_i \in S_i \ \forall s'_i \in S_i$

$$\mathbb{E}_{s \sim p} [c_i(s) | s_i] \leq \mathbb{E}_{s \sim p} [c_i(s'_i, s_{-i}) | s_i],$$

i.e., whenever p tells player i to play s_i , it is the best thing to do.

A *coarse correlated equilibrium* only demands

$$\mathbb{E}_{s \sim p} [c_i(s)] \leq \mathbb{E}_{s \sim p} [c_i(s'_i, s_{-i})],$$

i.e., player i is better off following p than always choosing s'_i .

A correlated equilibrium can be computed in polynomial time (via linear programming).

To find an (approximate) coarse equilibrium, the players can follow a *no-regret* algorithm. With two players, it would be:

- The player picks a distribution p_t over strategies;
- The adversary picks a cost vector ℓ_t ;
- The player picks an action from p_t , incurs the corresponding loss, and gets to know the cost vector.

The player tries to minimize the (external, expected) regret

$$\mathbb{E} \left[\sum_t \ell_t(a_t) - \min_a \sum_t \ell_t(a) \right]$$

(we compare the player's action with the best constant action in hindsight – the best action sequence in hindsight, $\sum_t \min_a \ell_t(a)$, would be too strong). For multiple players, each player chooses a distribution, and the loss vector is determined by the decisions of the other players

7. The *multiplicative weights algorithm* progressively updates the probabilities by increasing those with low cost and decreasing those with high cost:

$$w_1 = (1, \dots, 1)$$

$$p_t(i) \propto w_t(i)$$

$$w_{t+1}(i) \leftarrow w_t(i)(1 - \eta)^{\ell_t(i)}.$$

With $\eta = \sqrt{\log M / T}$, the regret is at most $2\sqrt{T \log M}$.

8. The *social cost* is the sum of the players' costs

$$\text{SC}(S) = \sum_i c_i(S).$$

The **price of anarchy** for pure Nash equilibria (PNE) compares the worst Nash equilibrium with the best societal outcome.

$$\text{PoA}_{\text{PNE}} = \frac{\max_{S \in \text{PNE}} \text{SC}(S)}{\min_S \text{SC}(S)}$$

In a congestion game with affine delay functions, $\text{PoA} \leq 5/2$. Other equilibrium concepts have a higher price of anarchy.

$$1 \leq \text{PoA}_{\text{PNE}} \leq \text{PoA}_{\text{MNE}} \leq \text{PoA}_{\text{CE}} \leq \text{PoA}_{\text{CCE}}$$

A game is (λ, μ) -smooth ($\lambda > 0, \mu < 1$) if

$$\forall s, s' \quad \sum_i c_i(s_i^*, s_{-i}) \leq \lambda \text{SC}(s^*) + \mu \text{SC}(s);$$

the price of anarchy for coarse correlated equilibria is then at most $\lambda/(1 - \mu)$.

9. The *price of stability* compares the best equilibrium (the PoA used the worst) with the best societal outcome.

$$\text{PoSEq} = \frac{\min_{s \in \text{Eq}} \text{SC}(s)}{\min_s \text{SC}(s)}$$

A *cost-sharing game* is a congestion game with $d_r(x) = c_r/x$; the societal cost is then $\text{SC}(s) = \sum_{r: n_r(s) \geq 1} c_r$. The price of stability of a cost-sharing game is at most

$$H_n = 1 + \frac{1}{2} + \frac{1}{3} + \dots + \frac{1}{n}.$$

For a symmetric cost sharing game (all players have the same strategies), it is 1, but the price of anarchy can be large.

A *market sharing game* is a (utility maximization) congestion game with $S_i \subset [1, m]$ and $u_i(s) = v_{s_i}/n_{s_i}(s)$, where v_j is the demand in market j , shared among the players entering it. The *social welfare* is then

$$\text{SW}(s) = \sum_{j: n_j(s) \geq 1} v_j.$$

The price of anarchy of a utility-maximization game is

$$\text{PoA}_{\text{Eq}} = \frac{\max_{s \in S} \text{SW}(s)}{\min_{p \in \text{Eq}} \text{SW}(p)}.$$

A utility-maximization game is (λ, μ) -smooth ($\lambda > 0, \mu \geq 0$) if

$$\forall s, s' \quad \sum_i u_i(s_i^*, s_{-i}) \geq \lambda \text{SW}(s^*) - \mu \text{SW}(s);$$

its PoA_{CCE} is at most $(1 + \mu)/\lambda$. The market-sharing game is (1,1)-smooth: $\text{PoA}_{\text{CCE}} \leq 2$.

10. In a *first-price auction*, where each player has a value v_i for the item, makes a bid b_i , and has utility $u_i(b, v_i) = v_i - b_i$ if he wins and zero otherwise, there is a Nash equilibrium: the highest value player bids the second highest value, and the others bid their value.

In a *second price auction* (Vickrey auction), $u_i(b, v_i) = v_i - \text{Max}_{j \neq i} b_j$; it is a dominant strategy to bid truthfully.

Given a set of players $[1, n]$, a set of outcomes X , valuation functions $v_i : X \rightarrow \mathbf{R}$, and possible bids $B = B_1 \times \dots \times B_n$, a *mechanism* is the datum of an outcome rule $f : B \rightarrow X$ and a payment rule $p : B \rightarrow \mathbf{R}^n$. The players' utilities are

$$u_i(b) = v_i(f(b)) - p_i(b).$$

If the bids are valuation functions, the mechanism is *direct*. A mechanism is **truthful** (dominant strategy incentive compatible, DSIC) if bidding the true value is a weakly dominant strategy.

11. In a *single-parameter mechanism*, $X \subset \mathbf{R}_{\geq 0}^n$ and $v_i(x) = v_i \cdot x_i$. In this case, if the allocation rule f is monotone, i.e., the $z \mapsto f_i(z, b_{-i})$ are non-decreasing, setting the payment rule to

$$p_i(b_i, b_{-i}) = b_i f_i(b_i, b_{-i}) - \int_0^{b_i} f_i(t, b_{-i}) dt$$

makes the mechanism truthful (**Myerson's lemma**).

12. In a *combinatorial auction*, there are n items and each bidder has a value for each subset of items. If bidders are *single-minded* (they only care whether they get all their desired items or not), if their preferences are public (but their valuations private), the *greedy-by-value* mechanism (give bidders what they want, if possible, starting bidders with the largest bids) is a d -approximation, where d is the size of the largest bundle. For large bundle sizes, prefer *greedy-my-sqrt-value-density* (order the bidders by $b_i/\sqrt{|S_i^*|}$): it is an \sqrt{m} -approximation.

13. A **VCG mechanism** is a mechanism whose allocation rule $f : V \rightarrow X$ maximizes social welfare, i.e., $f(b) \in \text{Argmax}_x \sum_i b_i(x)$, and whose payment rule is

$$p_i(b) = \text{Max}_x \sum_{j \neq i} b_j(x) - \sum_{j \in S} b_j(f(b))$$

(player i 's externality). It is DSIC. Examples include second-price single-item auction, sponsored search auctions ($v_i(x) = v_i \alpha_j$ if agent i gets slot j), unit-demand combinatorial auctions ($v_i(S) = \text{Max}_{j \in S} v_{ij}$).

VCG requires solving a welfare maximization problem: an approximation is not enough – for instance, VCG payments with a greedy allocation for unit-demand combinatorial auctions (a 2-approximation) do not give a truthful mechanism.

14. Given a (non-truthful) mechanism, with incomplete information (the bidders' values are drawn from a known distribution $v_i \sim \mathcal{D}_i$), a **Bayes-Nash equilibrium** is a profile of bidding functions $\beta_i : V_i \rightarrow B_i$ such that $\forall i \quad \forall v_i \in V_i \quad \forall b'_i \in B_i$

$$\mathbb{E}_{v_{-i} \sim \mathcal{D}_{-i}} u_i(\beta(v), v_i) \geq \mathbb{E}_{v_{-i} \sim \mathcal{D}_{-i}} u_i((b'_i, \beta_{-i}(v)), v_i).$$

15. A mechanism is (λ, μ) -smooth if

$$\forall v \in V \quad \forall i \quad \forall b_i^* \quad \forall b \in B$$

$$\sum_i u_i((b_i^*, b_{-i}), v_i) \geq \lambda \cdot \text{OPT}(v) - \mu \sum_i p_i(b);$$

the price of anarchy is then bounded (same bound for pure Nash equilibria, (coarse) correlated equilibria, and Bayes-Nash equilibria):

$$\text{PoA} \leq \frac{\text{Max}(\mu, 1)}{\lambda}.$$

Single-item first-price auction is $(\frac{1}{2}, 1)$ -smooth; single-item all-pay auction is $(\frac{1}{2}, 2)$ -smooth.

16. Combinatorial auction with unit-demand valuations and first-price payments is $(\frac{1}{2}, 1)$ -smooth. First-price greedy-by-sqrt-value-density for multi-minded combinatorial auctions is $(\frac{1}{2}, \sqrt{2m})$ -smooth.

17. A **Walrasian equilibrium** (in a combinatorial auction) is a *price vector* (Nash equilibria were about players' bids, not prices) $q \in \mathbf{R}_{\geq 0}^m$ and an allocation S such that each bidder gets a bundle maximizing his utility

$$\forall S'_i \quad v_i(S_i) - \sum_{j \in S_i} q_j \geq v_i(S'_i) - \sum_{j \in S'_i} q_j.$$

Walrasian equilibria (if they exist) maximize social welfare. Unit-demand VCG prices are a Walrasian equilibrium.

18. In the *posted prices* mechanism, buyers come one by one, and buy the set of unsold items maximizing their utility. For unit-demand, the expected social welfare of the posted prices mechanism is half the expected optimal welfare – set the prices to (the expectation of) half the value for the buyer getting it in the optimal welfare allocation.

19. If the values are drawn from distributions \mathcal{D}_i , the *virtual values* are

$$\phi_i(t) = t - \frac{1 - F_i(t)}{f_i(t)}.$$

For a truthful single-parameter mechanism, the expected revenue is the expected virtual welfare:

$$\mathbb{E} \sum_i p_i(v) = \mathbb{E} \sum_i \phi_i(v_i) x_i(v).$$

The *virtual welfare maximizing mechanism* (with Myerson's payments) is truthful and maximizes expected revenue among truthful payments.

20. The second-price auction maximizes the expected revenue among all truthful mechanisms (if valuations are drawn from the same distribution, if the item is always allocated). Posting a price

$$p^* = \text{Max}\{\phi^{-1}(0), F^{-1}(1 - \frac{1}{n})\}$$

gives a $1 - (1 - \frac{1}{n})^n \geq (1 - 1/e)$ -approximation of the optimal expected revenue. (Surprisingly, truthfulness is not a restriction.)

21. To match agents to houses, when agents have different preferences (without money), start by assigning the houses at random, then build a directed graph with

edges from each agent to the owner of the house he prefers best among the remaining ones, find a cycle, reallocate the houses in it, and remove the corresponding nodes; iterate until the graph is empty. The result allocation is *stable*.

22. The **Gale-Shapley** algorithm generalizes this to situations with preferences from both agents and items.

23. To cut a cake $[0, 1]$ between n agents with valuations

$$V_i(X) = \int_{x \in X} v_i(x) dx \quad X \subset [0, 1] \quad V_i([0, 1]) = 1,$$

we may want:

- Proportionality: $\forall i \quad V_i(A_i) \geq 1/n$;
- Envy-freeness: $\forall i, j \quad V_i(A_i) \geq V_i(A_j)$;
- Equitability: $\forall i, j \quad V_i(A_i) = V_i(A_j)$.

For two agents, the cut-and-choose mechanism is proportional, envy-free, but not necessarily equitable. For n agents, the *Dubins-Spanier algorithm* is proportional. Ensuring envy-freeness is more complicated. None of those algorithms is truthful.

24. A *ranking rule* for three or more candidates satisfying unanimity and independence of irrelevant alternatives is a dictatorship.

25. **Shapley values** formalize cost-sharing.

Mechanics for mathematicians J. Wunsch (2020)

2. Newton's law, $F = ma$, describes the evolution of a physical system as a second-order differential equation. Examples include:

- Gravitation (1d): $\ddot{x} = -1$;
- Spring: $\ddot{x} = -\omega^2 x$;
- Magnetism: $\ddot{x} = \dot{x} \times B$;
- Gravity: $\ddot{x} = -\hat{x} / \|x\|^2$.

3. The initial value problem has a unique solution (Picard-Lindelöf); it may not have a closed form solution: try Taylor expansions or numeric methods (Newton).

4. In dimension 1, if the force does not depend on time, it comes from a **potential**:

$$\ddot{x} = F(x) \rightsquigarrow \ddot{x}x = F(x)\dot{x} \rightsquigarrow \frac{d}{dt} \left(\frac{1}{2} \dot{x}^2 + V(x) \right) = 0$$

where $V'(x) = -F(x)$. The energy $E = \frac{1}{2} \dot{x}^2 + V(x)$ is constant.

5. Plot the level curves of the energy in the phase plane to identify periodic motion and distinguish between stable and unstable equilibria ($V(x_0) > 0$ and $V(x_0) < 0$).

6. In \mathbf{R}^n , we would also like to write $F(x) = -\nabla V(x)$, but that is only possible if $\text{curl } F = 0$, or, more generally, if the vector field F is conservative, *i.e.*, $\int_{\gamma} F(x) \cdot dx$ only depends on the endpoints of the path γ .

7a. The **Lagrangian** is the difference between kinetic T and potential V energy.

$$L = T - V \quad L(x, \dot{x}) = \frac{1}{2} |\dot{x}|^2 - V(x)$$

The *action* of a trajectory $\gamma : [0, T] \rightarrow \mathbf{R}^3$ is

$$S(\gamma) = \int_0^T L(\gamma(t), \dot{\gamma}(t)) dt.$$

The *principle of least action* states that the action is stationary, *i.e.*, its directional derivatives are zero:

$$\left. \frac{d}{ds} S(\gamma + s\phi) \right|_{s=0} = 0$$

for all paths ϕ with $\phi(0) = \phi(T) = 0$.

For a functional of the form

$$S(\gamma) = \int_0^T L(\gamma(t), \dot{\gamma}(t), t) dt,$$

the stationarity condition becomes

$$\int_0^T \left[\frac{\partial L}{\partial x} \cdot \phi(t) + \frac{\partial L}{\partial v} \cdot \phi'(t) \right] dt = 0$$

and, after integrating the second term by parts (and using $\phi(0) = \phi(T) = 0$),

$$\int_0^T \left(\frac{\partial L}{\partial x} - \frac{d}{dt} \frac{\partial L}{\partial v} \right) \cdot \phi(t) dt = 0$$

giving the **Euler-Lagrange equation**

$$\frac{\partial L}{\partial x} = \frac{d}{dt} \frac{\partial L}{\partial v}.$$

7b. If a coordinate x_i does not appear in L , then

$$\frac{d}{dt} \frac{\partial L}{\partial v_i} = \frac{\partial L}{\partial x_i} = 0,$$

i.e., $\partial L / \partial v_i$ is a conserved quantity.

There is a similar result for time: if $\partial L / \partial t = 0$,

$$\begin{aligned} \frac{dL}{dt} &= \frac{\partial L}{\partial x} \cdot \dot{\gamma} + \frac{\partial L}{\partial v} \cdot \ddot{\gamma} + \cancel{\frac{\partial L}{\partial t}} \\ &= \left(\frac{d}{dt} \frac{\partial L}{\partial v} \right) \cdot \dot{\gamma} + \frac{\partial L}{\partial v} \cdot \ddot{\gamma} \quad (\text{Euler-Lagrange}) \\ &= \frac{d}{dt} \left(\frac{\partial L}{\partial v} \cdot \dot{\gamma} \right) \quad (\text{product rule}) \end{aligned}$$

hence

$$\frac{d}{dt} \left(-L + \frac{\partial L}{\partial v} \cdot \dot{\gamma} \right) = 0$$

i.e., the *Hamiltonian*

$$H(x, v) = -L(x, v) + \frac{\partial L}{\partial v} \cdot v$$

is conserved. (In simple cases, $H = T + V$.)

The Lagrangian approach facilitates changes of coordinates and easily allows for constraints (e.g., with a reparametrization).

7c. More generally, a continuous symmetry

$$\begin{aligned} F^a : \mathbf{R}^n &\longrightarrow \mathbf{R}^n \\ F_*^a(x, v) &= (F(x), \nabla F(x) \cdot v) \\ L(F_*^a(x, v), t) &= L(x, v, t) \end{aligned}$$

gives rise to a conservation law (**Noether's theorem**)

$$p = \frac{\partial L}{\partial v} \cdot W \quad \text{where } W(x) = \left. \frac{d}{da} F^a(x) \right|_{a=0}.$$

Examples include momentum and angular momentum.

11. The Hamiltonian is defined as

$$H = \frac{\partial L}{\partial v} \cdot v - L.$$

With the change of variables

$$\begin{aligned} q &= x \\ p &= \frac{\partial L}{\partial v} \end{aligned}$$

it becomes $H = pv - L(x, v)$. We then have

$$\begin{aligned} \frac{\partial H}{\partial p} &= v + p \cancel{\frac{\partial}{\partial p}} - \cancel{\frac{\partial L}{\partial x} \frac{\partial x}{\partial p}} - \cancel{\frac{\partial L}{\partial v} \frac{\partial v}{\partial p}} \\ &= v \\ &= \dot{x} \\ &= \dot{q} \\ \frac{\partial H}{\partial q} &= p \cancel{\frac{\partial}{\partial p}} - \frac{\partial L}{\partial x} \frac{\partial x}{\partial p} - \cancel{\frac{\partial L}{\partial v} \frac{\partial v}{\partial p}} \\ &= -\frac{\partial L}{\partial x} \\ &= -\frac{d}{dt} \frac{\partial L}{\partial v} \quad (\text{Euler-Lagrange}) \\ &= -\dot{p} \end{aligned}$$

Hamilton's equations of motion are

$$\begin{aligned} \dot{q} &= \frac{\partial H}{\partial p} \\ \dot{p} &= -\frac{\partial H}{\partial q}. \end{aligned}$$

They define a vector field

$$v_H = \begin{pmatrix} \partial H / \partial p \\ -\partial H / \partial q \end{pmatrix}$$

and a flow $(\Phi_t)_t$.

The Hamiltonian vector field has vanishing divergence, $\nabla \cdot v_H = 0$; its flow is therefore volume-preserving (Liouville's theorem).

For a function defined on phase space, $a(q, p)$,

$$\begin{aligned} \frac{da}{dt} &= \frac{\partial a}{\partial q} \cdot \dot{q} + \frac{\partial a}{\partial p} \cdot \dot{p} \\ &= \frac{\partial a}{\partial q} \cdot \frac{\partial H}{\partial p} - \frac{\partial a}{\partial p} \cdot \frac{\partial H}{\partial q} \\ &= \{a, H\} \quad (\text{Poisson bracket}) \\ &= (v_H \cdot \nabla)a. \end{aligned}$$

The flow is a symplectomorphism,

$$(\nabla \Phi_t)J(\nabla \Phi_t)' = J$$

where $J = \begin{pmatrix} 0 & I \\ -I & 0 \end{pmatrix}$.

Portfolio construction with Gaussian mixture returns and exponential utility via convex optimization
E. Luxenberg and S. Boyd (2022)

The expected utility of a portfolio whose constituent returns are a Gaussian mixture has a simple closed form

$$\begin{aligned} r &\sim \text{GM}((\mu_i, \Sigma_i, \pi_i)_{1 \leq i \leq k}) \\ R &= w'r \\ U(r) &= 1 - e^{-\gamma R} \\ \mathbb{E}[U(R)] &= 1 - M(w, -\gamma) \\ M(w, t) &= \mathbb{E}[e^{tR}] = \sum \pi_i \exp\left[t\mu_i'w + \frac{1}{2}w'\Sigma_i w\right] \end{aligned}$$

and maximizing the *entropic value at risk*

$$\text{EVaR}_\alpha(R) = \inf_{\lambda > 0} \frac{\log M(w, -\lambda) - \log \alpha}{\lambda}$$

and can also be formulated as a convex problem. [Implementation in a few lines of `cvxpy`.]

Entropic portfolio optimization: a disciplined convex programming framework
D. Cajas (2021)

The EVaR (and the EDaR, entropic drawdown at risk) can also be optimized using samples. Implementation in `Riskfolio-Lib`.

OWA portfolio optimization: a disciplined convex programming framework
D. Cajas (2021)

The *ordered weighted average* (OWA) of $(y_i)_{1 \leq i \leq T}$ is a weighted average of order statistics, $\sum w_i y_{(i)}$. Examples include the *Gini mean deviation*

$$\text{GMD} = \text{Mean}_{i \neq j} |y_i - y_j|$$

or the *L-moments* ($\lambda_2 = \frac{1}{2}\text{GMD}$). They can be formulated with a linear program.

$$\begin{aligned} \text{Find} & \quad w, \alpha, \beta, y \\ \text{To maximize} & \quad w'\mu - \lambda \sum_i (\alpha_i + \beta_i) \\ \text{Such that} & \quad w'\mathbf{1} = 1 \\ & \quad w \neq 0 \\ & \quad w'r = y \\ & \quad \forall i, j \quad \alpha_i + \beta_j \geq w_i y_{(j)} \end{aligned}$$

where r_{ki} is the return of asset k in scenario i .

Causal matrix completion
A. Agarwal et al.

To solve the matrix completion problem

$$\begin{aligned} A &\in \mathbf{R}^{m \times n} && \text{latent} \\ \varepsilon &\in \mathbf{R}^{m \times n} && \text{noise} \\ \mathbb{E}[\varepsilon] &= 0 \\ \tilde{Y} &= A + \varepsilon \\ P &\in [0, 1]^{m \times n} && \text{propensity score} \\ D &\in \{0, 1\}^{m \times n} && \text{missingness mask} \\ \mathbb{E}[D] &= P \\ Y_{ij} &= \begin{cases} \tilde{Y}_{ij} & \text{if } D_{ij} = 1 \\ * & \text{otherwise} \end{cases} \end{aligned}$$

one can try

$$\begin{aligned} \text{USVT} & \quad \text{Minimize}_{Q: \text{rank } Q \leq \mu} \| (Y - Q) \odot D \|_2^2 \\ \text{softImpute} & \quad \text{Minimize}_Q \| (Y - Q) \odot D \|_2^2 + \lambda \|Q\|_* \end{aligned}$$

(but they may not perform well if the data is not MCAR) or inverse propensity weighting

$$\text{Minimize}_Q \sum_{i,j: D_{ij}=1} \frac{1}{P_{ij}} d(Y_{ij}, Q_{ij}) + \lambda R(Q).$$

To fill in a missing value Y_{ij} , *synthetic nearest neighbours*

- Look for several fully-observed blocks S_k , with non-overlapping rows (e.g., *maximal bicliques*),
- Approximate the row AC_k from S_k , with a principal component regression,
- Compute the corresponding prediction for Y_{ij} ,
- And average those predictions.

Matrix estimation by universal singular value thresholding
S. Chatterjee (2015)

Given a matrix $X \in [-1, 1]^{m \times n}$, $m \geq n$, with missing values, USVT completes it as follows:

- Fill in the missing values with 0;

- Compute the SVD;
- Only keep the singular values above $2\sqrt{np}$, where p is the proportion of observed values;
- Reconstruct the matrix;
- Clip the entries to $[-1, 1]$.

Applications include:

- Low-rank matrices;
- Latent space models $x_{ij} = f(\beta_i, \beta_j) + \varepsilon_{ij}$;
- Bradley-Terry models

$$p_{ij} = P[\text{team } i \text{ wins over } j] = \frac{a_i}{a_i + a_j}$$

$$X_{ij} \sim \text{Bernoulli}(p_{ij})$$

and its non-linear generalizations (p monotonic);

- Stochastic block models
- Graphons (estimation of a graphon from a single graph sampled from it);
- Distance matrices;
- Positive semi-definite matrices.

**Matrix completion and low-rank SVD
via fast alternating least squares
T. Hastie et al. (2015)**

The matrix completion problem

$$\text{Minimize}_M \frac{1}{2} \|(X - M) \odot O\|_F^2 + \lambda \|M\|_*$$

where $\|\cdot\|_*$ is the nuclear norm, the sum of the singular values (a convex relaxation of the rank) can be solved with the *softImpute* algorithm, iterating:

$$\hat{X} = \text{coalesce}(X, 0)$$

$$\hat{X} \stackrel{\text{SVD}}{=} UDV'$$

$$\hat{M} = US_\lambda(D)V'$$

$$\hat{X} = \text{coalesce}(X, \hat{M})$$

where the soft thresholding is $S_\lambda(D_{ii}) = (D_{ii} - \lambda)_+$; an efficient implementation can use a reduced rank SVD, and write \hat{X} as the sum of a sparse and a low-rank matrix, $\hat{X} = \text{coalesce}(X, \hat{M}) = (X - \hat{M}) + \hat{M}$.

The *maximum margin matrix factorization* (MMMF) problem

$$\text{Minimize}_{A,B} \frac{1}{2} \|(X - AB') \odot O\|_F^2 + \frac{\lambda}{2} (\|A\|_F^2 + \|B\|_F^2)$$

is biconvex and can be solved with alternating least squares (ALS); the solution is

$$\hat{A} = U_r S_\lambda(D_r)^{1/2}$$

$$\hat{B} = V_r S_\lambda(D_r)^{1/2}.$$

The *softImpute-ALS* algorithm combines both approaches.

$$\text{Minimize}_{A,B} \frac{1}{2} \|\hat{X} - AB'\|_F^2 + \frac{\lambda}{2} (\|A\|_F^2 + \|B\|_F^2).$$

A swiss army infinitesimal jackknife

R. Giordano et al. (2020)

To compute approximate bootstrap, cross-validation or jackknife samples for an estimator θ defined by

$$\frac{1}{N} \sum_n w_n g_n(\theta) = 0$$

(the g_n 's could be the gradients of a loss function – use automatic differentiation to compute them) use a first order approximation.

$$G(\theta, w) = \frac{1}{N} w' g$$

$$H(\theta, w) = \frac{1}{N} w' \nabla_\theta g$$

$$G(\theta(w), w) = 0$$

$$\frac{\partial G}{\partial \theta} \frac{\partial \theta}{\partial w} + \frac{\partial G}{\partial w} = 0$$

$$\frac{\partial \theta}{\partial w} = - \left(\frac{\partial G}{\partial \theta} \right)^{-1} \frac{\partial G}{\partial w}$$

$$= -H^{-1} \left(\frac{1}{N} g \right)$$

$$\hat{\theta}_{IJ}(w) = \hat{\theta}_1 + \frac{\partial \theta}{\partial w} \Big|_{w=1} (w - 1)$$

$$= \hat{\theta}_1 - H_1^{-1} G(\hat{\theta}_1, w - 1)$$

**Uncertainty prediction for deep sequential
regression using meta models**

J. Navrátil et al.

A *metamodel* predicts the error of a base model:

$$\text{Base model: } \text{Minimize}_{\phi} E[\text{loss}(\hat{y}, y)]$$

$$\text{Meta model: } \text{Minimize}_{\gamma} E[\text{loss}(\hat{z}, z)]$$

where $z = \text{loss}(\hat{y}, y)$ (those three loss functions can be different).

**Learning prediction intervals
for model performance**

B. Elder et al. (2021)

Use a meta model to predict the performance (e.g., accuracy) of the base model, and a meta-meta model to predict a confidence interval on it.

**Confidence scoring using whitebox
meta-models with linear classifiers**

T. Chen et al.

Build a meta model from linear features on the various layers of the base model.

Graph similarity learning for change point detection in dynamic networks
D. Sulem et al. (2022)

To detect changepoints in time-varying networks $(G_t)_{t \geq 0}$, train a Siamese GNN

and use its output as a similarity measure, e.g., $\text{Mean}_{i \in [1, L]} s(G_t, G_{t-i})$ or $\text{Mean}_{\substack{i, j \in [1, L] \\ i < j}} s(G_{t-i}, G_{t-j})$.

Sorted pooling in convolutional networks for one-shot learning
H. András (2020)

Max pooling can be replaced by:

- k -Max pooling, returning the k -th largest value in each patch;
- Sort- k pooling, returning a weighted average of the top- k values, with learned weights.

Rough volatility: fact or artefact
R. Cont and P. Das (2022)

Volatility clustering suggests $H > \frac{1}{2}$, even though the roughness of the realized volatility suggests $H < \frac{1}{2}$.

The p -variation of a function $x : [0, T] \rightarrow \mathbf{R}$ is the limit

$$\sum |x(t_{i+1}) - x(t_i)|^p \longrightarrow [x]^p$$

when the partition $(0, t_0, t_1, \dots, t_N = T)$ gets finer. The *variation index* and the *roughness index* are then

$$p(x) = \inf \{ p \geq 1 : [x]^p < \infty \}$$

$$H(x) = 1/p(x).$$

If x is a fractional Brownian motion with Hurst exponent H , then $H(x) = H$ a.s.. To estimate the Hurst exponent from a finite sample,

- Compute

$$W_p = \sum_i \frac{|\Delta_{K_i} x|^p}{\sum_{j: [t_{j-1}^L, t_j^L] \cap [t_{i-1}^K, t_i^K] \neq \emptyset} |\Delta_{L_j} x|^p}$$

where the partition π_L is a refinement of π_K ,

- Find \hat{p} such that $W_{\hat{p}} = T$,
- And let $\hat{H} = 1/\hat{p}$.

Realized volatility is rough ($H < \frac{1}{2}$), even if instantaneous volatility is not ($H = \frac{1}{2}$): roughness comes from market microstructure noise.

Error-correcting output codes with ensemble diversity for robust learning in neural networks
Y. Song et al. (2021)

Jointly train (end-to-end) a set of binary classifiers and the ECOC code matrix to combine their outputs, maximizing

- The distance between rows (codewords)
- And the shared information distance between columns (binary tasks), viz the variation of information

$$V(X, Y) = 2H(X \wedge Y) - H(X) - H(Y)$$

to mitigate adversarial attacks.

Time-aware language models as temporal knowledge bases
B. Dhingra et al.

To make your language model aware of time (some facts have an expiration date, e.g., the name of the president), model $P_\theta[\text{mask}|\text{context}, \text{time}]$, e.g., by prefixing each input with the date, “year: 2022”.

Density-preserving data visualization unveils dynamic patterns of single-cell transcriptomic variability
A. Narayam et al. (2020)

With t -SNE and UMAP, the cluster sizes correspond to the number of observations and ignore the density; *denSNE* and *densMAP* augment the objective with a differentiable measure of the total density, to preserve the average distance to the nearest neighbours

$$\frac{\sum_j p_{ij} \|x_i - x_j\|^2}{\sum_j p_{ij}}.$$

Available in `umap-learn`.

Comparing clusterings – an overview
S. Wagner and D. Wagner (2007)

Use an information-based measure, e.g., the normalized mutual information

$$\text{NMI}_1(C_1, C_2) = \frac{I(C_1, C_2)}{\sqrt{H(C_1)H(C_2)}}.$$

The stochastic collocation Monte Carlo sampler: highly efficient sampling from expensive distributions
L.A. Grzelak et al. (2016)

To sample from a distribution F_Y , one could use

$$u \sim \text{Unif}$$

$$y = F_Y^{-1}(u)$$

or, more generally, for an auxilliary distribution F_X (e.g., Gaussian)

$$x \sim F_X$$

$$y = F_Y^{-1}(F_X(x)).$$

If F_Y^{-1} is expensive to compute, stochastic collocation Monte Carlo (SCMC) approximates $F_Y^{-1} \circ F_X$ with *Lagrange polynomials* on *Gauss quadrature points*.

Predicting value at risk for cryptocurrencies using generalized random forests
K. G3rgen et al. (2022)

Random forests can be used for quantile regression: change the splitting criterion to classify the observations wrt the quantile(s) of interest. (Quantile regression forests only use quantile regression in the leaves, without adjusting the splitting criterion.)

A generalized precision matrix for t-Student distributions in portfolio optimization
K. Bax et al. (2022)

With a Gaussian random variable, the *precision matrix* (the inverse of the variance matrix) describes the conditional dependence structure; with non-Gaussian data, this is no longer the case. Alternatives to the precision matrix $\Omega = \Sigma^{-1}$ include:

$$\Omega_{ij} = -\mathbb{E}_x \left[\frac{\partial^2}{\partial x_i \partial x_j} \log f(x) \right]$$

$$\Omega_{ij} = -\mathbb{E}_{x_i, x_j} \left[\mathbb{E}_{x_{\setminus ij}} \left[\frac{\partial^2}{\partial x_i \partial x_j} \log f(x) \right] \mathbf{1}_{x_i^2 + x_j^2 \geq t} \right]$$

$$\Omega_{ij} = \mathbb{E}_x \left[\frac{\partial^2}{\partial x_i \partial x_j} \log f(x) \right]$$

Try them instead of Σ^{-1} in portfolio optimization. [Also check local Gaussian correlation.]

Community detection and portfolio optimization
L. Zhao et al. (2021)

Compute the correlation matrix from daily returns, on a 500-day moving window; build the PMFG (planar maximally filtered graph); compute communities (infomap); pick a stock at random (sic) in each community; build an optimized portfolio from those stocks.

Network diversification for a robust portfolio allocation
M. Jaeger and D. Marinelli

Use the inverse of the degree (or eigen-centrality) on the PMFG as portfolio weights.

LoCoV: low dimension covariance voting algorithm for portfolio optimization
J. Duan and I. Popescu

Compute the optimal portfolio on all subsets of k assets, and average the weights.

Lazy network: a word embedding based temporal financial network to avoid economic shocks in asset pricing models
G. Adosoglou et al. (2022)

- Compute the similarity between the companies' 10K filings for year t ;
- Compute the absolute value of the difference between the similarities in years t and $t - 1$;

- Invest in the periphery of the corresponding graph, i.e., companies with idiosyncratic changes.

A picture is worth a thousand words: measuring investor sentiment by combining machine learning and photos from news
K. Obaid and K. Pukthuanthong

News sentiment can be extracted from news photos; it contains the same information as the sentiment extracted from text. Try a pretrained Inceptionv3, with a head fine-tuned on DeepSent (1000 images) on data from the WSJ: it can predict return and volume at 1 day and 1 week (with different signs).

Realized semibetas: disentangling good and bad downside risks
T. Bollerslev et al.

Consider *four* semibetas, depending on the signs of the market and asset returns. Only $\beta_{\text{market} < 0, \text{asset} > 0}$ and $\beta_{\text{market} < 0, \text{asset} < 0}$ are priced.

The semibetas are defined from the decomposition

$$\beta = \frac{\text{Cov}(r_{\text{market}}, r)}{\text{Var } r_{\text{market}}}$$

$$= \frac{c_{++} + c_{--} - c_{+-} - c_{-+}}{\text{Var } r_{\text{market}}}$$

$$= \beta_{++} + \beta_{--} - \beta_{+-} - \beta_{-+}.$$

Investor attention and stock returns
J. Chen et al. (2020)

Combine 12 proxies of investor attention (aggregated over all stocks):

- Abnormal trading volume (1m vs 12m);
- Extreme returns (1m vs 12m);
- Past returns (12m);
- Nearness to the Dow 52-week high, and historical high;
- Analyst coverage;
- Change in advertising expenses;
- Mutual fund inflow, and outflow;
- Media coverage;
- Google search volume;
- Edgar search volume.

Aggregate with

- PCA,
- *scaled PCA* (sPCA)

$$\beta_i = \beta(y \sim x_i)$$

$$A = \text{PC}_1(\beta_1 x_1, \dots, \beta_n x_n)$$

y : future returns

x : proxies

- or *partial least squares* (PLS)

$$\pi_i = \beta(x_1 \sim y) \quad \text{time series regressions}$$

$$A_t = \beta(x_t \sim \pi) \quad \text{cross-sectional regressions.}$$

***Some applications of TDA
on financial markets***
M.A. Ruiz-Ortiz et al. (2022)

Using

- Daily returns of 4 indices, for 15 days (15 points in 4-dimensional space),
- or 4-dimensional delay embeddings of cryptocurrency returns, for 50 days (50 points)

compute the persistence landscape λ_t and $\text{Var} \|\lambda_t\|_1$ or $\|\lambda_t\|_1 + \|\lambda_t\|_1 - \|\lambda_{t-1}\|_1$ to detect crashes.

The persistent homology turbulence index (PHTI) is obtained by

- Taking 60 days of industry log-returns (60 points in k -dimensional space), or a delay embedding of a single time series;
- Computing the persistence diagram P_t , then the Wasserstein distances between P_t and P_{t-1} , then a 60-day moving average, then the quantile over a 5-year window,
- or, alternatively, by computing the persistence landscape and $\|\lambda_{t-\tau} - \lambda_t\|_2$.

***Tail-GAN: non-parametric scenario
generation for tail risk estimation***
R. Cont et al. (2022)

To generate scenarios to compute the VaR or the ES, train a GAN, whose discriminator evaluates the quality of VaR and ES estimates (sorting is a.e. differentiable) using a *scoring function* (the pair (VaR, ES) is *elicitable* – the formula is complicated) on a set of static and *dynamic* trading strategies.

***Sensitivity measures
based on scoring functions***
T. Fissler and S.M. Pesenti (2022)

A statistic T is *elicitable* if there is a scoring function S such that $T(X) = \text{Argmin}_t E[S(t, X)]$. For instance, mean $S(\mu, x) = (\mu - x)^2$, median $S(m, x) = |m - x|$, VaR_α , or the pair $(\text{VaR}_\alpha, \text{ES}_\alpha)$ are elicitable; for each of those, there is actually a (known) family of scoring functions.

The sensitivity of T wrt information Y is

$$\frac{E[S] - E[S|Y]}{E[S]}.$$

***Multi-objective reward generalization:
improving performance of deep reinforcement
learning for selected applications
in stock and cryptocurrency trading***
S. Cornalba and C. Disselkamp

If the reward is a vector rather than a scalar (e.g., $(\mu, \mu/\sigma)$), optimize a random positive linear combination of rewards, resampled at each step.

***Weisfeiler and Lehman go cellular:
CW networks***

The Weisfeiler-Lehman isomorphism test can be generalized to simplicial of CW complexes (*i.e.*, cells with arbitrary shapes). A cell has 4 types of neighbours:

- Boundary adjacent: cells on the boundary, one dimension smaller;
- Coboundary adjacent: cells on the boundary, one dimension larger;
- Lower adjacent cells: cells of the same dimension, sharing a lower-dimensional cell on their boundary;
- Upper adjacent cells: cells of the same dimension, on the boundary of the same higher dimensional cell.

Coboundary and lower adjacencies can be omitted without affecting the expressive power of the test.

A graph can be lifted to a CW complex in many ways, e.g., the *clique complex* (each $(k+1)$ -clique becomes a k -cell), limited to cliques of size at most n , or the *cycle complex*.

Message-passing GNNs can be generalized to those lifted graphs.

***A reverse expected shortfall
optimization formula***
Y. Guan et al. (2022)

To minimize the expected shortfall

$$\begin{aligned} \text{ES}_\alpha &= \frac{1}{1-\alpha} \int_\alpha^1 \text{VaR}_\beta(X) d\beta \\ &= \min_{t \in \mathbf{R}} t + \frac{1}{1-\alpha} E[(X-t)_+], \end{aligned}$$

it suffices to minimize a linear function plus the excess mean loss (for each t).

Conversely,

$$E[(X-t)_+] = \max_{\alpha \in [0,1]} (1-\alpha) [\text{ES}_\alpha(X) - t]$$

is useful in worst-case (*i.e.*, robust) optimization.

These formulas generalize to optimized certainty equivalent (OCE) risk measures of the form

$$R[X] = \int_{t \in \mathbf{R}} t + \frac{1}{\beta} E[v(X-t)].$$

***Improved iterative methods
for solving risk parity portfolio***
J. Choi and R. Chen (2022)

***Doubly truncated moment risk measures
for elliptical distributions***
B. Zuo and C. Yin (2022)

The *tail conditional moments* are

$$\begin{aligned} \text{TCM}_{q,n}(X) &= E[(X - \text{TCE}_q X)^n \mid X > x_q] \\ \text{TCE}_q(X) &= E[X \mid X > x_q] \\ x_q &= q\text{-th quantile.} \end{aligned}$$

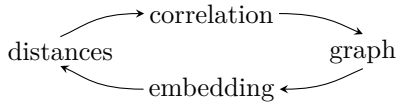

For the doubly truncated moments, replace the condition $X > x_q$ with $x_p < X < x_q$.

Multivariate doubly truncated moments for generalized skew-elliptical distributions with applications to multivariate tail conditional risk measures
B. Zuo and C. Yin (2022)

For many multivariate distributions, one can compute $E[Y|a \leq Y \leq b]$ and $E[YY'|a \leq Y \leq b]$.

RPS: portfolio asset selection using graph-based representation learning
M.A. Fazli et al.

In portfolio optimization, replace the correlation matrix with a similarity matrix computed from the distance matrix of a node embedding (Node2Vec) computed from the complete graph with correlations as weights.

Connecting Sharpe ratio and Student t -statistic, and beyond
E. Benhamou

If $X \sim N(\mu, \sigma^2)$, the $\widehat{SR} = \hat{\mu}/\hat{\sigma}$ is (non-centered) Student.

The statistics of Sharpe ratios
A.W. Lo (2002)

For iid returns,

$$\sigma(\widehat{SR}) = \sqrt{\frac{1 + \frac{1}{2}SR}{T}}.$$

For non-iid returns, annual and monthly Sharpe ratios are related by ($q = 12$)

$$\frac{SR(q)}{SR} = \frac{q}{\sqrt{q + 2 \sum_{k=1}^{q-1} (q-k)\rho_k}}.$$

In particular, for AR(1) returns,

$$\frac{SR(q)}{SR} = \sqrt{q} \left[1 + \frac{2\rho}{1-\rho} \left(1 - \frac{1-\rho^q}{q(1-\rho)} \right) \right]^{-1/2}.$$

The variance of \widehat{SR} increases by

$$\frac{\text{Var } \widehat{SR}(q)}{\text{Var } \widehat{SR}} = 1 + \frac{2 \sum_{j=1}^{q-1} (1-j/q)^2}{1 + 2/SR^2}.$$

Multi-portfolio internal rebalancing processes
K. Francis-Staite (2022)

The (internal) rebalancing problem

i : asset class

j : portfolio

a_i : value of asset class i

p_j : value of portfolio j

M_{ij} : desired proportion of asset class i in portfolio j

where $\sum_i M_{ij} = 1$, $\sum a_i = \sum p_j$, looks for A , as close to M as possible (in some sense), such that $\sum_i A_{ij} = 1$ and $Ap = a$ (one may add a constraint $\forall ij \ M_{ij} = 0 \Rightarrow A_{ij} = 0$).

In *banker rebalancing*, all the portfolios except one (the banker) are given their target allocation; the banker receives the remaining funds. In *linear rebalancing*, each asset class is considered separately, and the over-/under-weights are distributed equally (not in proportion of the weight of the portfolio). *Market-invariant rebalancing* is more equitable.

Modeling bid and ask price dynamics with an extended Hawkes process and its empirical applications for high-frequency stock market data
K. Lee and B.K. Seo

Four-dimensional Hawkes process, for the up and down bid and ask movements

$$\lambda_t = \mu_t + \int_{-\infty}^t e^{-\beta(t-u)} A_u dN_u$$

where μ_t and A_t are observed (or $A \in \mathbf{R}^{4 \times 4}$ constant).

Multi-asset spot and option market simulation
M. Wiese et al. (2021)

Do not directly generate a grid of call prices (for various expiries and strikes) but a grid of *discrete local volatilities* (DLV)

$$\sigma_{tk} = \sqrt{\frac{\theta_{tk}}{\frac{1}{2}k^2 \Delta t \Gamma_{tk}}}$$

$$\theta_{tk} = C_{t+\Delta t, k} - C_{t, k} \approx \partial_t C_{tk}$$

$$\Gamma_{tk} \approx \partial_{kk} C_{tk}$$

to enforce the “no static arbitrage” constraint.

Reduce the dimension of the DLV grid (from 26 to 3) with an auto-encoder $\sigma \mapsto x \mapsto \sigma$.

Train a conditional model $x_{t+1}|x_t, x_{t-1}$ with a normalizing flow

$$u_{t+1} \sim U(0, 1)^3$$

$$x_{t+1} \leftarrow f(u_{t+1}; x_t, x_{t-1}).$$

The result still has a drift: it is not a martingale.

For several assets, sample u_{t+1} from a Gaussian copula with a block structure (or a non-parametric, flow-based copula).

Risk-neutral market simulation **M. Wiese and P. Murray (2022)**

Remove the drift by reweighting the samples (the weights are the solution of a convex optimization problem).

Lazy prices **L. Cohen et al (2019)**

Changes in 10K reports have a (negative) predictive power (earnings, profitability, news, bankruptcies), especially the “risk factor” section and statements about the executive team (CEO, CFO) and litigation.

Introduction to causal inference **B. Neal (2020)**

1. Simpson’s paradox shows that omitting important variables can lead to the opposite conclusion: for instance, if two treatments are available for some medical condition, a non-invasive and an invasive one, the former used mostly for mild conditions and the latter for more severe ones, the invasive one can appear worse on the whole population, even though it is better on both sub-populations, simply because it tends to be used mostly on difficult patients.

But a different causal graph, e.g.,

(if the invasive treatment is administered with delays, letting the patient’s condition worsen), the same numbers lead to the opposite conclusion.

2. The **potential outcomes** $Y_i(0)$ and $Y_i(1)$ are the values of the outcome Y for subject i if it does not ($T = 0$) or does ($T = 1$) receive the treatment.

We only observe one of them,

i	T	Y	$Y(1)$	$Y(0)$	$Y(1) - Y(0)$
1	0	0	?	0	?
2	1	1	1	?	?
3	1	0	0	?	?
4	0	0	?	0	?
5	0	1	?	1	?
6	1	1	1	?	?

and we are interested in their differences, the *individual treatment effect*

$$\text{ITE}_i = Y_i(1) - Y_i(0)$$

or the *average treatment effect*

$$\text{ATE}_i = E[Y_i(1) - Y_i(0)].$$

In general, it is different from the *associational difference*, which is easy to compute.

$$\text{ATE} \neq E[Y|T = 1] - E[Y|T = 0]$$

They are equal if the *ignorability* (or *exchangeability*) assumption is satisfied:

$$Y(0), Y(1) \perp\!\!\!\perp T.$$

(We can ignore how the subjects were selected for the treatment; the treated and the control groups are comparable). This is the case for *randomized control trials* (RCT). More generally, if the *unconfoundedness* assumption is satisfied

$$Y(0), Y(1) \perp\!\!\!\perp T | X,$$

we can compute the ATE with the **adjustment formula**

$$\begin{aligned} \text{ATE} &= E[Y(1) - Y(0)] \\ &= E_X [E[Y | T = 1, X] - E[Y | T = 0, X]]. \end{aligned}$$

A few more assumptions are actually needed:

- Unconfoundedness;
- Positivity (overlap): the supports of $X | T = 0$ and $X | T = 1$ are the same, *i.e.*, all subgroups of data appear both in $[T = 1]$ and $[T = 0]$;
- Consistency: no multiple versions of the treatment;
- No interference: $Y_i(t_i)$ does not depend on $t_j, j \neq i$.

Causal inference has two steps:

- *Identification*, *i.e.*, converting a *causal estimand* (e.g., the ATE) into a *statistical estimand* (e.g., the adjustment formula);
- *Estimation*, *i.e.*, computing the statistical estimand from the data (this often involves some statistical or machine learning model).

3. A *Bayesian network* is a DAG encoding a joint probability distribution as

$$P(x_1, \dots, x_n) = \prod_i P(x_i | \text{pa}_i).$$

In particular, X_i is independent of its non-descendants given its parents (*local Markov assumption*). If adjacent nodes are dependent, the DAG is *minimal*.

Association flows along *chains*, *forks* and conditioned **immoralities** (*colliders*, *v-structures*)

Association is blocked by conditioned chains, conditioned forks, unconditioned immoralities (for immoralities, we need to condition, or avoid conditioning, on any descendant of the immorality).

Blocked paths contain one of

Unblocked paths only contain

Two nodes are **d-separated** if all paths between them are blocked; *d*-separation implies conditional independence (global Markov property).

$$X \perp\!\!\!\perp_G Y | Z \implies X \perp\!\!\!\perp_P Y | Z$$

4. Causal quantities, such as $P[Y|\text{do}(T = t)]$, can be computed

- From the **structural causal model** (SCM) by replacing the equation for T with $T = t$;
- From the Bayesian network factorization, by setting the factor for T to $\mathbf{1}_{T=t}$;
- From the causal graph, by cutting all edges into T (**manipulated graph**).

It is sometimes possible to convert a causal quantity (with the “do” operator) into a statistical one, *i.e.*, computable from observational data (identification). For instance, if W satisfies the **backdoor criterion** $T \rightarrow Y$, *i.e.*,

- W blocks all backdoor (*i.e.*, non-causal) paths from T to Y ;
- W does not contain any descendant of T ,

then, W is a **sufficient adjustment set**:

$$P[Y|\text{do}(T = t)] = \sum_w P[Y, t, w]P[w]$$

(*backdoor adjustment*).

Beware of *M-bias*: in the following graph, do not condition on Z – it opens a backdoor path.

5. In **randomized experiments**, association is causation. This can be seen by:

- Covariate balance: the treatment and the control groups are identical

$$P[X | T = 1] \stackrel{d}{=} P[X | T = 0]$$

- Exchangeability (unconfoundedness)

$$E[Y(1) | T = 1] = E[Y(1) | T = 0]$$

$$E[Y(0) | T = 0] = E[Y(0) | T = 1]$$

- Absence of backdoor path, because T has no incoming edges: $W = \emptyset$ is a sufficient adjustment set.

6. Backdoor adjustment is sufficient but not necessary for identifiability. For instance, in presence of unobserved confounders W ,

we may be able to use the *frontdoor adjustment*, by separately computing the causal effects $T \rightarrow M$ and $M \rightarrow Y$, and combining them.

$$P[Y|\text{do}(t)] = \sum_m P[m|t] \sum_t P[y|m, t']P[t'].$$

The **do-calculus** gives a complete list of (3) transformations to identify causal quantities, whenever possible.

7. To estimate the ATE with a sufficient adjustment set W ,

$$\begin{aligned} \tau &= E[Y(1) - Y(0)] \\ &= E_W[E[Y | T = 1, W] - E[Y | T = 0, W]] \end{aligned}$$

we can fit a statistical model to

$$\mu(t, w) = E[Y | T = t, W = w]$$

(conditional outcome modeling, COM), or separate models to

$$\mu_0(w) = E[Y | T = 0, W = w]$$

$$\mu_1(w) = E[Y | T = 1, W = w]$$

(grouped conditional outcome modeling, GCOM) or with a neural net learning a representation of w (TAR-Net).

The X -learner approach:

- Fits models $\hat{\mu}_0(x)$, $\hat{\mu}_1(x)$;
- Fits models

$$\hat{\tau}_1(x) = Y(1) - \hat{\mu}_0(x),$$

$$\hat{\tau}_0(x) = \hat{\mu}_1(x) - Y(0);$$

- Combines them

$$\hat{g}(x)\hat{\tau}_0(x) + (1 - g(x))\hat{\tau}_1(x)$$

for some $g : \mathcal{X} \rightarrow [0, 1]$, e.g., the propensity score, or 1/2, or 0, or 1.

The conditioning set W can be high-dimensional, but it can be replaced with the (1-dimensional) *propensity score* $e(w) = P[T = 1 | W = w]$:

$$Y(0), Y(1) \perp\!\!\!\perp W \implies Y(0), Y(1) \perp\!\!\!\perp e(W).$$

In particular,

$$E[Y(t)] = E \left[\frac{\mathbf{1}_{T=t} \cdot Y}{P[t|W]} \right].$$

The propensity score is unknown, but can be estimated, leading to the *inverse propensity weighting* (IPW) estimator

$$\hat{\tau} = \text{Mean}_{i: t_i=1} \frac{y_i}{\hat{e}(w_i)} - \text{Mean}_{i: t_i=0} \frac{y_i}{1 - \hat{e}(w_i)}$$

(to trade variance for bias, trim the propensity scores \hat{e} to $[\varepsilon, 1 - \varepsilon]$).

Other methods include:

- Doubly robust methods, which model both $\mu(t, w)$ and $e(w)$;
- Matching;

- Double machine learning:

$$\text{res}(Y \sim W) \sim \text{res}(T \sim W);$$

- Causal trees and forests.

For confidence intervals, use the bootstrap.

8. The *observational-counterfactual decomposition* of the ATE

$$\tau = E[T(1) - Y(0)]$$

$$= P[T = 1] E[Y|T = 1] + P[T = 0] E[Y(1)|T = 0]$$

$$- P[T = 1] E[Y(0)|T = 1] + P[T = 0] E[Y|T = 0]$$

gives **bounds** on τ , (rather large but) finer if we make more assumptions, such as:

- Monotone treatment response: $\forall i Y_i(1) \geq Y_i(0)$;
- Monotone treatment selection

$$E[Y(1)|T = 1] \geq E[Y(1)|T = 0]$$

$$E[Y(0)|T = 1] \geq E[Y(0)|T = 0];$$

- Optimal treatment selection

$$Y_i = 1 \implies Y_i(1) \geq Y_i(0)$$

$$Y_i = 0 \implies Y_i(0) \geq Y_i(1).$$

Sensitivity analysis examines the question “how strong should the effect of an unobserved confounder W on T and Y be for the causal effect of T on Y to drop below some threshold” (as a contour plot, causal effect \sim confounding effects).

7. Instrumental variables allow identification in presence of unobserved confounders, but they require parametric assumptions.

For instance, if the structural equations are linear, we can measure α and $\alpha\delta$ and use the *Wald estimand*

$$\delta = \frac{E[Y | Z = 1] - E[Y | Z = 0]}{E[T | Z = 1] - E[T | Z = 0]}.$$

In the continuous linear setting,

$$\delta = \frac{\text{Cov}(Y, Z)}{\text{Cov}(T, Z)};$$

it can also be estimated with *2-stage least squares* (2sls)

$$\text{lm}(Y \sim \text{predict}(T \sim Z)).$$

If the instrument is an encouragement to take the treatment, we can stratify the population into

- Compliers: $T = Z$;

- Always-takers: $T = 1$;
- Always deniers: $T = 0$;
- Defiers: $T = \neg Z$.

If there are no defiers (*monotonicity*), we can compute the *complier average causal effect*, non-parametrically, still with the Wald estimand.

$$\begin{aligned} \text{CACE} &= E[Y(1) - Y(0) | T(1) = 1, T(0) = 0] \\ &= \frac{E[Y | Z = 1] - E[Y | Z = 0]}{E[T | Z = 1] - E[T | Z = 0]} \end{aligned}$$

10. Adding a time dimension

and making the *parallel trends assumptions*

$$Y_1(0) - Y_0(0) \perp\!\!\!\perp T,$$

the *average treatment effect on the treated* (ATT) can be estimated with the **difference-in-differences**

$$\begin{aligned} \text{ATT} &= E[Y_1(1) - Y_0(0) | T = 1] \\ &= E[Y_1 - Y_0 | T = 1] - E[Y_1 - Y_0 | T = 0]. \end{aligned}$$

(But the parallel trends assumption is not stable under data transformations, e.g., log.)

11. Conditional independence and d -separation are equivalent if the graph is Markov and *faithful* to the probability distribution.

Faithfulness is not always possible: some effects could cancel out.

Two graphs are *Markov equivalent* iff they have the same *skeleton* and *immoralities*.

The **PC algorithm** identifies the Markov equivalence class of a probability distribution:

- Find the skeleton, with conditional independence tests;
- Find the immoralities, with conditional independence tests;
- Orient the remaining edges, whenever possible, assuming we have detected all the immoralities.

In the linear Gaussian setting, we cannot distinguish between $A \rightarrow B$ and $A \leftarrow B$, but in the

- Linear, non-Gaussian noise,
- Or nonlinear, additive noise

settings, we can.

12. While it is not possible to identify the essential graph $A \rightarrow B$, it is possible with **interventions**. For instance, an intervention on B gives

For $n \geq 3$, $n - 1$ 1-node interventions are sufficient. For multinode interventions, $\lceil \log_2 n \rceil + 1$, or $\lceil \log_2 c \rceil$ are sufficient (and necessary, in the worst case), where c is the size of the largest clique, if you already know the essential graph.

There are similar results for parametric interventions, *i.e.*, if we change $P[X_i | \text{pa}_i]$ instead of removing pa_i .

13. Covariate shift refers to the situation where the distribution of (x, y) changes between training and testing, but that of $y|x$ remains. More generally, let us assume that the distribution of x changes e.g., through some (possibly unknown) intervention, but the causal structure remains. Without intervention, we can predict Y from its *Markov blanket* (parents, children, lovers),

but with intervention, we should only use the *causal parents* of Y .

To study the *transportability* of causal effects across populations, add a “selection node” to indicate which nodes have their causal mechanism changed.

14. Counterfactuals, such as $P[Y(t) | T = t', Y = y]$, can be computed from a structural causal model, but they cannot be written with the do operation, or obtained from observations.

For instance, $Y := UT + (1 - U)(1 - T)$, where

- $Y = 1$ happy
- $T = 1$ get a dog
- $U = 1$ dog person.

If we observe $T = 0$, $Y = 0$, we can compute U (*abduction*), modify the SCM by setting $T := t$, and compute $Y(t)$. If $Y = f(U)$ is not invertible, use a prior on U to get a *probabilistic counterfactual*.

While unit-level counterfactuals require an SCM, *population-level counterfactuals* $E[Y(t)|T = t']$ can be computed as the CATE (“potential outcome calculus” generalizes do-calculus).

Causal inference: what if
M.A. Hernán and J.M. Robins (2020)

***DoWhy: an end-to-end library
for causal inference***
A. Sharma and E. Kiciman

Causal inference requires 4 steps:

- Provide the causal graph and specify the “treatment” and “outcome” variables;
- Identify the ATE (average treatment effect), *i.e.*, convert the causal estimand $E[Y|\text{do}(X = x)]$ into a statistical estimand (*i.e.*, something computable from observational data): backdoor criterion, front-door criterion, instrumental variables, etc.
- Compute the ATE (propensity score, linear regression, 2-stage least squares, etc.)
- Robustness tests:
 - Add a random variable;
 - Replace the treatment with a random variable (placebo), or the outcome;
 - Use a subset of the data;
 - Add an unmeasured common cause.

***Approximate kernel-based
conditional independence tests
for fast non-parametric causal discovery***
E.V. Strobl and S. Visweswaran

Replace X, Y, Z with random Fourier features and define $\Sigma_{XY \cdot Z} = \Sigma_{XY} - \Sigma_{XZ}\Sigma_{ZZ}^{-1}\Sigma_{ZY}$; then $\Sigma_{XY \cdot Z} = 0$ iff $X \perp\!\!\!\perp Y|Z$.

R implementation in RCIT.

***Learning functional causal models
with generative neural networks***
O. Goudet et al.

The causal generative neural network (CGNN) builds a functional causal model (FCM) by combining

- A global approach, selecting a (small number of) CPDAG(s)
- And a local approach (explaining the asymmetry between $Y = f(X)$ and $X = f(Y)$ – one is often simpler than the other), fitting models of the form $X_i = f(\text{pa}_i, E_i)$ where f is a shallow network and the E_i ’s are independent noises selecting the best generative model by looking at the maximum mean

discrepancy (MMD)

$$\text{MMD}(\mathcal{D}, \hat{\mathcal{D}}) = \frac{1}{n^2} \sum_{ij} k(x_i, x_j) + \frac{1}{n^2} \sum_{ij} k(\hat{x}_i, \hat{x}_j) - \frac{1}{n^2} \sum_{ij} k(x_i, \hat{x}_j)$$

for some kernel k (e.g., Gaussian).

***Structural agnostic modeling:
adversarial learning of causal graphs***
D. Kalainathan et al.

For each variable X_i , train a neural network $X_i = f(a_i \odot X_{\setminus i}, E_i)$, where the a_i ’s are binary gates (with penalties to ensure sparsity and acyclicity).

***Efficient differentiable quadratic programming
layers: an ADMM approach***
A. Butler and R.H. Kwon (2021)

Quadratic optimization problems

$$\begin{array}{ll} \text{Find} & z \\ \text{To minimize} & \frac{1}{2} z' Q z + z' p \\ \text{Such that} & A z = b \\ & \ell \leq z \leq u \end{array}$$

can be solved with ADMM

$$\begin{aligned} f(x) &= \frac{1}{2} z' Q z + z' p + I_{Ax=b} \\ g(z) &= I_{\ell \leq z \leq u} \end{aligned}$$

$$\begin{array}{ll} \text{Find} & x, z \\ \text{To minimize} & f(x) + g(z) \\ \text{Such that} & x = z; \end{array}$$

each step can be solved analytically.

$$\begin{aligned} x &\leftarrow \underset{x: Ax=b}{\text{Argmin}} \frac{1}{2} x' Q x + x' p + \frac{\rho}{2} \|x - z + \mu\|^2 \\ z &\leftarrow \underset{\ell \leq z \leq u}{\text{Argmin}} \|x - z + \mu\|^2 \\ \mu &\leftarrow \mu + x - z \end{aligned}$$

It can also be used for optimization as a layer (when Q, p, A, b, ℓ, u depend on θ): to compute the gradient, use the fixed point property of the ADMM iteration: it is less computationally-intensity than the KKT conditions.

1. Machine learning on graphs covers the following tasks:

- Node classification,
- Relation prediction,
- Graph classification (or regression)

but also: node clustering (community detection), graph clustering, etc.

2. Traditional node and graph features include: degree, centralities (eigenvector, closeness, betweenness), clustering coefficient (different normalizations), graphlet count, Weisfeiler-Lehman kernel, path-based kernel (e.g., distribution of degree sequences in random walks, or in shortest paths).

Measures of neighbourhood overlap include:

$$\frac{|N(u) \cap N(v)|}{d_u + d_v}, \quad \frac{|N(u) \cap N(v)|}{\sqrt{d_u d_v}}, \quad \frac{|N(u) \cap N(v)|}{|N(u) \cup N(v)|}$$

$$\sum_{w \in N(u) \cap N(v)} \frac{1}{d_w}, \quad \sum_w \frac{1}{\log d_w}, \quad \sum \beta^i (A^i)_{uv};$$

some can be directly computed from the adjacency matrix:

$$(I - \beta A)^{-1} - I, \quad D^{-1}(I - \beta A)^{-1}D^{-1}.$$

The graph Laplacian $L = D - A$ satisfies

$$x' L x = \sum_{u,v \in E} (x_u - x_v)^2;$$

it is often normalized as $L_{\text{sym}} = D^{-1/2} L D^{1/2}$ or $L_{\text{rw}} = D^{-1} L$. The *ratio cut* and *normalized cut*

$$\text{RCut}(\mathcal{A}_1, \dots, \mathcal{A}_n) = \sum_k \frac{|(u, v) \in E : u \in \mathcal{A}_k, v \notin \mathcal{A}_k|}{|\mathcal{A}_k|}$$

$$\text{NCut}(\mathcal{A}_1, \dots, \mathcal{A}_n) = \sum_k \frac{|(u, v) \in E : u \in \mathcal{A}_k, v \notin \mathcal{A}_k|}{\sum_{u \in \mathcal{A}_k} d_u}$$

are maximized (after relaxation) by the second smallest eigenvector of L or L_{rw} . Spectral clustering applies k -means to the smallest eigenvectors of L .

3. We can compute node embedding with an encoder-decoder architecture (for a fixed graph)

$$\begin{aligned} \text{ENC} : \quad & V \longrightarrow \mathbf{R}^d \\ \text{DEC} : \quad & \mathbf{R}^d \times \mathbf{R}^d \longrightarrow \mathbf{R}^+. \end{aligned}$$

The decoder could be $(a, b) \mapsto \|a - b\|^2$, $a'b$, or $e^{a'b}$; the loss could be $\text{DEC}(z_u, z_v) \cdot S_{u,v}$, $\|\text{DEC}(z_u, z_v) - S_{u,v}\|$, $-S_{u,v} \log \text{DEC}(z_u, z_v)$ for some node similarity measure S , e.g., $S = A$, or $S = (A, A^2, \dots, A^k)$, or some node neighbourhood overlap measure.

These can often be seen as matrix factorizations, e.g.,

$$\underset{Z}{\text{Minimize}} \|ZZ' - S\|_2^2,$$

or random walk embeddings.

Those shallow embeddings have limitations.

4. These decoders can be generalized to multirelational graphs, e.g., knowledge graphs (KG), and matrix factorizations become tensor factorizations:

$$\begin{aligned} & z'_u R_\tau z_v \\ & - \|z_u + r_\tau - z_v\| \\ & - \|g_{1,\tau}(z_u) + r_\tau = g_{2,\tau}(z_v)\| \\ \langle z_u, r_\tau, z_v \rangle &= \sum_i z_{ui} r_{\tau i} z_{vi} \\ \text{Re} \langle z_u, r_\tau, \bar{z}_v \rangle & \\ & - \|z_u \odot r_\tau = z_v\| \end{aligned}$$

(the complex decoder allows for asymmetric relations).

5. GNNs are neural networks transforming the adjacency matrix of a graph in a permutation-equivariant (or -invariant) way: $f(PAP') = Pf(A)$ (or $f(PAP') = f(A)$), by message passing:

$$\begin{aligned} m_{N(u)} &\leftarrow \text{AGGREGATE}(\{h_v, v \in N(u)\}) \\ h_u &\leftarrow \text{UPDATE}(h_u, m_{N(u)}). \end{aligned}$$

It is common to add self-loops and omit the explicit update step:

$$h_u \leftarrow \text{AGGREGATE}(\{h_v, v \in N(u) \cup \{u\}\}).$$

The aggregation can be

$$m_u = \sum_v h_v \quad (\text{GNN})$$

$$m_u = \frac{1}{|N(u)|} \sum_v h_v$$

$$m_u = \sum_v \frac{h_v}{\sqrt{|N(u)||N(v)|}} \quad (\text{GCN}).$$

The sum can be replaced by

$$m_u = \text{MLP}\left(\sum_{v \in N(u)} \text{MLP}(h_v)\right)$$

$$m_u = \text{MLP}\left(\frac{1}{|N(u)|!} \sum_{\pi \in \mathfrak{S}_{|N(u)|}} \text{LSTM}(h_{v_1}, \dots, h_{v_{|N(u)|}})\right)$$

(approximated with a random set of permutations, or even a single one, corresponding to some canonical ordering, e.g., by degree).

We can also add attention

$$\begin{aligned} m_{N(u)} &= \sum_v \alpha_{u,v} h_v \\ \alpha_{u,v} &\propto \exp a'[Wh_u \oplus Wh_v] \quad (\text{GAT}) \\ \alpha_{u,v} &\propto \exp(h'uWh_v) \quad (\text{bilinear attention}) \\ \alpha_{u,v} &\propto \exp \text{MLP}(h_u, h_v). \end{aligned}$$

To limit oversmoothing, try skip connections, gated updates,

$$h_u \leftarrow \text{GRU}(h_u, m_{N(u)})$$

or jumping knowledge (JK) connections.

GNNs can be generalized to multirelational graphs, *i.e.*, graph with several edge types (or edge features).

Graph pooling is needed for graph-level predictions:

- Sum or mean aggregation of the node embeddings
- Attention with LSTM:

$$\begin{aligned} q &\leftarrow \text{LSTM}(o, q) \\ e_v &\leftarrow f(z_v, q) \\ a_v &\propto \exp e_v \\ o &= \sum a_v z_v \end{aligned}$$

- Graph coarsening

$$\begin{aligned} A &\leftarrow S'AS \\ X &\leftarrow S'X \end{aligned}$$

for some cluster assignment matrix S .

6. Pretraining with neighbourhood reconstruction loss does not work well. Try to maximize the mutual information between node embeddings and graph embeddings:

$$- \mathbb{E}_{\text{data}} \log D(z_u, z_G) - \mathbb{E}_{\text{corrupted data}} \log(1 - D(\tilde{z}_u, z_G)).$$

For deep networks, use gated updates.

7. A GNN layer is a convolution: it can be expressed without message passing, with the adjacency matrix A , or $A_{\text{sym}} = D^{-1/2}AD^{-1/2}$, or some Laplacian, $L = D - A$, $L_{\text{sym}} = D^{-1/2}LD^{-1/2}$

$$Z = \text{MLP}(f(A) \text{MLP}(X))$$

with, *e.g.*,

$$\begin{aligned} f(A) &= \sum (I - \alpha \tilde{A})^k \\ \tilde{A} &= (D + I)^{-1/2}(A + I)(D + I)^{-1/2}. \end{aligned}$$

GNNs reproduce the operations in the Weisfieler-Lehman graph isomorphism test (which cannot distinguish between \square and ∇ – this is a strong limitation, and breaking it is an open problem).

9. Variational graph autoencoders generate graphs from node embeddings with a dot product decoder:

$$\begin{aligned} \mu, \sigma &= \text{GNN}(A, X) \\ z &\sim N(\mu, \sigma) \\ P[A_{ij} = 1] &= \sigma(z'_i z_j). \end{aligned}$$

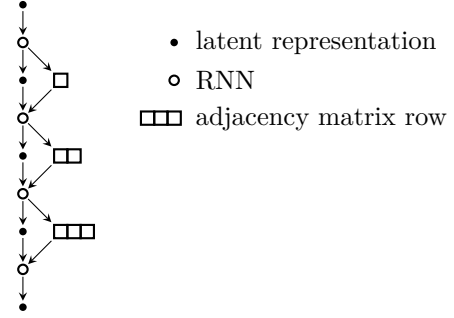

They are good for reconstruction, but not for graph generation. A graph-level VAE uses a graph (not node) embedding and generates an adjacency matrix in one

go: $A = \sigma(\text{MLP}(z_G))$; the nodes of the generated graph need to be matched to the original ones, *e.g.*, with a heuristic ordering.

Autoregressive decoders generate the rows (of the lower triangular part) of A one by one, each conditioned on the previous ones, as with the preferential attachment model

with a graph-level RNN

where each row $\circ \rightarrow \square$ is generated by a node-level RNN

The graph recurrent attention network (GRAN) also generates the rows one by one, but each new row is computed by a GNN on the graph built so far.

NodePiece:
compositional and parameter-efficient representations of large knowledge graphs
M. Galkin et al.

Node embeddings do not scale to very large networks: we would have to learn and store the embedding of all the nodes. Instead, select (a smaller number of) “anchor” nodes (at random), whose preliminary embeddings will be learned, and compute the embeddings of all the nodes on the fly, with a (learned) MLP, taking as inputs the preliminary embeddings of the k closest anchors, their distances (numbers of hops), and the features of the edges to/from that node.

Graphon pooling in graph neural networks
A. Parada-Mayorga et al. (2020)

Pooling, in graph neural networks (GNN), is often deterministic and arbitrary. Instead, consider the input graph as a locally constant graphon and sample from it, to have increasingly coarser approximations of the input graph.

There are two ways of sampling from a graphon $W : [0, 1]^2 \rightarrow [0, 1]$: either pick points at random $x_i \sim U(0, 1)$ and link them with probabilities $W(x_i, x_j)$, or randomly partition the interval $[0, 1]$ into $\sqcup U_i$ and link nodes i and j with probability $\iint_{U_i \times U_j} W(x, y) dx dy / |U_i \times U_j|$; use the latter.

**DDG-DA: data distribution generation
for predictable concept drift adaptation**
W. Li et al. (2022)

To deal with slow concept drift, forecast the evolution of the data distribution to adapt the model.

**Conditional Sig-Wasserstein GANs
for time series generation**
H. Ni

By analogy with the Wasserstein distance

$$W_1(\mu, \nu) = \sup_{f: X \rightarrow \mathbf{R}} \mathbb{E}_{X \sim \mu} f(X) - \mathbb{E}_{X \sim \nu} f(X),$$

$$\|f\|_{\text{Lip}} \leq 1$$

define the signature-Wasserstein distance between (distributions on) time series

$$\text{Sig-}W_1(\mu, \nu) = \sup_{\substack{L \text{ linear} \\ \|L\|_2 \leq 1}} L \left(\mathbb{E}_{X \sim \mu} S(X) - \mathbb{E}_{X \sim \nu} S(X) \right)$$

$$= \left\| \mathbb{E}_{X \sim \mu} S(X) - \mathbb{E}_{X \sim \nu} S(X) \right\|_2$$

$$\approx \left\| \mathbb{E}_{X \sim \mu} S_M(X) - \mathbb{E}_{X \sim \nu} S_M(X) \right\|_2$$

(this is the MMD (maximum mean discrepancy) with the truncated signature S_M as features).

For time series continuation, $\mathbb{E}[S(X_{>t})|X_{\leq t}]$ can be computed by linear regression $S(X_{>t}) \sim S(X_{\leq t})$.

Use as a discriminator, with generator:

To compute the signature: `signatory` (Python).

**Fractional SDE-Net: generation
of time series data with long-term memory**
K. Hayashi and K. Nakagawa (2022)

Neural ODEs can be generalized to neural SDEs (by adding noise) and neural fractional SDEs (if $H \neq \frac{1}{2}$, Itô calculus no longer applies but, for $H > \frac{1}{2}$, we can still define a stochastic integral).

**Holdout-based fidelity and privacy assessment
of mixed-type synthetic data**
M. Platzer and T. Reutterer

To measure fidelity and privacy risk of generated data, look at:

- 1- and 2-dimensional distributions;
- The distance to the closest observation in the training data

and compare them with the holdout set.

Multi-asset spot and option market simulation
M. Wiese et al.

Generate synthetic time series with normalizing flows

$$(\mathcal{F}_t, Z_{t+1}) \mapsto X_{t+1}$$

$$Z_{t+1} \leftarrow (\mathcal{F}_t, X_{t+1})$$

where X is observed, Z latent, and $\mathcal{F}_t = (X_t, X_{t-1}, \dots)$. For option prices, enforcing the no-arbitrage condition complicates things.

**A hybrid deep learning approach to
purchasing strategy of carbon emission rights**
J. Xu and Y. Fu

Stack GARCH and GRU to forecast carbon emission prices.

Predictors include carbon markets, equity index, FX, energy (oil, etc.), futures, industrial indices, air quality.

**Cryptocurrency valuation:
an explainable AI approach**
Y. Liu and L. Zhang

“Fundamental ratios” for crypto currencies, such as miners’ earnings/price, market value/traded value, market value/number of users², are bad predictors of future returns. Instead, the utility/price ratio has some predictive power on long-term returns.

$$\text{utility} = \frac{\text{velocity} \times \text{staking ratio}}{\text{volatility} \times \text{dilution rate}}$$

$$\text{velocity} = \frac{\text{tokens traded (past day)}}{\text{tokens available}}$$

$$\text{staking ratio} = \frac{\text{inactive tokens (past year)}}{\text{tokens available}}$$

$$\text{dilution rate} = \text{token supply annual growth rate}$$

**Price impact of order flow imbalance:
multi-level, cross-sectional and forecasting**
R. Cont et al. (2021)

The order flow imbalance (OFI) is the difference between:

- The change in bid volume at level m and
- The change in ask volume at level m ;

normalize by dividing with the volume in levels up to m ; aggregate by taking the first principal component of $\text{ofi}_1, \dots, \text{ofi}_{10}$; use to explain contemporaneous returns, or forecast future returns; also try to use the ofi_m or $\text{PC}_1(\text{ofi})$ of other stocks (lasso).

Analysis of a five-factor capital market model
S.F. Jarnier and M. Preisel (2017)

The Munk capital market model is

$$\begin{aligned} dr &= \kappa(\bar{r} - r)dt + \sigma dW && \text{short interest rate} \\ dS/S &= (r + x)dt + \sigma dW && \text{stock index} \\ dx &= \alpha(\bar{x} - x)dt + \sigma dW && \text{equity risk premium} \\ dI/I &= \pi dt + \sigma dW && \text{price index (inflation)} \\ d\pi &= \beta(\bar{\pi} - \pi)dt + \sigma dW && \text{expected inflation} \end{aligned}$$

Optimal portfolio choice and stock centrality for tail risk events
C. Katsouris (2021)

Replace the variance matrix with the VaR matrix:

$$\begin{aligned} P[R_i \leq \text{VaR}_i^\alpha] &= \alpha \\ P[R_i \leq \text{CoVaR}_{ij}^\alpha | R_j \leq \text{VaR}_j^\alpha] &= \alpha \\ \Delta \text{CoVaR}_{ij} &= \text{CoVaR}_{ij} - \text{VaR}_{ij} \\ V_{ii} &= \text{VaR}_i^+ \\ V_{ij} &= \sqrt{\text{VaR}_i^+ \text{VaR}_j^+ \Delta \text{CoVaR}_{ij}} \\ \tilde{V} &= \frac{1}{2}(V + V') \end{aligned}$$

Optimal trend following portfolios
S. Valeyre (2022)

To estimate the trend, also use inter-asset cross-correlations. The maximum Sharpe portfolio is then $w \approx C^{-1}(\alpha C_\xi + \beta \mu \mu') C^{-1}$, where C is the variance matrix of the asset returns, and C_ξ that of the stochastic trend.

$$\begin{aligned} X_{it} &= \mu_i + \sum_{s < t} S_{t-s} \xi_{is} + \varepsilon_{it} \\ C_t &= \text{Var } X_{\cdot, t} \quad C_{\xi t} = \text{Var } \xi_{\cdot, t} \end{aligned}$$

The agnostic risk parity portfolio is the risk parity portfolio on the first eigenvectors of the variance matrix.

From tether to libra: stablecoins, digital currency and the future of money
A. Lipton et al.

Stable coins are often classified according to their collateral (fiat-, commodity-, crypto- or uncollateralized). Instead, look if the ability to redeem the coin is guaranteed by a legal framework, technology, or not guaranteed.

Combining reinforcement learning and inverse reinforcement learning for asset allocation recommendations
I. Halperin et al.

IRL learns a reward function from trajectories. T-REX is an IRL algorithm learning the reward function from non-optimal trajectories: for this, it relies on extra information, viz a ranking of all trajectories.

Combine RL and IRL:

- Learn the reward function of a group of portfolio managers (following the same type of strategy);
- Solve the corresponding RL problem, to improve their decisions.

To deal with the paucity of data, aggressively reduce the dimension to sector weights (for the benchmark and the strategies).

Limiting spectral distribution of high-dimensional Hayashi-Yoshida estimator of integrated covariance matrix
A. Chakrabarti and R. Sen (2022)

The Hayashi-Yoshida estimator of the integrated covariance matrix

$$\Sigma_{HY}^{X,Y} = \sum_{ij} \Delta X_i \cdot \Delta Y_j \cdot \mathbf{1}_{I_i^X \cap I_j^Y \neq \emptyset}$$

is inconsistent and unreliable in high dimension.

Tone at the top? Quantifying management presentation
Wolfe Research (2018)

Extract the following features from call transcripts:

- Readability
- Tone (Harvard-IV, Loughran-McDonald, Vader)
- POS (proportion of adjectives, adverbs (subjectivity), first-person singular vs plural pronouns)
- Ratio of digits to letters
- Number of analysts participating
- Topics (LDA), after removing sector-specific words or phrases (otherwise, the topics just identify the sectors)
- Change in those features.

and forecast future returns or earnings surprises.

Text mining form 8-K disclosures
Wolfe Research (2020)

Companies need to report “material information” within 4 days in SEC form 8-K. Forecast future returns (event study) with:

- Filing frequency;
- Positive and negative sentiment;
- Readability;
- Proportion of numbers in the text;
- Filing delay;
- Event abnormal return;
- Event type (SEC classification).

Network of economically-linked firms
Wolfe Research (2021)

Use the average momentum (k -month, or k -month minus 1-month) of nearby firms to forecast future returns, where “nearby” is determined by:

- Business segment

- Geographic exposure (US, CA, EU, UK, ANZ, AxJ, JP, CN, EMEA, LATAM, rest);
- Number of sell-side analysts in common;
- Key executives
- Patent citations;
- Supply chain (bipartite graph of landlords and tenants for REITs in the Russell 3000);
- Shipping network.

***NLP 5G Evolution:
text mining global corporate filings
Wolfe Research (2019)***

Compute the following features on 10K/10Q filings:

- Conformity to the SEC's requirements;
- YoY or QoQ similarity with the previous one (cosine similarity on bags of words, [try (sliced) Wasserstein distance]);
- POS (adjectives, adverbs, pronouns).

Forecast future returns with an ensemble of elastic net and xgboost.

For international companies, build a multilingual sentiment lexicon.

For languages with no spaces: `jieba` (Chinese), `tinysegmenter` (Japanese), `konlpy` (Korean).

***Patent, innovation and alpha
Wolfe Research (2019)***

Innovative industries (more than 50% of the companies have patents) outperform.

Define the R&D intensity as $R\&D/Sales$, or $\log(R\&D/MCap)$, or the residuals of $\log(R\&D) \sim \log(MCap)$.

Compute features from patents:

- Innovation intensity: number of patents in a 3-year window;
- Originality: (effective) number of patent classes or subclasses;
- Number of citations, back-citations, number of unique assignees in citations or back-citations, divided by the number of patents;
- Number of foreign applications;
- Maintenance fee non-payment;
- HITS, PageRank.

Adjust those factors for size (regress against $\log(MCap)$).

***Optimal expected utility risk measures
S. Geissel et al. (2017)***

Risk measures defined from a utility function include:

$$\begin{aligned}\rho^{SR}(X) &= \inf\{\eta : E[u(X + \eta)] \geq q\} \\ \rho^{CE}(X) &= -CE[X] = -u^{-1} E[u(X)] \\ \rho^{OCE}(X) &= -\sup_{\eta} -\eta + E[u(X + \eta)] \\ \rho^{OEU}(X) &= -\sup_{\eta} -\eta + \alpha CE[X + \eta] \quad \alpha \in (0, 1)\end{aligned}$$

***Deep quantile and
deep composite model regression
T. Fissler et al. (2021)***

Quantile regression, for several quantiles, can be fitted with a neural network, with constraints to ensure the quantiles are in the correct order. This can be generalized to “ES regression”: the expected shortfall (ES) is not elicitable (not an M-estimator), but the triplet (quantile, lower ES, upper UE) is.

$$\left(F^{-1}(\tau), \frac{1}{\tau} \int_0^{\tau} F^{-1}, \frac{1}{1-\tau} \int_{\tau}^1 F^{-1}\right)$$

***2T-POT Hawkes model
for dynamic left- and right-tail
quantile forecasts of financial returns
M.F. Tomlinson et al. (2022)***

Model quantiles of a time series with a (2-tailed) peaks-over-threshold Hawkes model (Hawkes model with generalized Pareto excess magnitudes – the GPD parameters are constant) rather than a GARCH model.

***Multinomial backtesting
of distortion risk measures
S. Bettels et al. (2022)***

The *distorsion risk measure* defined by a decreasing $g : [0, 1] \rightarrow [0, 1]$ is

$$\begin{aligned}\rho_g(X) &= \int_{-\infty}^0 (g(P[X > x]) - 1)dx + \int_0^{\infty} g(P[X > x])dx \\ &= \int_0^1 q_X^+(1-u)dg(u) \\ &= \int_0^1 F_X^{-1}(1-u)dg(u) \\ q_X^+(u) &= \sup\{x : F_X(u) \leq u\}.\end{aligned}$$

Examples include:

$$\begin{aligned}g(u) &= 1 - (1 - u)^n & \text{MinVaR: } E[\text{Max}(X_1, \dots, X_n)] \\ g(u) &= u^{1/n} & \text{MaxVaR} \\ g(u) &= 1 - (1 - u^{1/n})^n & \text{MinMaxVaR} \\ g(u) &= (1 - (1 - u)^n)^{1/n} & \text{MaxMinVaR} \\ & \text{etc.}\end{aligned}$$

**Decomposable sums and their implications
on naturally quasiconvex risk measures**
Ç. Ararat et al. (2022)

A risk measure is *naturally convex* if

$$\forall X, Y \quad \forall \lambda \quad \exists \mu \quad \rho(\lambda X + (1-\lambda)Y) \leq \mu \rho(X) + (1-\mu)\rho(Y).$$

The *convexity index* of $f : \mathbf{R}^m \rightarrow \bar{\mathbf{R}}$ is

$$c(f) = \sup\{\lambda < 0 : r_\lambda \text{ convex}\} \\ \text{or } c(f) = \sup\{\lambda \geq 0 : r_\lambda \text{ concave}\}$$

where $r_\lambda = e^{-\lambda f(x)}$.

A function of the form

$$s(x_1, \dots, x_n) = f_1(x_1) + \dots + f_n(x_n)$$

is quasi-convex iff

$$c(f_1) + \dots + c(f_n) \geq 0,$$

iff either all the f_i 's are convex, or at most one is non-convex and

$$\frac{1}{c(f_1)} + \dots + \frac{1}{c(f_n)} \leq 0.$$

If the f_i 's are convex,

$$\frac{1}{c(s)} = \sum \frac{1}{c(f_i)}.$$

**Model aggregation for risk evaluation
and robust optimization**
T. Mao et al. (2022)

Given a risk measure $\rho : \mathcal{M} \rightarrow \mathbf{R}$ and an uncertainty set $\mathcal{F} \subset \mathcal{M}$, the worst case risk is

$$\rho^{\text{WR}} = \sup_{F \in \mathcal{F}} \rho(F).$$

Instead, given an order relation \preceq on \mathcal{M} , e.g., first or second order dominance,

$$F \preceq_1 G \text{ iff } \forall u \text{ increasing } \int u dF \leq \int u dG$$

$$F \preceq_2 G \text{ iff } \forall u \text{ increasing convex } \int u dF \leq \int u dG$$

one can consider the *model aggregation risk*

$$\rho^{\text{MA}}(\mathcal{F}) = \rho\left(\bigvee_{F \in \mathcal{F}} F\right).$$

For \preceq_1 and \preceq_2 , the supremum is easy to compute:

$$\begin{aligned} \bigvee_1 \mathcal{F} &= \inf_{F \in \mathcal{F}} F && \text{cdf} \\ \left(\bigvee_1 \mathcal{F}\right)^{-1} &= \sup_{F \in \mathcal{F}} F^{-1} && \text{icdf} \\ \pi_{\bigvee_2 \mathcal{F}} &= \sup_{F \in \mathcal{F}} \pi_F && \text{integrated survival function} \\ \bigvee_2 \mathcal{F} &= 1 + \left(\sup_{F \in \mathcal{F}} \pi_F\right)'_+ \end{aligned}$$

where the integrated survival function is

$$\pi_F = \mathbb{E}_{X \sim F}[(X - x)_+] = \int_x^\infty (1 - F(t)) dt.$$

Under reasonable assumptions on \mathcal{F} ,

$$\begin{aligned} \text{VaR}_\alpha^{\text{MA}, \preceq_1} &= \text{VaR}_\alpha^{\text{WR}} \\ \text{ES}_\alpha^{\text{MA}, \preceq_2} &= \text{ES}_\alpha^{\text{WR}}. \end{aligned}$$

Other risk measures include

$$\text{RVaR}_{\alpha, \beta}(F) = \frac{1}{\alpha - \beta} \int_\alpha^\beta \text{VaR}_s(F) ds \quad \text{range VaR}$$

$$\text{PD}_k(F) = \int_0^1 k s^{k-1} \text{VaR}_s(F) ds \quad \text{power distortion}$$

or the *expectile*, defined as the unique solution $t = \text{ex}_\alpha(F)$ of

$$\alpha \mathbb{E}_{X \sim F}[(X - t)_+] = (1 - \alpha) \mathbb{E}_{X \sim F}[(X - t)_-].$$

Common uncertainty sets include

– The Wasserstein ball around F_0 :

$$W_p(F, F_0) = \left(\int_0^1 |F^{-1}(s) - F_0^{-1}(s)|^p ds \right)^{1/p} \quad \text{dim}=1$$

$$W_p(F, F_0) = \inf_{\substack{X \sim F \\ Y \sim F_0}} (\mathbb{E} \|X - Y\|_a^p)^{1/p}$$

– The mean-variance uncertainty set

$$\mathcal{F}_{\mu, \sigma} = \{F \in \mathcal{M} : \mathbb{E}[F] = \mu \text{ and } \text{Var}[F] = \sigma^2\}$$

**Influence functions
for risk and performance estimators**
S. Zhang et al. (2020)

The functional of an estimator $\hat{\theta}$ is

$$\theta(F) = \lim_{\substack{n \rightarrow \infty \\ r_i \sim F}} \hat{\theta}_n(r_1, \dots, r_n).$$

Its influence function is

$$\begin{aligned} \text{IF}(r, \theta, F) &= \left. \frac{d}{d\gamma} \theta(F_\gamma) \right|_{\gamma=0} \\ F_\gamma &= (1 - \gamma)F + \gamma \delta_r \end{aligned}$$

It satisfies

$$\mathbb{E}_{r \sim F} [\text{IF}(r, \theta, F)] = 0$$

$$\hat{\theta}_n - \theta(F) = \frac{1}{n} \sum \text{IF}(r_i, \theta, F) + \text{remainder}$$

hence

$$\text{Var}[\hat{\theta}_n] \approx \frac{1}{n} \sum \text{IF}^2(r_i, \theta, F_n)$$

(the variance of the estimator is the variance if the IF-transformed returns).

We can compute the IF of most performance measures (Sharpe, Sortino, Rachev, Omega ratios, etc.) and therefore estimate their standard deviation (assuming iid returns).

R implementation in RPEIF and RPESE.

Standard errors of risk and performance estimators for serially correlated returns
X. Chen and R.D. Martin (2019)

If the returns are not iid, the variance should be corrected with the ACF,

$$\text{Var}[\hat{\theta}_n] = \text{E}[\text{IF}^2(r)] + 2 \sum_{k \geq 1} \text{E}[\text{IF}(r_0)\text{IF}(r_k)]$$

which can be computed from the periodogram, which can be smoothed with a GLM model for exponential distributions (polynomial regression with a lasso penalty to control the degree).

PerformanceAnalytics: estimation of higher order moments
D. Cornilly and B.G. Peterson (2020)

Factor model for the skewness and kurtosis tensors.

Dependence model assessment and selection with DecoupleNets
M. Hofert et al. (2022)

Learn a transformation from a known copula in dimension $d \geq 2$ to the uniform copula in dimension 2, and use it for gof tests (try several copulas, and keep that for which the result is closest to uniform).

Continuous-time stochastic gradient descent for optimizing over the stationary distribution of stochastic differential equations
Z. Wang and J. Sirignano (2022)

To find the parameters θ of an SDE

$$dX = \mu_\theta(X)dt + \sigma_\theta(X)dW$$

to minimize

$$F(\theta) = \left\| \mathbb{E}_{Y \sim \pi_\theta} [f(Y) - \beta] \right\|^2$$

where $E[f(Y)]$ are some generalized moments of the invariant distribution π_θ :

$$\begin{aligned} \partial_t \theta &= -2\alpha [f(\bar{X}) - \beta] \tilde{X}' \nabla_x f(X) \\ d\tilde{X} &= (\tilde{X} \partial_x \mu + \partial_\theta \mu)dt + (\tilde{X} \partial_x \sigma + \partial_\theta \sigma)dW \\ dX &= \mu dt + \sigma dW \\ d\bar{X} &= \mu dt + \sigma d\bar{W} \end{aligned}$$

(\tilde{X} estimates $\partial_\theta X$, α is the learning rate).

Multivariate matrix-exponential affine mixtures and their applications in risk theory
E.C.K. Cheung et al. (2021)

The matrix-exponential distribution on $[0, \infty)$, $X \sim \text{ME}(\alpha, T, t)$ has density $f(x) = \alpha e^{T^x t}$, $\alpha \in \mathbf{R}^{1 \times p}$, $T \in \mathbf{R}^{p \times p}$, $t \in \mathbf{R}^{p \times 1}$ and cdf $F(x) = 1 + \alpha e^{T^x t} T^{-1} t$. These are the distributions whose Laplace transform is

rational. They are stable by mixtures and affine mixtures (mixtures $f = \sum c_i f_i$, with potentially negative weights c_i as long as $f \geq 0$).

Multivariate matrix-exponential affine mixtures have density

$$f(x_1, \dots, x_M) = \sum_{1 \leq i_1, \dots, i_M \leq L} p_{i_1, \dots, i_M} f_{i_1}(x_1) \cdots f_{i_M}(x_M).$$

Graph neural networks for asset management
G. Pacreau et al.

Feed pricing data (and your model's alpha) to an LSTM, and the result to a GCN or GAT (or the hypergraph equivalent) to forecast future returns (or their signs), with a penalty to get the correct order (learning to rank)

$$\lambda \sum_{ij} [(\hat{y}_i - \hat{y}_j)(y_i - y_j)]_+.$$

Portfolio selection models based on interval-valued conditional value at risk (ICVaR) and empirical analysis
J. Zhang and K. Zhang (2022)

To extend portfolio construction to return intervals $[x^L, x^U]$, use the elxicographic order of (mean, left) for the objective and replace the constraint $Ax \leq B$ with $a^U x \leq b^U$, $\Gamma(B, Ax) \leq \gamma$, where

$$\begin{aligned} \Gamma(A, B) &= \frac{m(B) - m(A)}{w(B) + w(A)} \\ A &= [a^L, a^U] \\ B &= [b^L, b^U] \\ m(A) &= \frac{1}{2}(a^L + a^U) \\ w(A) &= a^U - a^L \\ \gamma &\in [0, 1] \text{ fixed.} \end{aligned}$$

VaR and CVaR can be similarly generalized to interval-valued random variables.

The growth of relative wealth and the Kelly criterion
A.W. Lo et al. (2017)

The Kelly portfolio f , for two assets a and b with ratio returns X_a and X_b , maximizes

$$\mu(f) = \text{E}[\log(1 + fX_a + (1 - f)X_b)]$$

and satisfies

$$\text{E} \left[\frac{X_a - X_b}{1 + fX_a + (1 - f)X_b} \right] = 0$$

(unless $\text{E}[(1 + X_b)/(1 + X_a)] < 1$ or $\text{E}[(1 + X_a)/(1 + X_b)] < 1$, in which case $f = 1$ or $f = 0$).

Alternatively, given two investors f and g , we can look for f maximizing the relative final wealth $W_f/(W_f + W_g)$.

Fat tails and optimal liability driven portfolios

J. Rosenzweig

In portfolio optimization, replace the variance with some other even moment (larger exponents give an approximation of the minimum return).

Traversing the local polytopes of ReLU neural networks: a unified approach for network verification

S. Xu et al.

A ReLU network defines a piecewise linear function. Each neuron splits the space along a hyperplane: this partitions the space into polytopes, each defined by a set of inequalities; non-redundant inequalities (flipping them gives a non-empty polytope) define the faces of that polytope. Neighbouring polytopes (they differ by the direction of one non-redundant inequality) form a *polytope graph*, which can be explored with breadth-first search (BFS). This graph, with BFS traversal, can be used to prove properties of the network, e.g., existence of local adversarial attacks, or to generate counterfactual samples. Previous approaches used mixed integer programming (MIP), but the polytope graph can be explored with linear programming (LP) alone (to check if a set of linear inequalities defines the empty set).

Explainable neural networks based on additive index models

J. Vaughan et al. (2018)

The explainable neural network (xNN) is an *additive index model*

$$f(x) = \mu + \sum \gamma_i h_i(\beta_i x)$$

where the h_i 's are scalar functions defined by neural nets.

Enhancing explainability of neural networks through architecture constraints

Z. Yang et al.

The generalized additive index model (GAIM, aka projection pursuit learning)

$$f(E[y|x]) = \mu + \sum h_i(w'_i x)$$

can be estimated with neural networks h_i ,

$$f(E[y|x]) = \mu + \sum \beta_i h_i(w'_i x),$$

with an L^1 penalty on both β and w , a smooth penalty on h_i , $\text{Mean}_x h_i''(w_i x)^2$, a normalization constraint for the h_i 's,

$$E[h_i(z)] = 0, \quad E[h_i(z)^2] = 1,$$

imposed by a batchnorm layer, and an orthogonality constraint $W'W = I_k$, i.e., $W \in \text{Stiefel}(p, k)$, imposed with the *Cayley transform*, i.e., by replacing the gradient step

$$W \leftarrow W - \tau G, \quad G = \nabla_W \mathcal{L}$$

with

$$A = GW' - WG'$$

$$W \leftarrow \left(I + \frac{\tau}{2} A \right)^{-1} \left(I - \frac{\tau}{2} A \right) W.$$

GAMI-Net: an explainable neural network based on generalized additive models with structured interactions

Z. Yang et al.

One can estimate a GAM, with neural networks instead of (1- and 2-dimensional) splines, and with:

- Pruning of less important main effects (proportion of explained variance);
- Pairwise interactions, estimated on the residuals of the main effects model, only for pairs for which one variable has already been selected, chosen by looking at the proportion of variance explained by forests of shallow trees on each pair, pruned as above;
- An orthogonality penalty

$$\sum_{ij} \text{Mean } f(x_i) f(x_i, x_j)$$

to clearly separate the main effects from the interactions.

Unwrapping the black box of deep ReLU networks: interpretability, diagnostics and simplification

A. Sudjianto et al.

A neural network with ReLU activations is a locally linear model:

- Look at the parallel plot of the coefficients of those linear functions;
- For each feature x_i , plot the segments $\beta_i x_i \sim x_i$, one for each cell (“activation region”).

To simplify the model, merge nearby cells with similar coefficients (not unlike the fused lasso).

Python implementation: `aletheia-dnn`.

Adaptive explainable neural networks (AxNNs)

J. Chen et al. (2020)

Fit an AIM (additive index model) on the residuals of a GAM (generalized additive model), both estimated with neural networks: the GAM estimates the main effects, the AIM the residual interactions. Train with AdaBoost, with 1-variable GAMs and 2-variable AIMs as weak learners.

***Surrogate locally-interpretable models
with supervised machine learning algorithms***
L. Hu et al. (2020)

A regression tree (with linear models with an L^1 penalty, or GAMs, in the leaves), trained on the output of a neural net, gives an interpretable surrogate model, not unlike LIME (a linear model on a neighbourhood of each observation) or KLIME (a linear model on each k -means cluster – k -means is an unsupervised clustering algorithm, while a regression tree is a supervised one).

***Designing inherently
interpretable machine learning models***
A. Sudjianto and A. Zhang (2021)

To measure the interpretability of a model, look

- if constraints such as additivity, sparsity, linearity, smoothness, monotonicity can be imposed, globally or locally, at least approximately,
- if the model can be visualized,
- if it uses an (orthogonal) projection of the input features,
- if it segments the input space in a small number of regions.

***General pitfalls
of model-agnostic interpretation methods
for machine learning models***
C. Molnar et al.

- Confusion between feature effect (Shapley score) and feature importance (e.g., permutation feature importance, PFI): use both;
- Interpreting a model that does not generalize well: this gives an interpretation of the model, not of the data generation process;
- Non-intrinsically interpretable models – try GAM boosting;
- Ignoring feature dependence: most methods assume features are independent;
- Using only correlation to measure dependence: check KCCA (kernel canonical correlation), HSIC (Hilbert-Schmidt independence criterion), MI (mutual information – more difficult to estimate);
- Ignoring interactions (when aggregated, significant effects can cancel out): look at ICE curves;
- Ignoring uncertainty: use the bootstrap;
- Drawing causal conclusions.

Learning Wasserstein embeddings
N. Courty et al. (2018)

A *Deep Wasserstein embedding* is a mapping (of probability distributions, or images – the examples given are MNIST and doodles) transforming the Wasserstein distance into the Euclidean distance, trained on data ($x_i = (x_i^1, x_i^2)$, $y_i = d_W(x_i^1, x_i^2)$), with a Siamese network, regularized with a decoder and a reconstruction loss.

Applications include Wasserstein barycenter (interpolation) and principal geodesic analysis.

***Set representation learning
with generalized sliced-Wasserstein embeddings***
N. Naderializadeh et al.

To process sets with a neural net, one usually uses permutation equivariant modules (e.g., self-attention, or, more generally, processing each point in the same way) and permutation invariance modules (multi-head attention, pooling): DeepSets, SetTransformers. Instead:

- View the elements of a set as samples from a probability distribution μ_i ;
- Project them on random 1-dimensional subspaces, $\nu_{i\theta} = g_\theta \# \mu_i$;
- Compute the Monge map between each $\nu_{i\theta}$ and some reference distribution $\nu_{0\theta}$: $F_{\nu_{i\theta}}^{-1} \circ F_{\nu_{0\theta}}$;
- Use the cumulative distribution transforms $F_{\nu_{i\theta}}^{-1} \circ F_{\nu_{0\theta}} - \text{Id}$ as representation of the μ_i .

The projection g_θ , can be learned from data, using contrastive learning (SimCLR, SiamSiam).

Wasserstein embedding for graph learning
S. Kolouri et al. (2021)

Represent a graph with its node embedding, *i.e.*, a set of points in \mathbf{R}^d , and then, the linear Wasserstein embedding.

Do not compute all pairwise distances, but only distances to some reference graph.

***Generalized sliced distances
for probability distributions***
S. Kolouri et al.

The *Radon transform* recovers a distribution p from its slices p_f along hyperplanes

$$p_{f_\theta}(t) = \int_{\mathbf{R}^d} p(x) \delta(t - \langle x, \theta \rangle) dx$$

$$p(x) = \int_{\mathbf{S}^{d-1}} (p_{f_\theta} * \eta)(\langle x, \theta \rangle) d\theta$$

where $\hat{\eta}(\omega) = c|\omega|^{d-1}$.

The *generalized Radon transform* uses a family of hypersurfaces $H = \{x \in \mathbf{R}^d : f_\theta(x) = t\}$ instead, where the f_θ are called “defining functions”. A metric ξ between 1-dimensional probability measures can be extended to higher dimensions

$$\zeta(p, q) = \left(\int \xi(p_{f_\theta}, q_{f_\theta})^r d\theta \right)^{1/r}, \quad r \geq 1$$

(generalized sliced probability metric) or

$$\zeta^*(p, q) = \sup_{\theta} \xi(p_{f_{\theta}}, q_{f_{\theta}}),$$

For instance:

$$\begin{aligned}\zeta^2(p, q) &= \int \|Ap_{f_{\theta}} - Aq_{f_{\theta}}\| d\theta \\ A &= \text{Id} \\ Ap(t) &= \int_{-\infty}^t p(s) ds \\ Ap(t) &= \int_{-\infty}^{\infty} p(t)k(t, s) ds.\end{aligned}$$

**Parameter prediction
for unseen deep architecture
B. Knyazev et al. (2021)**

Hypernetworks learn to compute the parameters of another neural network from training data in a single forward pass:

training data \mapsto weights

but they require the neural net to have a fixed architecture. Graph neural nets (GNN) allow an arbitrary architecture (for a fixed set of node types):

training data, architecture \mapsto weights.

**Squeeze-and-excitation networks
J. Hu et al.**

A squeeze-and-excite block combines:

- A convolution layer, outputting C channels;
- Global averaging, separately for each channel, outputting a vector of length C ;
- A simple transformation,

$$z \mapsto s = \sigma(w_2 \text{ReLU}(w_1 z)),$$

to compute the channel-specific scale, outputting a vector of length C ;

- Multiplication of the convolution output and the scale.

**Learning in high dimension
always amounts to extrapolation
R. Balestriero**

Interpolation occurs when a new sample is in the convex hull of the training data; in high dimension, this is unlikely to happen.

$$\begin{aligned}x_1, \dots, x_N &\sim \text{Unif}(B_d) \\ x &\sim \text{Unif}(B_d) \\ P[x \in \text{chull}(x_1, \dots, x_N)] &\xrightarrow[N < 2^{d/2}/d]{d, N \rightarrow \infty} 0\end{aligned}$$

**Task-based end-to-end model learning
in stochastic optimization
P.L. Donti et al.**

Traditional machine learning, for

x : features $f(x, y, z)$: loss
 y : predictions
 z : policy

is often a 2-step process

$$\begin{aligned}\theta &= \underset{\theta}{\text{Argmin}} \mathbb{E}_{x, y \sim \text{data}} [-\log p(y|x; \theta)] \\ z(x) &= \underset{x}{\text{Argmin}} \mathbb{E}_{y \sim p(y|x; \theta)} [f(x, y, z)].\end{aligned}$$

Black-box, end-to-end optimization is not very data-efficient:

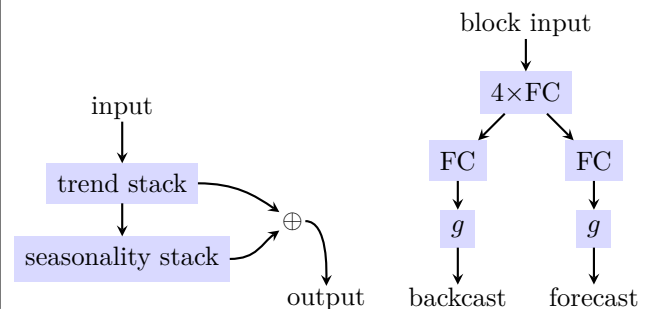

$$\underset{\theta}{\text{Minimize}} \mathbb{E}_{x, y \sim \text{Data}} [f(x, y, z(x; \theta))].$$

Modeling the data distribution (instead of the policy) in an end-to-end fashion (*i.e.*, with the correct loss function, instead of the log-likelihood) is more data-efficient. Iterate:

$$\begin{aligned}x, y &\sim \text{Data} \\ z^*(x, \theta) &= \underset{z}{\text{Argmin}} \mathbb{E}_{y \sim p(y|x; \theta)} f(x, y, z) \\ \theta &\leftarrow \theta - \alpha \nabla_{\theta} f(x, y, z^*(x, \theta)).\end{aligned}$$

**N-Beats: neural basis expansion analysis
for interpretable time series forecasting
B.N. Oreshkin et al. (2020)**

To forecast time series, stack blocks with two outputs, to forecast/backcast the next/previous periods, taking the residual of the previous block as input; the nonlinearities are given by basis function expansions $\sum \theta_i \mathbf{v}_i$, to extract the trend (first stack) and the seasonality (second stack).

Ensemble several models: different loss functions (SMAPE, MASE, MAPE), window lengths, random initialization.

How powerful are graph neural networks?

K. Xu et al. (2019)

For $\varepsilon \in \mathbf{R} \setminus \mathbf{Q}$, there exists $f : \mathbf{R} \rightarrow \mathbf{R}$ such that

$$\begin{cases} \mathbf{Q} \times \text{Multisets}(\mathbf{Q}) & \rightarrow \mathbf{R} \\ (u, (v_i)_i) & \mapsto (1 + \varepsilon)f(u) + \sum_i f(v_i) \end{cases}$$

be injective. This suggests the following aggregation, for graph neural nets (GIN):

$$h_v \leftarrow \text{MLP}\left((1 + \varepsilon)h_v + \sum_{u \in N(v)} h_u\right)$$

where ε is learned.

Principal neighbourhood aggregation for graph nets

G. Corso et al. (2020)

Do not use a single aggregation operator, but several (mean, standard deviation, minimum, maximum), and rescale them with the degree (on a logarithmic scale, otherwise the messages would be amplified or attenuated exponentially).

$$\left(\frac{\log(d+1)}{\langle \log(d+1) \rangle} \right)^{+1, -1, \text{ or } 0}$$

Learning aggregation functions

G. Pellegrini et al. (2021)

Principal neighbourhood aggregation (PNA) uses a finite set of ($4 \times 3 = 12$) aggregations. Instead, try

$$\text{LAF}(x) = \frac{\alpha L_{a,b}(x) + \beta L_{c,d}(1-x)}{\gamma L_{d,f}(x) + \delta L_{g,h}(1-x)}$$

$$L_{a,b}(x) = \left(\sum_i x_i^b \right)^a \quad x \in [0, 1]^n$$

Neural message passing for quantum chemistry

J. Gilmer et al. (2017)

$$m_v \leftarrow \sum_{w \in N(v)} M(h_v, h_w, e_{vw})$$

$$h_v \leftarrow U(h_v, m_v)$$

Rethinking graph transformers with spectral attention

D. Kreuzer et al. (2021)

Transformers use positional embeddings, with sines and cosines. For graphs, we could use the first eigenvectors of the Laplacian (GT), but this ignores the eigenvalues. Instead, SAN learns the positional embedding: for each node, transform the eigenvalues $\lambda_1, \dots, \lambda_m$ and eigenvectors $\phi_{1j}, \dots, \phi_{mj}$ as

$$(2 \times m) \xrightarrow[2 \times k]{\text{linear}} (k \times m) \xrightarrow[m \times m]{\text{transformer}} (k \times m) \xrightarrow{\text{sum}} (k \times 1).$$

Randomly flip the sign of the eigenvectors to make the model sign-invariant.

A generalization of transformer networks to graphs

V. P. Dwivedi and X. Bresson (2021)

The graph transformer (GT) layer uses the low-frequency eigenvectors of the Laplacian as positional encoding.

Training graph neural networks with 1000 layers

G. Li et al. (2021)

Use reversible (block-triangular) connections.

A dual-stage attention-based recurrent neural network for time series prediction

Y. Qin et al.

Stack two LSTM layers with attention (DARNN).

$$\alpha_{st} \propto f(h_{t-1}, x_t) \quad s < t$$

$$h_t = \text{LSTM}(h_{t-1}, \sum_{s < t} \alpha_{st} x_s)$$

$$\beta_{st} \propto g(\ell_{t-1}, h_s) \quad s < t$$

$$d_t = \text{LSTM}(d_{t-1}; y_{t-1}, \sum_{s < t} \beta_{st} h_s)$$

$$\hat{y}_T = \phi(d_T, \sum_{s < T} \beta_{sT} h_s)$$

Gradients are not all you need

L. Metz et al. (2021)

Exact gradients (from automatic differentiation) may be less informative than approximate (black-box) ones.

This phenomenon appears, in particular, in iterated systems: RNNs, rigid body physics, ODE solvers, optimization layers, etc.

To limit the problem: initialize the RNNs close to the identity, use LSTMs, use conservation laws (and other known properties), try truncated BPTT, truncated gradients, or, even black-box gradients.

Top2vec: distributed representations of topics

D. Angelov

top2vec = doc2vec + UMAP + HDBScan

Supervised linear dimension reduction

methods: review, extensions and comparisons

S. Xu et al.

Prefer PLS (an eigen decomposition) or LSPCA (manifold optimization).

PCA: Minimize $\|X - XU U'\|^2$
s.t. $U'U = I$

PLS: Maximize $[(Xu)'y]^2$
s.t. $\|u\|=1$
(and iterate after projecting X and y on u^\perp)

LSPCA: Minimize $\|y - XU\beta\|^2 + \lambda \|X - XU U'\|^2$
s.t. $U'U = I$

A new coefficient of correlation

S. Chatterjee

To assess if $Y = f(X)$ (for f measurable but not necessarily monotonic):

- Sort the observations along X :

$$(X_{(1)}, Y_{(1)}), \dots, (X_{(n)}, Y_{(n)});$$

- Compute the ranks r_i of $Y_{(i)}$;
- Let $\xi(X, Y) = 1 - \frac{3}{n^2 - 1} \sum_i \|r_{i+1} - r_i\|$.

It converges to

$$\frac{\int \text{Var}_X \mathbb{E}_Y[\mathbf{1}_{Y \geq t} | X] dp_Y(t)}{\int \text{Var}_Y[\mathbf{1}_{Y \geq t}] dp_Y(t)}$$

which is 0 iff $X \perp\!\!\!\perp Y$ and 1 iff $Y = f(X)$ a.s. for some measurable f . If $X \perp\!\!\!\perp Y$, it is asymptotically Gaussian:

$$\sqrt{n} \xi_n(X, Y) \xrightarrow{d} N(0, 2/5).$$

Alternatives include:

- The maximum information coefficient (MIC): maximum of $\text{MI}(U; V) / \log \text{Min}(x, y)$, where $\text{MI}(U; V) = \text{KL}(p_{U,V} \| p_U p_V)$ and (U, V) is the discretization of the scatterplot of (X, Y) on an $x \times y$ grid, with $xy \leq n^{0.6}$;

- The distance correlation

$$a_{ij} = \|X_i - X_j\|$$

$$b_{ij} = \|Y_i - Y_j\|$$

$$A_{ij} = a_{ij} - a_{i\cdot} - a_{\cdot j}$$

$$B_{ij} = b_{ij} - b_{i\cdot} - b_{\cdot j}$$

$$\text{dCor} = \text{Cor}(A, B)$$

- HHG: for each pair (i, j) , $i \neq j$, compute the χ^2 statistic to test independence on the 2×2 contingency table for $|X_i - X| < |X_i - X_j|$ and $|Y_i - Y| < |Y_i - Y_j|$
- Hilbert-Schmidt independence criterion (HSIC)

$$\text{HSIC} = \frac{1}{n^2} \sum_{ij} k_{ij} \ell_{ij} + \frac{1}{n^4} \sum_{ijqr} k_{ij} \ell_{qr} - \frac{2}{n^3} \sum_{ijq} k_{ij} \ell_{iq}$$

$$k_{ij} = k(X_i, X_j)$$

$$\ell_{ij} = \ell(Y_i, Y_j)$$

$$k(x, y) = \ell(x, y) = \exp - \frac{1}{2} \left(\frac{x - y}{\sigma} \right)^2$$

R implementations in XICOR, energy (dCor), minerva (MIC), HHG, dHSIC.

On the power of Chatterjee's rank correlation

H. Shi et al.

Prefer Hoeffding's D , Blum-Kiefer-Rosenblatt's R , or Bergsma-Dassios-Yanagimoto's τ^* to Chatterjee's rank correlation.

$$D = \int [F(x, y) - F(x)G(y)]^2 dF(x, y)$$

$$R = \int [F(x, y) - F(x)G(y)]^2 dF(x) dF(y)$$

$$\begin{aligned} \tau^* = & 4I(x_1, x_3 < x_2, x_4; y_1, y_3 < y_2, y_4) \\ & + 4I(x_1, x_3 < x_2, x_4; y_2, y_4 < y_1, y_3) \\ & - 8I(x_1, x_3 < x_2, x_4; y_1, y_4 < y_2, y_3) \end{aligned}$$

where $I(x_1, x_2 < x_3, x_4) = \mathbf{1}_{\text{Max}(x_1, x_2) < \text{Min}(x_3, x_4)}$.

A simple measure of conditional dependence

M. Azadkia and S. Chatterjee

Conditional independence can be measured as

$$T(Y, Z|X) = \frac{\int \mathbb{E}_X \text{Var}_Z[P_Y(Y \geq t|Z, X)|X] dF_Y(t)}{\int \mathbb{E}_X \text{Var}_Y[\mathbf{1}_{Y \geq t}|X] dF_Y(t)}.$$

To estimate it:

- Let $N(i)$ be the index of the nearest neighbour of X_i ;
- Let $M(i)$ be the index of the nearest neighbour of (X_i, Z_i) ;
- Let $R_i = \sum_j \mathbf{1}_{Y_j \geq Y_i}$ be the rank of Y_i ;

$$T_n = \frac{\sum \text{Min}(R_i, R_{M(i)}) - \text{Min}(R_i, R_{N(i)})}{\sum R_i - \text{Min}(R_i, R_{N(i)})}.$$

It can be used for variable selection: add the variable X_j maximizing $T_n(Y, X_j|X_{j_1}, \dots, X_{j_k})$ until $T_n \leq 0$.

R implementation in FOCI.

The oracle estimator is sub-optimal for global minimum variance portfolio optimization
C. Bongiorno and D. Challet

Rotationally invariant estimators (RIE) of the variance matrix

$$\forall U \in O_n \quad \Sigma(U' \hat{S} U) = U' \Sigma(\hat{S}) U$$

filter the eigenvalues of the sample variance matrix \hat{S} while keeping its eigenvectors. The RIE optimal for the Frobenius distance (between the estimator and the (unknown) true variance matrix) is not optimal for minimum variance portfolio optimization.

A new parametrization of correlation matrices
I. Archakov and P.R. Hansen (2020)

A correlation matrix C can be parametrized with the off-diagonal elements of $\log C$: $C \mapsto \text{veclog } C$. This generalizes the Fisher transform:

$$\log \begin{pmatrix} 1 & \rho \\ \rho & 1 \end{pmatrix} = \begin{pmatrix} \frac{1}{2} \log(1 - \rho^2) & \frac{1}{2} \log \frac{1 + \rho}{1 - \rho} \\ \frac{1}{2} \log \frac{1 + \rho}{1 - \rho} & \frac{1}{2} \log(1 - \rho^2) \end{pmatrix}.$$

For covariance matrices, add $(\log \sigma_i)_i$.

To compute the inverse (without the diagonal elements of $\log C$), iterate $x \mapsto x - \log \text{diag } e^{A[x]}$, where $A[x]$ is A with its diagonal replaced by x , and return $C = e^{A[x]}$; we then have $\text{veclog } C = \text{vecl } A$.

Completing correlation matrices
O. Dreyer et al. (2021)

Complete concentration matrices by maximizing the entropy of the resulting Gaussian distribution. If the known correlations form a chordal graph, this can be done efficiently.

The Hurst roughness exponent and its model-free estimation
X. Han and A. Schied (2021)

The *standard Hurst exponent* measures the long-range dependence of a time series (or function), using its autocorrelation. The *Hurst roughness exponent* (the p th variation of x converges to 0 if $p > 1/H$ and to infinity if $p < 1/H$) measures the roughness of a function. They sometimes coincide (fBM), but not always.

The Gladyshev estimator is not scale-invariant, but can be made so.

Portfolio optimization with idiosyncratic and systemic risks for financial networks
Y. Yang et al. (2021)

Replace the variance matrix V with $\lambda \Sigma + (1 - \lambda)H$, where Σ is the matrix of covariances (V), or Kendall's τ 's, or tail dependence coefficients, and $H = (\sigma \sigma') \odot (CC')$ where $\sigma = \text{diag } V$ and C is the vector of clustering coefficients.

Portfolio optimization with options
J.R. Chan et al. (2021)

For portfolios of options, replace the variance matrix, in the Markowitz optimization problem, with

$$\Lambda_{ij} = \frac{P(O_i^+, O_j^+)}{P(O_i^+)P(O_j^+)},$$

where O_i^+ is the event “option i expires in the money” (it can be computed from the pairwise copulas of stock prices and the option strikes).

Online estimation and optimization of utility-based shortfall risk
A.S. Menon et al.

Utility-based shortfall risk (UBSR) generalizes CVaR (it is no longer coherent):

$$\text{SR}_\lambda(X) = \inf\{t \in \mathbf{R} : \mathbb{E}[U(t + x)] \geq -\lambda\}.$$

Mean-covariance robust risk measurement
V.A. Nguyen et al. (2021)

The *Chebychev ambiguity set* around a mean-covariance pair (μ, Σ) is the set of probability distributions with that expectation and that variance. The *Gelbrich distance* between mean-covariance pairs (μ_1, Σ_1) and (μ_2, Σ_2) is

$$\sqrt{\|\mu_1 - \mu_2\|^2 + \text{Tr}[\Sigma_1 + \Sigma_2 - 2(\Sigma_2^{1/2} \Sigma_1 \Sigma_2^{1/2})^{1/2}]}$$

It is the Wasserstein distance between $N(\mu_1, \Sigma_1)$ and $N(\mu_2, \Sigma_2)$.

The *Gelbrich ambiguity set* $G_\rho(\mu, \Sigma)$ is the set of distributions q whose mean-variance pair is at distance at most ρ of (μ, Σ) .

For a (translation-invariant, positive homogeneous, law-invariant) risk measure R ,

$$\sup_{q \in G_\rho(\mu, \Sigma)} R[-w'X] = -\mu'w + \alpha \sqrt{w' \Sigma w} + \rho \sqrt{1 + \alpha^2} \|w\|$$

where the risk coefficient α can be computed explicitly for VaR, CVaR, spectral risk measures, Kusuoka risk measures (supremums of spectral risk measures), distortion measures ($R[X] = \int_{\mathbf{R}} \tau dh(F_X(\tau))$ for some non-decreasing $[0, 1] \rightarrow [0, 1]$).

Optimal investment with risk controlled by weighted entropic risk measures
J. Xia (2021)

$$h(X) = \int_0^\infty \frac{1}{a} \mathbb{E}[e^{-aX}] d\mu(a)$$

Deep reinforcement learning for the optimal placement of cryptocurrency limit orders
M. Schnaubelt (2020)

Reinforcement learning (PPO) from limit order book features:

- Queue imbalance (difference between bid and ask volumes at various levels);
- Liquidity cost (cost of a market buy or sell order for 10, 20, 30, 50, 100 BTC or ETH);
- Volatility, drift, spread.

Deep partial hedging
S. Hou et al. (2021)

Partial hedging (hedging with less capital than needed, minimizing $P[\text{loss} > 0]$ (quantile hedging) or $E[\text{loss}|\text{loss} > 0]$ (efficient hedging)) is equivalent to Δ -hedging with a modified payoff.

Use a neural net to approximate that payoff, while accounting for transaction costs; also add a penalty $(\text{Min}_t V_t)_-$ to avoid being too much in the red.

A meta-method for portfolio management using machine learning for adaptive strategy selection
D. Kisiel and S. Gorse

Use xgboost to decide when to switch between hierarchical risk parity and $w_i \propto 1/\sigma_i^2$ (naive risk parity) on 18 ETFs. Features include:

- Returns, volatility, downside deviation, maximum drawdown of the strategies;
- Average return and volatility of the ETFs;
- Average and standard deviation of the correlations;
- Quality ratios: number of independent bets (square of the diversification ratio $\sum w_i \sigma_i / \sigma_{\text{port}}$ of the maximum diversification portfolio) divided by the number of assets;
- Non-parametric k -NN entropy estimator;
- Cophenetic correlation coefficient (correlation between distances and distances on a dendrogram);
- Standardized generalized variance: $\text{GV} = \det V$, $\text{SGV} = \det(V)^{1/p}$;
- Correlation matrix features: determinant, condition number, fraction of the variance explained by the eigenvalues outside the Marchenko-Pastur distribution.

Estimating security betas via machine learning
W. Drobetz et al.

Random forest (or neural network, or linear regression) to forecast realized beta (computed from daily returns over the next year) from stock characteristics (30 ratios, industries, historical (3m, 1y, 5y) betas).

A transformer-based model for default prediction in mid-cap corporate markets
K. Korangi et al. (2021)

Predict the term structure of default from

- Quarterly fundamental ratios,
- Quarterly financial ratios,
- Daily prices,

with a separate transformer for each, whose outputs are then combines, with the time series of default indicators (3m, 6m, 9m, 1y, 2y, 3y) as targets. Attention weights and Shapley contributions help interpret the model.

Market impact decay and capacity
H. Chan (2021)

When a trade is split over several days, subsequent days still feel the market impact of previous days – market impact does not immediately drop to zero but decays (it drops to zero after a month).

w_{it}^* : target weights

$$w_{it} = (1 - \tau)w_{i,t-1} + \tau w_{it}^*$$

τ : trading speed

$$\text{Impact} = \alpha \sqrt{\frac{\text{size}}{\text{ADV}}}, \quad \alpha = 100 \text{ bp}$$

$$\text{Decay}_t = \gamma^t, \quad \gamma = 0.85$$

$$\text{Cost}_{it} = C \Delta_{it} \sum_{s \leq t} \text{sign}_{is} \text{Decay}_{t-s} \text{Impact}_{is}$$

C : Capital

$$\text{Capacity} = \text{Max}\{C : \text{Max}_{\tau} \text{Sharpe}_{\tau} \geq \text{threshold}\}$$

The correlation risk premium: international evidence
G. Faria et al.

The correlation risk is the difference between the implied correlation

$$\text{IC} = \frac{\text{SV}_{\text{index}} - \sum_i w_i^2 \text{SV}_i}{\sum_{i \neq j} w_i w_j \sqrt{\text{SV}_i \text{SV}_j}}$$

SV = variance swap rates

and the realized correlation

$$\begin{aligned} \text{RC} = & \int_{S_t}^{\infty} \frac{2}{K^2} \left(1 - \log \frac{K}{S_t}\right) \text{Call}_{[t,T]}(K) dK \\ & + \int_0^{S_t} \frac{2}{K^2} \left(1 + \log \frac{K}{S_t}\right) \text{Put}_{[t,T]}(K) dK \end{aligned}$$

Similarly, the variance risk factor is the difference between the implied and the realized variance.

Sustainable investing in equilibrium
L. Pástor et al. (2020)

Green (ESG) have lower returns in equilibrium, but (by definition) positive returns when positive shocks hit the “ESG factor”.

**Deep differentiable reinforcement learning
and optimal trading**
T. Jaisson (2021)

Policy gradient, to trade one asset, with a 2-scale alpha: the optimal strategy uses the fast alpha to time the trades, and the slow alpha for the target weights.

**Time series simulation by conditional
generative adversarial net**
R. Fu et al.

To generate synthetic (univariate) time series, use a conditional GAN

$$\min_G \max_D \mathbb{E}_{x \sim \text{Data}} [\log D(x)] + \mathbb{E}_{x \sim \text{noise}} [\log(1 - DGx)]$$

or a WGAN

$$\min_G \max_D \mathbb{E}_{x \sim \text{Data}} [\log D(x)] - \mathbb{E}_{x \sim \text{noise}} [\log D(G(x))] \\ \|D\|_{\text{Lip}} \leq 1$$

with weight clipping, no batchnorm, 3 FC layers of 100+ nodes, leaky ReLU ($\alpha = .1$) activations and 30 inputs.

**qgam: Bayesian nonparametric
quantile regression modeling in R**
M. Fasiolo et al. (2021)

GAMs can be generalized to GAMs for location, scale and shape (GAMLSS) and quantile GAMs. To estimate a QGAM model, replace the pinball loss $\rho(z) = \tau z_+ + (1 - \tau)z_-$ with the smooth *extended log-f loss* (ELF)

$$\rho(z) = \lambda \log(1 + e^{z/\lambda\sigma}) - (1 - \tau) \frac{z}{\sigma}.$$

**JointAI: joint analysis and imputation
of incomplete data in R**
N.S. Erler et al. (2021)

Bayesian missing data imputation with MCMC (Gibbs sampling, via Jags) for GLMM (mixed GLM) and CLM (cumulative logit) multilogistic (mixed), survival models.

Informed Bayesian inference for the A/B test
Q.F. Gronau et al. (2021)

abtest: A/B testing for 3 hypotheses (positive, negative, or no effect), with a prior (expert knowledge).

**BFPack: flexible Bayes factor
testing of scientific theories in R**
J. Mulder et al. (2021)

Bayesian statistical tests for multiple hypotheses involving inequalities and equalities (e.g., $\mu = 0$ vs $\mu > 0$ vs $\mu < 0$, or $\sigma_1 = \sigma_2 < \sigma_3$ vs $\sigma_1 < \sigma_2 = \sigma_3$ vs $\sigma_1 = \sigma_2 = \sigma_3$ vs neither).

**Shrinkage in the time-varying parameter model
framework using the R package shrinkTVP**
P. Knaus et al. (2021)

MCMC estimation of the Bayesian time-varying parameter (TVP) model

$$y_t = x_t \beta_t + \varepsilon_t \\ \beta_t = \beta_{t-1} + w_t$$

with a normal-gamma-normal (NGG) prior (normal gamma, horseshoe, and lasso are limiting cases).

**Modeling univariate and multivariate
stochastic volatility in R
with stochvol and factorstochvol**
D. Hosszejni and G. Kastner (2021)

Efficient (C++) MCMC estimation of (uni- or multivariate) non-Gaussian, asymmetric (leverage effect) stochastic models (non-linear state space models).

**dalmatian: a package for fitting
double hierarchical linear models
in R via Jags and Nimble**
S. Bonner et al. (2021)

Mixed model, with fixed and random effects for both mean and variance.

**Machine learning optimization algorithms
and portfolio allocation**
S. Perrin and T. Roncalli (2019)

Four machine learning algorithms are applicable to portfolio optimization (e.g., with a Herfindahl penalty to increase diversification): coordinate descent, ADMM, proximal gradient, and Dykstra's algorithm.

Coordinate descent optimizes one variable at a time, keeping the others fixed; those 1-dimensional optimization problems often have an explicit solution (e.g., soft-thresholding, for the lasso) or can be solved with line search.

ADMM solves problems of the form

$$\begin{array}{ll} \text{Find} & x, y \\ \text{To minimize} & f(x) + g(y) \\ \text{Such that} & Ax + By = c \end{array}$$

by iterating

$$\begin{aligned} x &\leftarrow \underset{x}{\text{Argmin}} f(x) + \lambda \|Ax + By - c + u\|_2^2 \\ y &\leftarrow \underset{y}{\text{Argmin}} g(y) + \lambda \|Ax + By - c + u\|_2^2 \\ u &\leftarrow u + (Ax + By - c). \end{aligned}$$

Finding a good value of λ is tricky:

- Increase λ if $\|r\| \gg \|s\|$,
- Decrease λ if $\|r\| \ll \|s\|$,

where $r = Ax + By - c$ and $s = 2\lambda A'B\Delta y$.

Convergence to a moderately accurate solution is fast; convergence to a more accurate solution much slower.

To put an optimization problem in ADMM form, consider the following “tricks”:

- To minimize $f(x) + g(x)$, minimize $f(x) + g(y)$ subject to $x = y$;
- To minimize $f(x)$ subject to $x \in \Omega$, minimize $f(x) + \mathbf{1}_\Omega(y)$ subject to $x = y$;
- To minimize $f(x) + g(x)$ subject to $x \in \Omega_1 \cap \Omega_2$, minimize $f(x) + \mathbf{1}_{\Omega_1}(x) + g(y) + \mathbf{1}_{\Omega_2}(y)$ subject to $x = y$;
- To minimize $f(x) + g(Ax + b)$, minimize $f(x) + g(y)$ subject to $y = Ax + b$.

The **proximal operator** is

$$\text{prox}_f(v) = \underset{x}{\text{Argmin}} f(x) + \frac{1}{2} \|x - v\|_2^2;$$

it generalizes the Euclidean projection (for $f = \mathbf{1}_\Omega$) and can often be computed explicitly.

There is no formula for $\text{prox}_{f_1+f_2}$, but it can be computed by iterating

$$\begin{aligned} x &\leftarrow \text{prox}_{f_1}(y + p) \\ p &\leftarrow y + p - x \\ y &\leftarrow \text{prox}_{f_2}(x + q) \\ q &\leftarrow x + q - y \end{aligned}$$

starting with $x = y = v$ and $p = q = 0$. **Dykstra’s algorithm** generalizes this to a sum of m terms. It can be used to project on an intersection: $\mathbf{1}_{\Omega_1 \cap \dots \cap \Omega_m} = \mathbf{1}_{\Omega_1} + \dots + \mathbf{1}_{\Omega_m}$, e.g., an intersection of half-spaces (*i.e.*, general inequality constraints, $Ax = b$, $Cx \leq d$).

Dykstra’s algorithm, ADMM and coordinate descent: connections, insights, and extensions
R.J. Tibshirani (2017)

The best approximation problem

$$\begin{aligned} \text{Find} \quad & u \in \mathbf{R}^n \\ \text{To minimize} \quad & \|y - u\|^2 \\ \text{Such that} \quad & u \in C_1 \cap \dots \cap C_d \end{aligned}$$

can be solved with Dijkstra’s algorithm, iterating

$$\begin{aligned} u &\leftarrow P_{C_k}(u + z_k) \\ z_k &\leftarrow z_k - \Delta u \end{aligned}$$

with a different k at each iteration (use a different dual variable for each C_k).

Its dual is the regularized regression problem

$$\begin{aligned} \text{Find} \quad & w \in \mathbf{R}^p \\ \text{To minimize} \quad & \frac{1}{2} \|y - Xw\|^2 + \sum_i h_i(w_i) \end{aligned}$$

and the coordinate descent algorithm is equivalent to Dykstra’s.

A note on portfolio optimization with quadratic transaction costs
P. Chen et al. (2019)

The transaction costs should be included in the budget constraint: for linear costs, $w'\mathbf{1} = 1$ becomes $w'\mathbf{1}_\tau \|w - w_0\|_1 = 1$ – and we should also distinguish between bid and ask prices. For quadratic transaction costs, the problem is no longer convex, but still amenable to ADMM.

[$w'\mathbf{1} + C(w, w_0) = 1$ is not convex, but $w'\mathbf{1} + C(w, w_0) \leq 1$ is.]

Improving the robustness of trading strategy backtesting with Boltzmann machines and generative adversarial networks

Use a convolutional Wasserstein GAN to generate synthetic time series.

Portfolio optimization with sparse multivariate modelling
P.F. Procacci and T. Aste (2021)

Use the TMFG-LoGo variance matrix for portfolio optimization (the sparsity structure of Σ^{-1} is given by the TMFG-filtered graph, and the correlation of TMFG-linked assets is preserved).

Sparse causality network retrieval from short time series
T. Aste and T. Di Matteo

An information filtering approach to stress testing: an application to FTSE markets
I. Seabrook et al. (2021)

Given a multivariate Gaussian

$$\begin{pmatrix} X \\ Y \end{pmatrix} \sim N \left[\begin{pmatrix} \mu_X \\ \mu_Y \end{pmatrix}, \begin{pmatrix} \Omega_{XX} & \Omega_{XY} \\ \Omega_{YX} & \Omega_{YY} \end{pmatrix} \right],$$

the impact of X on Y is the average change of the variables in Y for a unit change of the variables in X

$$\begin{aligned} L_{X \rightarrow Y} &= \underset{i}{\text{Mean}} (E[Y_i | X = \mu_X + 1] - E[Y_i]) \\ &= \frac{1}{n_Y} \mathbf{1}'_Y \Omega_{YX} \Omega'_{XX} \mathbf{1}_X. \end{aligned}$$

Make Ω^{-1} sparse with TMFG filtering.

Cluster the dates into market states, with a log-likelihood penalized for frequent cluster changes (Viterbi algorithm).

The most central groups (industrial sectors) have a higher response but a lower impact, because of the number of links within those groups rather than their centrality.

***Simplicial persistence of financial markets:
filtering, generative processes
and portfolio risk***
J.D. Turiel et al. (2020)

Check which triangles, separators, tetrahedra of the TMFG (triangulated maximally filtered graph) are persistent, *i.e.*, present at times t and $t + \tau$ (and the number of such triangles as τ varies).

***A universal end-to-end approach
to portfolio optimization via deep learning***
C. Zhang et al. (2021)

End-to-end portfolio construction, from daily price data, with a few constraints, *e.g.*, leverage, maximum weight, number of assets (with a sorting operation – it is differentiable).

Deep learning for portfolio optimization
Z. Zhang et al.

Only 4 assets (ETFs), with an LSTM trained on 10 years of daily price data.

***End-to-end risk budgeting portfolio
optimization with neural networks***
A.S. Uysal et al. (2021)

End-to-end portfolio construction, from 10 years of daily price data, for 7 assets, with or without an optimization layer (risk budgeting).

***Integrating prediction
in mean-variance portfolio optimization***
A. Butler and R.H. Kwon (2021)

End-to-end portfolio optimization has a quadratic optimization reformulation in the special case where the return forecasts are a linear combination of the features. Application to 24 commodities, with trend and carry as features.

Scenario-based risk evaluation
R. Wang and J.F. Ziegel

The conditional value at risk (VaR) and expected shortfall (ES) of X given the market state S are

$$\begin{aligned}\text{CoVaR}_{S|X} &= \text{VaR}[X | S = \text{VaR}_S] \\ \text{ES}_S X &= \text{E}[X | X \leq \text{CoVaR}_S X].\end{aligned}$$

More generally, given scenarios Q_1, \dots, Q_n , one can define

$$\begin{aligned}\text{MES } X &= \text{Max}_i \text{ES}^{Q_i} X \\ \text{MVaR } X &= \text{Max}_i \text{VaR}^{Q_i} X \\ \text{AES } X &= \text{Mean}_i \text{ES}^{Q_i} X \\ \text{iMES } X &= \text{Mean}_{q \in [p, 1]} \text{MVaR}_q X \\ \text{rMES } X &= \text{ES}[\text{Max}_i X_i], \quad X_i \underset{\text{indep.}}{\sim} Q_i.\end{aligned}$$

AES and eMES are coherent and comonotonic additive.

Basel III and IV require a *stress adjustment*, ES calibrated on the worst 12 months (MES), and a *dependence adjustment*, average of the ES calibrated on the worst 12 months and that calibrated on the worst possible dependence structure (comonotonic risk factors: compute an ES separately for each category of risk factors and add them).

***A framework
for measures of risk under uncertainty***
T. Fadina et al.

(Coherent) risk measures are computed (in the case of a portfolio) from portfolio weights and a distribution of asset retruns. A generalized risk measure uses, instead, a *set* of distributions on asset returns, *i.e.*, a set of scenarios. One can then compute the worst case (or average, etc.) VaR, ES, etc.

Forecasting market states
P.F. Procacci and T. Aste

Markov switching model (Viterbi algorithm) for the precision matrix, estimated with the TMFG-LoGo network filtering approach (intuitively, k -means, with the Mahalanobis distance, and a penalty for cluster changes).

***Toeplitz inverse covariance-based clustering
of multivariate time series data***
D. Hallac et al. (2017)

To estimate the correlation matrix between $\mathbf{x}_t, \dots, \mathbf{x}_{t+k}$, use the graphical lasso, but impose a Toeplitz constraint to ensure $\text{Cor}(\mathbf{x}_t, \mathbf{x}_{t+\ell}) = \text{Cor}(\mathbf{x}_s, \mathbf{x}_{s+\ell})$.

***The adoption of blockchain-based
decentralized exchanges***
A. Capponi and R. Jia (2021)

The pricing function $F : \mathbf{R}^2 \rightarrow \mathbf{R}^2$ of an automated market maker (AMM) satisfies

$$\begin{aligned}F_x, F_y &> 0 \\ F_{xx}, F_{yy} &< 0 \\ F_{xy} &> 0 \\ F(\lambda x, \lambda y) &= \lambda^k F(x, y), \quad k > 0 \\ F_x/F_y &\xrightarrow{x \rightarrow 0} \infty \\ F_x/F_y &\xrightarrow{x \rightarrow \infty} 0 \\ F_x/F_y &\xrightarrow{y \rightarrow 0} 0 \\ F_x/F_y &\xrightarrow{y \rightarrow \infty} \infty.\end{aligned}$$

The number of assets in the AMM (usually 2), and the volatility of their exchange rates, increase arbitrage opportunities and lowers the incentives for liquidity

providers. Higher curvature mitigates arbitrage, but benefits more investors than liquidity providers.

G-learner and GIRL: goal-based wealth management with reinforcement learning
M.F. Dixon and I. Halperin (2020)

G-learning is Q-learning (off-policy RL) with an entropy penalty $H(\pi)$ or $KL(\pi||\pi_0)$. The *free energy* F is the entropy-regularized state value function. The *G-function* is the entropy-regularized state-action value function.

With a few (Gaussian) assumptions and (quadratic) approximations, the problem is tractable.

AlphaPortfolio: direct construction through deep reinforcement learning and interpretable AI
L.W. Cong (2019)

Train a neural network, computing portfolio weights, from 12 months of 50 features (price, investments, profitability, intangibles, value, liquidity) for 3000 stocks, over 50 years, on 2-year mini-batches, to directly minimize the information ratio. One can add interactions with the environment:

- Trading costs;
- Trade impact;
- Fund failure (loss beyond 50% within 1 year).

The portfolio is Q stocks long, Q stocks short, with exponentially decaying weights.

The network could be an LSTM with attention

$$\begin{aligned} h_k &= \text{LSTM}(h_{k-1}, x_k) \\ r &= \sum_k \text{ATT}(h_K, h_k) h_k \\ \text{ATT}(h_K, h_k) &= \frac{\exp \alpha_k}{\sum_\ell \exp \alpha_\ell} \\ \alpha_k &= W'_0 \tanh(W_1 h_k + W_2 h_K) \end{aligned}$$

or a transformer (concatenation of several attention blocks)

$$\begin{aligned} V, K, Q &= W_0 x, W_1 x, W_2 x \\ \text{Attention}(Q, K, V) &= \text{Softmax} \left(\frac{QK'}{\sqrt{d_k}} \right) V \end{aligned}$$

(here, $\sqrt{d_k}$ helps keep the variance around 1).

Each asset is processed separately, and the results are combined with a *cross-asset attention network*

(CAAN)

$$\begin{aligned} q_i, k_i, v_i &= W_Q r_i, W_K r_i, W_V r_i \\ \beta_{ij} &= \frac{q'_i k_j}{\sqrt{d_k}} \\ a_i &= \sum_j \text{SATT}(q_i, k_j) v_j \\ \text{SATT}(q_i, k_j) &= \frac{\exp \beta_{ij}}{\sum_\ell \exp \beta_{i\ell}} \\ s_i &= \tanh(w' a_i + e). \end{aligned}$$

To interpret the model:

- Take the features with the largest $E \left[\left| \frac{\partial \text{IR}(x)}{\partial x_i} \right| \right]$ and use them in a polynomial regression with a lasso penalty;
- Alternatively, use “textual factors” (topics) from SEC filings to reproduce (distill) the model outputs.

Multi-horizon forecasting for limit order books: novel deep learning approaches and hardware acceleration using intelligent processing units
Z. Zhang and S. Zohren (2021)

Sequence-to-sequence (seq2seq) model, with attention, for multi-step forecasts of price changes (direction or value) from limit order book (LOB) data). Process the LOB (bid, ask, volume, price) as if it were an image, with inception modules.

input	x_t
encoder	$h_i = f(h_{i-1}, x_i)$
context	$c_t = \sum_i \alpha_{it} h_i$
decoder	$h'_t = f(h'_{t-1}, t_{t-1}, c_t)$
output	$y_t \sim g(h'_t, c_t)$
attention weights	$\alpha_{it} \propto \exp h_i^\top h'_{t-1}$ or $\exp h_i^\top W h'_{t-1}$ or $\exp \tanh W[h_i; h'_{t-1}]$
	i : time (past)
	t : time (future)

Textual factors: a scalable, interpretable, and data-driven approach to analyzing unstructured information
L.W. Cong et al. (2018)

Combine word embeddings and topic models:

- Compute word2vec embeddings
- Group the words into clusters, using LSH (locality-sensitive hashing);
- Assume that the topics are the clusters, and estimate a topic model, one topic at a time.

Applications:

- Macroeconomic (CPI, GDP, housing prices, unemployment, S&P, investment) forecasts from news (WSJ);
- VIX back-filling (1889 to 1986);
- Model interpretation.

Forest through the trees: building cross-sections of stock returns
S. Bryzgalova et al. (2019)

Instead of double and triple sorts (decision trees, to forecast or explain future returns, using the same variable and threshold for all nodes at the same depth), use a more general “asset pricing tree”.

Towards realistic market simulations: a generative adversarial networks approach
A. Coletta et al. (2021)

Train a cGAN (WGAN-GP) to generate new orders mimicking real orders, and feed them (as an aggregated agent) to a market simulator (ABIDES) on which you can train new trading strategies.

Zero-liquidation loans: a structured product approach to DeFi lending
A. Sardon (2021)

A zero-liquidation loan is a loan, say of USD, with an ETH collateral, at whose expiry the borrower can choose to repay the loan in USD or ETH (*i.e.*, leave the ETH collateral to the lender).

Hist: a graph-based framework for stock trend forecasting via mining concept-oriented shared information
W. Xu et al.

Forecast future stock returns from:

- Stock features,
- Known “concepts” (sectors, industries, regions, etc.),
- Unknown concepts (initialize them with stock embeddings; link each stock to the nearest concept, excluding its own; discard unlinked concepts).

The GNNs (graph neural networks) are applied to the

bipartite stock-concept graphs.

Embracing advanced AI/ML to help investors achieve success: RL for financial goal planning
S. Mohammed et al.

RL (DQN, OpenAI Gym) for financial planning [not unlike what I did at SRLGlobal]:

- Action: proportion of the wealth used for consumption, each year, discretized;
- State: tax rate, life expectancy, wealth, market state;
- Environment: Monte Carlo simulations;
- Reward: piecewise linear function of the probability of success.

FinEAS: Financial embedding analysis of sentiment
A. Gutiérrez-Fandiño et al. (2021)

BERT provides good token embeddings, but poor sentence embeddings: prefer *sentenceBERT*, a pre-trained BERT model (masked language model, trained for next-sentence prediction), fine-tuned on an entailment task. For sentiment analysis, either use sentenceBERT for feature extraction, or fine-tune it.

MAD risk parity portfolios
C. Ararat et al. (2021)

The mean absolute deviation

$$\text{MAD}(X) = \mathbb{E} |X - \mathbb{E} X|$$

is a *deviation measure*; the corresponding risk measure is

$$\rho(X) = \mathbb{E} [-X + |X - \mathbb{E} X|].$$

The MAD is not differentiable, but it has subgradients; Euler’s theorem is still valid:

$$\forall s \in \partial \text{MAD}(w) \quad \text{MAD}(w) = s'w.$$

A MAD-risk-parity portfolio w is such that

$$\exists s' \in \partial \text{MAD}(w) \quad \forall i, j \quad s_i w_i = s_j w_j.$$

For long-only portfolios: $w_i \propto \text{MAD}(x_i)^{-1}$.

Forecasting financial market structure from network features using machine learning
D. Castilho et al.

Take the current correlation matrix (on 100 assets), turn it into a graph (e.g., the minimum spanning tree, or edges for correlations in the top quartile, or above some fixed threshold), compute node and edge features (centralities, similarities, etc.) and use them to forecast the next correlation matrix (or graph).

Hierarchical information clustering by means of topologically embedded graphs
W.M. Song et al.

- Compute a correlation matrix;
- Build its PMFG;
- Find the non-separating 3-cliques, *i.e.*, the 3-cliques separating the graph into a (non-empty) interior and a (non-empty) exterior;
- The interior and the clique form a planar graph (“bubble”); the exterior and the clique form another planar graph; they can be processed, recursively, in the same way;
- We obtain a tree, with the bubbles as nodes, and the cliques as edges;
- Orient the edges by comparing the weights of the edges between clique and bubble;
- Converging bubbles define clusters.

Data considerations in graph representation learning for supply chain networks
A. Aziz et al. (2021)

To forecast missing edges in the supply chain, use a GNN on a knowledge graph, with several node types (company, country, capability, product, certification) and edge types (supplier, located, produces, complementary product, etc.), after completing the knowledge graph using cooccurrence frequencies.

A machine learning approach for predicting hidden links in supply chain with graph neural networks
E.E. Kosasih and A. Brintrup

For each pair of nodes x, y , consider the union of their (1-hop?) egonets, colour the nodes with the double radius distance $f(z) = [d(z, x), d(z, y)]$, and feed the corresponding 1-hot embedding to a GNN to predict the presence or absence of an edge x – y (there is one such graph for each (x, y) pair).

Previous approaches to link prediction relied on node similarity (but this assumes homophily – similar companies are more likely to be competitors than supplier/customer), maximum likelihood, or hand-crafted features.

General compound Hawkes processes for mid-price prediction
M. Sjogrena and T. DeLise (2021)

Model mid-prices as a compound Hawkes process

$$S_t = S_0 + \sum_{k=0}^{N(t)} X_k$$

where N is a Hawkes process and X an n -state Markov chain (e.g., taking values $\{\pm\delta\}$, or $\{-a, +b\}$, etc.).

Data-driven hedging of stock index options via deep learning
J. Chen and L. Li (2021)

To choose the hedge rate δ of an option, fit a

- Non-linear, but parametric model, combining Black-Scholes (BS) delta and vega (Hull-White);
- Non-linear (splines) model, combining moneyness, BS delta, and time-to-maturity;
- Non-linear model (neural network), combining moneyness, BS delta, time-to-maturity, VIX level (for calls), index returns (for puts) – using a GRU or LSTM for the VIX and the index returns does not improve things.

Deep reinforcement learning for active high-frequency trading
A. Briola et al.

PPO (stable baselines + SMBO for hyperparameter optimization) for single-stock intraday trading, from LOB data. The state includes the volumes of the first 10 levels for the past 10 ticks, the agent’s position, the mark-to-market value of its position, the current bid-ask spread.

FinRL: a deep reinforcement learning library for automated stock trading in quantitative finance
X.Y. Liu et al. (2020)

Media abnormal tone, earnings announcements, and the stock market
D. Ardia et al. (2021)

To estimate the “abnormal tone” present in news (*news contextualize information*):

- Compute the tone of the news;
- Subtract the average for other companies in the universe;
- Aggregate around events;
- Remove the effect of B/P , size, and earnings call tone.

A model of text for experimentation in the social sciences
M.E. Roberts et al.

Topic model whose weights are parametrized by observed variables.

**Clustering market regimes
using the Wasserstein distance
B. Horvath et al. (2021)**

To cluster a time series into regimes, use the Wasserstein k -means algorithm on time series windows (seen as empirical distributions).

**Measuring geopolitical risk
D. Caldara and M. Iacoviello (2021)**

The geopolitical risk (GPR) index counts the number of words or articles, in 10 US, UK, Canadian newspapers, related to war threats, peace threats, military build-up, nuclear threat, terrorist threat, beginning of war, escalation of war, terrorist attacks, with a few excluded words (“movie”, “obituary”, “cancer”, etc.). Add country and city mentions for country-specific measures.

Dictionary and data available.

**Online estimation and optimization
of utility-based shortfall risk
A.S. Menon et al.**

Utility-based shortfall risk (UBSR) generalizes CVaR (it is no longer coherent):

$$\text{SR}_\lambda(X) = \inf \{ t \in \mathbf{R} : \mathbb{E}[U(t+x)] \geq -\lambda \}.$$

**Risk measures beyond frictionless markets
M. Arduca and C. Munari (2021)**

Many risk measures can be defined as the minimum amount x to invest in some asset $(S_t)_t$ (e.g., cash, $S_t \equiv 1$), to make the strategy X acceptable (e.g., $\mathcal{A} = \{X : q_\alpha(X) \geq 0\}$).

$$\rho(X) = \int \{ x S_0 : X + x S_1 \in \mathcal{A} \}$$

This can be generalized to more reference assets $S_{i,t}$, or even strategies on those assets.

**Forecasting crude oil price
using event extraction
J. Liu and X. Huang (2021)**

**Exploration of the parameter space
in macroeconomic agent-based models
K. Naumann-Woleske et al.**

Macroeconomic agent-based models (ABM) have many parameters, but only changes in a few directions, in parameter space, actually influence the output. These directions (eigenvectors of the Hessian for the largest eigenvalues) are not axis-aligned.

**Investor sentiment in the stock market
M. Baker and J. Wurgler**

Define a sentiment index as the first principal component of several sentiment proxies:

- Trading volume;
- Dividend premium;
- Closed-end fund discount;
- Number of IPOs;
- First day return on IPOs;
- Equity share in new issues

and also VIX, mutual fund flows, insider trading, etc.

**Non-asymptotic estimation of risk measures
using stochastic gradient Langevin dynamics
J. Chu and L. Tangpi (2021)**

The expected shortfall can be computed as the solution of an optimization problem,

$$\text{ES}_u X = \inf_{q \in \mathbf{R}} \frac{1}{1-u} \mathbb{E}[(X-q)^+] + q$$

For $X = f(r, S)$, where $S = (X_0, \dots, X_n)$ is a set of risk factors and r the parameters of the strategy f , e.g., $f(r, S) = \sum r_i S_i$ for a portfolio, it can be computed with gradient descent.

**Heterotic risk models
Z. Kakushadze (2015)**

Hierarchical industry classifications define nested factor models (for the correlation matrix, not the variance)

$$V_0 = \beta_{01} V_1 \beta'_{01} + \Delta_0$$

$$V_1 = \beta_{12} V_2 \beta'_{12} + \Delta_1$$

$$V_2 = \beta_{23} V_3 \beta'_{23} + \Delta_2$$

(where 0, 1, 2, 3 are stocks, subindustries, industries, sectors).

**ETF risk models
Z. Kakushadze and W. Yu (2021)**

To compute the variance matrix of ETFs, estimate a “heterotic risk model” after building an ETF taxonomy:

- Largest sector, industry, subindustry (if one dominates, othersize “broad”);
- Largest capbin;
- Largest region or country;
- “Value” or “growth” or “mixed”;
- Bond type
- Duration bin;
- Credit rating
- Commodity type;
- “Leveraged”, “inverse”, “normal”.

Statistical industry classification
Z. Kakushadze and W. Yu (2016)

Cluster *normalized returns* (not raw returns, or correlations), after “smoothing” stocks with an unreasonably small volatility.

Use the *effective rank* as the number of clusters.

If you already have an industry classification, it is likely better: only apply the clustering inside large subindustries.

Cryptoasset factor models
Z. Kakushadze (2018)

(1-day) momentum, intraday volatility, and size – volume has little effect.

4-factor model for overnight returns
Z. Kakushadze (2015)

Size, intraday volatility (or $(H - L)/C$, averaged over 21 days), momentum, liquidity (volume).

Momentum residual networks
M.E. Sander et al. (2021)

Residual networks are discretizations of first order differential equations, $x_{n+1} = x_n + f_\theta(x_n)$. Momentum residual networks are discretizations of second-order ODEs.

$$v_{n+1} = \gamma v_n + (1 - \gamma)f(x_n)$$

$$x_{n+1} = x_n + v_{n+1}$$

$$\varepsilon \ddot{x} + \dot{x} = f(x), \quad \varepsilon = \frac{1}{1 - \gamma}$$

They are invertible.

Loss surface simplexes
for mode-connecting volumes
and fast ensembling
G.W. Benton et al.

Global minima are believed to be connected by multi-dimensional submanifolds. Search for simplicial complexes $K = \text{chull}(x_1, \dots, x_n)$ minimizing

$$\mathbb{E}_{x \sim \text{Unif}(K)} [\ell(x)] - \lambda \log \text{volume}(K)$$

where the expected loss in the simplex is approximated from 5 random points in it, and the number of vertices, n , progressively increases.

GRAND: graph neural diffusion
B.P. Chamberlain et al. (2021)

GNNs are equivalent to the explicit, single-step Euler discretization of a diffusion PDE: multi-step (Runge-

Kutta) and implicit schemes perform better.

x : node features (scalar field)

\mathcal{X} : edge features (vector field)

$$\langle x, y \rangle = \sum_i x_i y_i$$

$$\langle\langle \mathcal{X}, \mathcal{Y} \rangle\rangle = \sum_{i>j} w_{ij} \mathcal{X}_{ij} \mathcal{Y}_{ij} \quad w_{ij} \in \{0, 1\}$$

$$\mathcal{X}_{ij} = -\mathcal{X}_{ji} \quad \text{alternating edge field}$$

$$(\nabla x)_{ij} = x_j - x_i$$

$$(\text{div } \mathcal{X})_i = \sum_{j:(i,j) \in E} \mathcal{X}_{ij} = \sum_j w_{ij} \mathcal{X}_{ij}$$

$$\langle\langle \nabla x, \mathcal{X} \rangle\rangle = \langle x, \text{div } \mathcal{X} \rangle \quad \text{adjunction}$$

The diffusion equation

$$\frac{\partial x}{\partial t} = \text{div}(G(x) \nabla x), \quad G_{ij,ij} = a(x_i, x_j),$$

for some attention function a , is of the form

$$\frac{\partial x_t}{\partial t} = (A(x_t) - I)x_t = \bar{A}(x_t)x_t.$$

The explicit scheme is

$$x_i \leftarrow x_i + \sum_j a_{ij}(x_j - x_i),$$

i.e., $\mathbf{x}_{k+1} = (I + \tau A_k) \mathbf{x}_k$. The implicit scheme is $(I - \tau A_k) \mathbf{x}_{k+1} = x_k$ (it requires solving a linear system). Multi-step schemes are of the form

$$\sum_{j=0}^s \alpha_j x_{k+j} = \tau \sum_{s=0}^s \beta_j \bar{A}(x_{k+j}) x_{k+j}.$$

There are also adaptive schemes.

For the attention matrix A , either learn it (linear PDE), or use

$$A(X_i, X_j) = \text{Softmax} \frac{(W'_k X_i)' (W'_Q X_j)}{d_k}$$

where W_K and W_Q are learned.

Try to re-wire the graph after each backward step by thresholding the attention.

Fit without fear: remarkable mathematical phenomena of deep learning through the prism of interpolation
M. Belkin

Interpolating models, which overfit the data, may perform well out of sample. Examples include:

- k -nearest neighbour with a singular kernel, $k(x, z) = \|x - z\|^{-\alpha}$, $\alpha > 0$ (or a logarithmic kernel)

- Random ReLU features, $f_w(x) = \sum w_k(a_k x + b_k)_+$;

- Random Fourier features

$$f_w(x) = \sum_{k=1}^m w_k e^{i\langle v_k, x \rangle}$$

$$v_k \stackrel{\text{iid}}{\sim} N(0, I) \quad \text{fixed}$$

$$w = \underset{w: \forall i f_w(x_i) = y_i}{\text{Argmin}} \|w\|$$

```

- Linear regression $\beta = X^\dagger y$.

In the under-parametrized regime, we minimize the loss. In the over-parametrized regime, we minimize some penalty (it does not really matter which one) under the constraint that the loss be zero. The test error exhibits a “double descent” pattern.

Since global minima form a (potentially curved) sub-manifold, the problem is not locally convex. Instead, the *PL condition* suffices for gradient descent convergence:

$$\forall w \quad \frac{1}{2} \|\nabla \ell(w)\|^2 \geq \mu [\ell(w) - \ell(w^*)].$$

It is non-local, but may be replaced by PL^* , locally:

$$\frac{1}{2} \|\nabla \ell(w)\|^2 \geq \mu \cdot \ell(w)$$

with $\mu = \lambda_{\min}(k)$, where k is the tangent kernel:

$$k_{x,y}(w) = \langle \nabla_w f(x), \nabla_w f(y) \rangle.$$

Decoupled weight decay regularization

I. Loshchilov and F. Hutter (2019)

Gradient descent $\theta \leftarrow \theta - \alpha \nabla f(\theta)$ can be regularized with weight decay

$$\theta \leftarrow (1 - \lambda)\theta - \alpha \nabla f(\theta).$$

For SGD, this is equivalent to L^2 regularization; for Adam, it is not: weight decay works, L^2 regularization does not – do not put it in the loss function, keep it separate.

Lookahead optimizer:

k steps forward, 1 step back

M.R. Zhang et al. (2019)

Iterate:

- Run the optimizer for k steps, from $\phi_0 = \theta_t$ to ϕ_k ;
- Update θ in the direction of ϕ_k : $\theta_{t+1} = \phi_0 + \alpha(\phi_k - \phi_0)$.

There is a principled way of choosing α .

Unsupervised deep embedding for clustering analysis

J. Xie et al. (2016)

Jointly learn a low-dimensional data representation and a clustering:

- Initialize the data representation with an autoencoder $x \mapsto z = f_\theta(x)$;

- Initialize the cluster centroids $(\mu_j)_{1 \leq j \leq k}$ (k known), e.g., with k -means on the z_i 's';
- Measure the similarity between point z_i and centroid μ_j with a t distribution (as with t -SNE) with $\alpha = 1$ degrees of freedom,

$$q_{ij} \propto (1 + \alpha^{-1} \|z_i - \mu_j\|^2)^{(\alpha+1)/2}, \quad \sum_j q_{ij} = 1;$$

- As in self-training, define target distributions using the high-confidence predictions,

$$p_{ij} \propto q_{ij}^2 / f_j, \quad f_j = \sum_i q_{ij};$$

- Jointly optimize θ and μ to minimize

$$\sum_i \text{KL}(p_i \| q_i) = \sum_{ij} p_{ij} \log \frac{p_{ij}}{q_{ij}}.$$

**MLP-Mixer:
an all-MLP architecture for vision**
I. Tolstikhin et al.

The MLP mixer processes images by splitting them into patches and successively applying two types of layers:

- MLP on the patch dimension (the same for all channels and offsets (columns));
- MLP on the offset and channel dimensions (the same for each patch (row)).

Patches are all you need

Replace the MLP operations in MLP-mixer with convolutions.

Liquid time-constant networks
R. Hasani et al. (2021)

There are many variants of neural ODEs:

NODE	$\frac{dx_t}{dt} = f_\theta(x_t, I_t, t)$
CT-RNN	$\frac{dx_t}{dt} = -\frac{x_t}{\tau} + f_\theta(x_t, I_t, t)$
LTC	$\frac{dx_t}{dt} = -\frac{x_t}{\tau} + f_\theta(x_t, I_t, t)(A - x_t)$

The effective time scale is no longer a constant τ :

$$\frac{1}{\tau_{\text{eff}}} = \frac{1}{\tau} + f.$$

**Bayesian algorithm execution: estimating
computable properties of black-box functions
using mutual information**
W. Neiswanger et al. (2021)

Bayesian optimization can be generalized to black-box algorithms \mathcal{A} estimating some property of a function f from a set of points $(x_1, y_1), \dots, (x_n, y_n)$ (execution

path), with increasing precision as $n \rightarrow \infty$: optimization, numeric integration, root finding. Use the acquisition function

$$\text{EIG}(x) = H[\mathcal{A}|\text{Data}] - \mathbb{E}_{y_x \sim \text{GP}(\text{Data})} H[\mathcal{A}|\text{Data} \cup \{(x, y)\}],$$

approximated using the execution path and/or approximate Bayesian computation (ABC).

**Fast and accurate network embeddings
via very sparse random projection**
H. Chen et al. (2019)

Node embeddings are often computed in two steps:

- Form a node similarity matrix: DeepWalk, *i.e.*, A^k , or, more generally, $\sum_{\ell=1}^k \alpha_\ell A^\ell$;
- Reduce its dimension: SVD, or skipgram, *i.e.*, factorization of

$$M_{uv} = \log \frac{S_{uv} \cdot |S|}{D_u \cdot D_v} - b.$$

Use:

- A sparse random projection

$$P_{ij} = \begin{cases} +\sqrt{s} & \text{with probability } 1/2s \\ 0 & \text{with probability } 1 - 1/s \\ -\sqrt{s} & \text{with probability } 1/2s \end{cases}$$

- Normalize A^k (its entries have a heavy-tailed distribution):

$$\widetilde{A_{ij}^k} = A_{ij}^k \left(\frac{d_j}{2m} \right)^{\lambda-1}$$

where the normalization strength $\lambda - 1$ is chosen by the user.

Available in Neo4j.

**Database-friendly random projections:
Johnson-Lindenstrauss with binary coins**
D. Achlioptas (2002)

**Accurate intelligible models with pairwise
interactions**
Y. Lou et al. (2013)

Generalized additive models with interactions (GA²M), aka *explainable boosting machines* (EBM) can be estimated efficiently (greedily, after estimating and fixing the 1-dimensional functions, and approximating the interactions on the residuals using cuts).

Implementation in `interpret` (R/Python).

**Landscape of R packages for explainable
artificial intelligence**
S. Maksymiuk et al. (2021)

Start with DALEX (also available in Python), `flashlight` or `iml`; look at: feature importance (permutations), Shapley score, ceteris paribus curve, partial dependence plot.

(In Python: aix360, eli5, interpret, lime, shap, skater.)

AutoGL:
a library for automated graph learning
C. Guan et al.

Uncertainty, volatility and persistence norms of financial time series
S. Rudkin et al. (2021)

Multilevel Monte Carlo methods
M.B. Giles

Monte Carlo variance reduction with control variates uses

$$E[f] = E[f - \lambda(g - E[g])]$$

where $E[g]$ is known; the optimal value of λ is

$$\lambda = \text{Cor}(f, g) \sqrt{\frac{\text{Var } f}{\text{Var } g}}.$$

Two-level MLMC uses $E[P_1] = E[P_0] - E[P_1 - P_0]$ where P_0 is a cheap approximation of P_1 (and we have taken $\lambda = 1$).

More generally, MLMC uses

$$E[P_L] = E[P_0] + \sum E[P_\ell - P_{\ell-1}]$$

where the expectation at level ℓ uses $N_\ell \propto \sqrt{V_\ell/C_\ell}$ samples, and V_ℓ , C_ℓ are the variance and cost of one sample.

Generalizations include:

- Randomized MLMC: use a fixed number N of samples, but randomly select the level ℓ of each;
- Richardson approximation;
- Multi-index monte Carlo (time and space discretizations);
- Non-geometric grid;
- Quasi Monte Carlo.

Applications include: SDEs (Euler and Milstein), Lévy processes, SPDE, nested simulations

$$E_Z[f(E_W[g(Z, W)])].$$

Parametric integration is related: to estimate $E[f_\lambda(X)]$ as a function of λ , first estimate $E[f_0(X)]$, $E[f_1(X)]$, then $E[f_{1/2}(X)]$ using $(f_0 + f_1)/2$ as a covariate and continue recursively.

Multilevel Monte Carlo path simulation
M.B. Giles

Pair-copula constructions for financial applications: a review
K. Aas (2016)

Financial applications of vine copulas in finance include:

- VaR or CVaR for small portfolios;
- Vine CAPM (with C-vines (stars) or R-vines (unconstrained));
- Credit risk (probability of default), systemic risk (CDS), liquidity risk (bid-ask spread), operational risk;
- Scenario generation, for CVaR optimization or multivariate option pricing.

Bayesian inference for latent factor copulas and application to financial risk forecasting
B. Schamberger et al. (2017)

In the 1-factor latent model, $u_i \perp\!\!\!\perp u_j | v$, we can infer the values of v (unobserved) and of the copulas c_j of (u_j, v) (assuming their families, Gaussian or Gumbel, are known, and parametrizing them with the Fisher z transform of their Kendall τ 's, $z = \tanh^{-1}(\tau)$) with Gibbs sampling and *adaptive rejection metropolis sampling* (ARMS).

Application: portfolio VaR.

Asymmetric CAPM dependence for large dimensions: the canonical vine autoregressive model
A. Heinen and A. Valdesogo

As an alternative to the multivariate GARCH model, for more than 30 assets, use a *C*-vine (star-shaped), whose bivariate copula parameter vary with time in a DCC fashion, with GARCH residuals

and a Gaussian copula for $x_{ij}|M, S_1, S_2$ where M is the market, S_i the sectors, x_{ij} the stocks in sector i .

Risk management with high-dimensional vine copulas: an analysis of the Euro Stoxx 50
E.C. Brechmann and C. Czado (2013)

A regular (*i.e.*, unconstrained) vine copula (with constant parameters) with GARCH marginals, estimated on 50 stocks and indices (Euro Stoxx 50 and country indices) performs better than CAVA, a canonical (*i.e.*, star-shaped) vine, with time-varying parameters and

GARCH marginals.

**Copula-based factor models
for multivariate asset returns**
E. Ivanov et al. (2017)

**COPAR: multivariate time series modeling
using copulas autoregressive model**
E.C. Brechmann and C. Czado (2012)

A univariate copula-AR(p) model specifies copulas for

$$\begin{aligned} &X_{n-1}, X_n \\ &X_{n-2}, X_n | X_{n-1} \\ &X_{n-3}, X_n | X_{n-1}, X_{n-2} \\ &\vdots \\ &X_{n-p}, X_n | X_{n-1}, \dots, X_{n-p+1}. \end{aligned}$$

The COPAR model similarly generalizes the VAR(p) model; for two variables and $s < t$:

$$\begin{aligned} &X_s, X_t | X_{s+1:t-1} \\ &X_s, Y_t | X_{s+1:t} \\ &Y_s, X_t | X_{1:t-1}, Y_{s+1:t-1} \\ &Y_s, Y_t | X_{1:t}, Y_{s+1:t-1}. \end{aligned}$$

**The realized hierarchical archimedean copula
in risk modelling**

O. Okhriv and A. Tetereva

Estimate the structure of a *hierarchical archimedean copula* (HAC – an alternative to the pair copula construction (PCC) of vine copulas) by testing if each triplet of variables p, q, r is closer to

from the (rank) correlation (of intraday returns) – contrary to a dendrogram, the tree is not constrained to be binary. Estimate the copula parameters (the copula family is assumed known) by “inverting” the average correlation (there can be more than two variables at a time).

**Nonparametric estimation of the tree structure
of a nested Archimedean copula**
J. Segers and N. Uyttendaele (2018)

A *rooted tree* on a finite set of nodes (leaves) X is a set of subsets $\lambda \in \mathcal{P}(X)$ such that

- (i) $X \in \lambda$;
- (ii) $\forall x \in X \quad \{x\} \in \lambda$;
- (iii) $\forall A, B \in \lambda \quad A \subset B$ or $B \subset A$ or $A \cap B = \emptyset$.

The triplet trees can be estimated from data (for a known, 1-parameter copula family) with statistical tests on Kendall’s τ . If they are not compatible, lower the confidence level of the tests, α , until they are.

Implicit generative copulas
T. Janke et al.

To fit a nonparametric copula to data, train a neural network with two components:

- The first transforms $N(0, 1)$ random data into another distribution Q , without paying attention to the margins;
- The second makes the margins of Q uniform, to have a copula, not with the (sample) probability integral transform (it is not differentiable), but with a soft-rank,

$$\begin{aligned} v_i &= \frac{1}{M} \frac{1}{2} \sum_{j=1}^M \frac{1}{1 + \exp \alpha(y_i - y_j)} \\ &\approx \frac{1}{M} \sum_j \mathbf{1}_{y_i \leq y_j}. \end{aligned}$$

Use the *energy distance* as loss function

$$d^2 = \mathbb{E}_{\substack{U, U' \sim \text{data} \\ V, V' \sim \text{network}}} [2 \|U - V\| - \|U - U'\| - \|V - V'\|].$$

**Copulas as high-dimensional generative
models: vine copula autoencoders**
N. Tagasovska et al.

Learn a low-dimensional representation of the data with an autoencoder; fit a vine copula to that representation; use it to sample new data.

Principal component-guided sparse regression
J.K. Tay et al (2018)

Ridge regression (and elastic net) slightly bias the solution towards the leading singular vectors of X . **PClasso** provides a more aggressive shrinkage by replacing the ridge penalty $\beta' \beta$ with $\beta' V Z V' \beta$ where $X = U D V'$ is the SVD and $Z = \text{diag}(d_1^2 - d_k^2)_{1 \leq k \leq m}$.

If the factors are known to form groups, treat each separately.

The contours of the plasso penalty are ℓ^1 balls more or less elongated in the direction of the first singular vectors.

***Efficient scalable algorithms
for hierarchically semiseparable matrices***

S. Wang et al.

HSS matrices are block matrices, with dense diagonal blocks and low-rank off-diagonal blocks.

The fast kernel transform

J.P. Ryan et al.

Kernel methods require matrix-vector products $x \mapsto Kx$, where the kernel K may be large. To speed up computations, one can use a low-rank approximation of K (the Nyström method uses a random sample of the columns). Fast multipole methods use a low-rank approximation of the off-diagonal blocks, but they require a kernel-specific (Laurent series) expansion of the kernel.

Modern automatic differentiation (AD) tools can automatically compute those expansions.

Implementation in `fastKernelTransform.jl`.

A short course on fast multipole methods

R. Beatson and L. Greengard

We want to compute $u(x_i) = \sum_j w_j k(x_i, x_j)$ for some specific kernel k (it is a matrix-vector product $u = kw$) using a low-rank approximation

$$k(x, y) = \sum_{k=1}^p \phi_k(x) \psi_k(y)$$

(at least for off-diagonal blocks of k).

For instance, in dimension 1, for

$$u(x) = \sum_j w_j \sqrt{(x - x_j)^2 + c^2},$$

one can use a Laurent expansion in x around (away from) x_j ; it can be used with a hierarchical decomposition of \mathbf{R} into “panels” T : use the exact function

$$s_T(x) = \sum_{j \in T} w_j \sqrt{(x - x_j)^2 + c^2}$$

for the panel containing x and nearby panels, and the Laurent expansion for distant ones.

For the *Gauss transform* in dimension 2,

$$U(x) = \sum_{i=1}^N w_i e^{-\|x - x_i\|^2}$$

use the expansion into Hermite functions

$$e^{-\|x - x_i\|^2} = \sum_{n_1, n_2 \geq 0} \Phi_{n_1, n_2}(x - c) \Psi_{n_1, n_2}(x_i - c)$$

$$\Phi_{n_1, n_2}(\mathbf{x}) = h_{n_1}(x) h_{n_2}(y)$$

$$\Psi_{n_1, n_2}(\mathbf{x}) = \frac{x^{n_1} y^{n_2}}{n_1! n_2!}$$

The *multipole expansion*, in dimension 2 ($z \in \mathbf{C}$) is

$$\begin{aligned} \phi(z) &= \sum_i q_i \log(z - z_i) \\ &= \left(\sum_i q_i \right) \log z + \sum_{k \geq 1} \frac{1}{k} \sum_i q_i \frac{z_i^k}{z^k}. \end{aligned}$$

This gives an $O(N \log N)$ algorithm and, with more work (formula to translate a multipole expansion and/or convert it to a Taylor expansion) $O(N)$.

This generalizes to dimension 3 (but the expansion is more complicated).

***Do vision transformers see
like convolutional neural networks?***

M. Raghu et al.

The *centered kernel alignment* (CKA) compares neural network layers (activations) $X \in \mathbf{R}^{m \times p_1}$, $Y \in \mathbf{R}^{m \times p_2}$ on m samples (with p_1 and p_2 neurons) using the Gram matrices $K = XX'$, $L = YY'$.

$$\text{CKA}(K, L) = \frac{\text{HSIC}(K, L)}{\sqrt{\text{HSIC}(K, K) \text{HSIC}(L, L)}}$$

$$H = I_n - \frac{1}{n} \mathbf{1} \mathbf{1}'$$

$$K_c = H K H$$

$$L_c = H L H$$

$$\text{HSIC}(K, L) = \frac{\text{vec}(K_c) \cdot \text{vec}(L_c)}{(m-1)^2}$$

Text generation with efficient (soft) Q-learning

H. Guo et al.

Policy-gradient is on-policy: it is not data-efficient. Q -learning is off-policy, but noisy, and it converges slowly. Try the following variants (soft Q -learning):

- Q -learning with an entropy penalty;
- In the Bellman equation, replace $\text{Max}_a Q(s_{t+1}, a)$ with $\log \sum_a \exp Q(s_{t+1}, a)$;
- Instead of the state action value Q , path consistency learning (PCL) uses the state value function V and $V(s_t) - \gamma V(s_{t+1}) = r_t - \log \pi(a_t|s_t)$.

Curiosities and counterexamples in smooth convex optimization

J. Bolte and E. Pauwels (2020)

Given an increasing sequence of compact convex subsets of \mathbf{R}^2 with positively curved boundaries $(C_n)_{n \in \mathbf{Z}}$, there is a \mathcal{C}^k convex function with the C_n 's as level sets, and a positive definite Hessian outside $\text{Argmin } f = \bigcap_{n \in \mathbf{Z}} C_n$. The proof uses:

- The parametrization of ∂C_n by its normals, $c_n : \mathbf{R}/2\pi\mathbf{Z} \rightarrow \partial C_n$
- The boundary of the Minkowski sum $\lambda C_n + (1 - \lambda)C_{n+1}$: $\lambda c_n + (1 - \lambda)c_{n+1}$;
- Bernstein interpolation to smooth piecewise linear functions.

This can be used to build counter-examples, corresponding to paths of infinite length, jiggling or spiralling (e.g., the Newton flow need not converge, the Tikhonov path may have infinite length, etc.)

VICReg: variance-invariance-covariance regularization for self-supervised learning

A. Bardes et al.

Siamese networks learn image representations by maximizing the agreement between embeddings of different views of the same image. To avoid collapse problems, use a loss made of three terms:

- Invariance: $s(z, z') = \frac{1}{n} \sum \|z_i - z'_i\|_2^2$;
- Variance: $\frac{1}{d} \sum \text{hinge}_\gamma \sqrt{\text{Var } z_j}$;
- Covariance: $c(z) = \frac{1}{d} \sum_{j_1 \neq j_2} \text{Cov}(z)_{j_1, j_2}^2$.

Compositional processing emerges in neural networks solving math problems

J. Russin et al.

Tensor product (TP) transformers replace the atten-

tion mechanism

$$\text{Att}(Q, K, V) = \text{softmax} \left(\frac{QK'}{\sqrt{d}} \right) V$$

with

$$\text{TP-Att}(Q, K, V, R) = \text{softmax} \left(\frac{QK'}{\sqrt{d}} \right) V \odot R.$$

The devil is in the detail: simple tricks improve systematic generalization of transformers

R. Csordás et al.

Tests on human language to code translation datasets suggest the following advice.

- Use *universal transformers*, i.e., transformers with weights shared between layers: they are less sensitive to the order of the operations seen during training.
- Prefer relative (vs absolute) positional embedding, to help generalization to longer output lengths.
- Avoid early stopping for model selection.
- Have validation and test sets for both the iid and generalization splits.
- Use accuracy (not loss) for model selection.
- Try different scaling: $N(0, 1)$, Glorot multiplied by \sqrt{d} , Kaiming divided by \sqrt{d} .

Optimal design generation and power evaluation in T: the skpr package

T. Morgan-Wall and G. Khoury (2021)

There are many notions of “optimal design” (choice of a binary model matrix X):

- D-optimal: maximize $\det(X'X)$
- I-optimal: minimize $\text{tr}[(X'X)^{-1}M]$
- A-optimal: minimize $\text{tr}(X'X)^{-1}$
- G-optimal: minimize $\text{tr}(X'X)^{-1}$
- E-optimal: maximize $\sigma_{\min}(X'X)$
- T-optimal: maximize $\text{tr}(X'X)$
- Alias-optimal: minimize $\text{tr}(A'A)$ where $A = (X'X)^{-1}X'X_2$ where X_2 is the model matrix for the interaction terms.

In R: `skpr`, `AlgDesign`, `DoEbase`, `FrF2`, `conf.design`, `planor`, `rsm`.

svars: an R package for data-driven identification in multivariate time series analysis

A. Lange et al. (2021)

VAR models are of the form

$$y_t = \mu + A_1 y_{t-1} + \dots + A_p y_{t-p} + u_t \\ u_t \sim N(0, \Sigma).$$

Structural VAR (SVAR) models further decompose the innovations u_t as

$$u_t = B\varepsilon_t \\ \varepsilon_t \sim N(0, 1)$$

where B is invertible and $\Sigma = BB'$; it is not identifiable: B can be replaced by BO , for $O \in O_n$. To identify it, make additional assumptions, such as:

- Assume Σ changes with time, e.g., $\Sigma_1 = BB'$ until time t_0 , and $\Sigma_2 = B\Lambda B'$, Λ diagonal, after;
- Assume Σ smoothly transitions from Σ_1 to Σ_2 ,

$$\Sigma_t = (1 - \lambda_t)\Sigma_1 + \lambda_t\Sigma_2$$

with a logistic transition function

$$\lambda_t = \frac{1}{1 + e^{-\gamma(s_t - c)}}$$

for some state s_t ;

- Assume $\Sigma_t = B \text{diag}(\text{GARCH}_t) B'$;
- Use independent component analysis (ICA) to find $O \in O_n$, parametrized as a product of $n(n-1)/2$ Givens rotations, using:
 - The Cramer-von Mises distance between the empirical and the independence copulas;
 - FastICA, steadyICA;
 - or a Student likelihood.

***DC3: a learning method
for optimization with hard constraints***
P.L. Donti et al. (2021)

To solve (constrained) optimization problems with deep learning:

- Train a neural net, on solved problems, to produce partial solutions; item Complete them so satisfy the equality constraints (this is differentiable, thanks to the implicit function theorem);
- Perform a few gradient steps, along the manifold defined by the equality constraints, to enforce the inequality constraints (still differentiable).

***A unifying modeling abstraction
for infinite-dimensional optimization***
J.L. Pulsipher et al.

InfiniteOpt.jl solves infinite dimensional optimization problems, *i.e.*, problems involving functions, probability distributions, differential operators, expectations; it automatically discretizes the problem.

A text-based analysis of corporate innovation
G. Bellstam et al. (2017)

Fit a latent Dirichlet allocation (LDA) model, with 15 topics, to 800,000 analyst reports for S&P companies; identify the “innovation” topic as the closest (for the KL divergence) to the word distribution of a textbook on innovation (first Google hit for “innovation textbook pdf”); combine with the Loughran-McDonald sentiment lexicon.

***Language and domain specificity:
a Chinese financial sentiment dictionary***
Z.Du et al. (2021)

Using news articles from finance.sina.com.cn and manually selected words in 3 sentiment categories (positive, negative, and a China-specific “politically positive”, from 500 articles), train a word2vec model to find similar words and extend the lexicon.

Factor models for Chinese A-shares
M.X. Hanauer et al. (2021)

For China, instead of the Fama-French factors, use market, size, E/P (not B/P), and perhaps “abnormal turnover”.

$$\begin{aligned} \text{Turnover} &= \frac{\text{shares traded}}{\text{shares outstanding}} \\ \text{Abnormal turnover} &= \frac{\text{MA}(\text{turnover}, 20 \text{ days})}{\text{MA}(\text{turnover}, 250 \text{ days})} \end{aligned}$$

A comparison of global factor models
M.X. Hanauer (2019)

Replace the Fama-French factors with market, size, E/P, cash-based profitability, change in assets, momentum.

Spectral factor models
F.M. Bandi (2020)

In the 1-factor model (CAPM), $y_t = \alpha + \beta x_t + \varepsilon_t$, decompose the factor returns $(x_t)_t$ into high and low frequency components (Wold decomposition)

$$y_t = \alpha + \beta^{\text{LF}} x_t^{\text{LF}} + \beta^{\text{HF}} x_t^{\text{HF}} + \varepsilon_t$$

The classical model imposes $\beta^{\text{LF}} = \beta^{\text{HF}}$. Those spectral betas can be obtained from the high and low frequency components of y :

$$\begin{aligned} y_t^{\text{LF}} &= \alpha + \beta^{\text{LF}} x_t^{\text{LF}} + \varepsilon_t^{\text{LF}} \\ y_t^{\text{HF}} &= 0 + \beta^{\text{HF}} x_t^{\text{HF}} + \varepsilon_t^{\text{HF}}. \end{aligned}$$

***Weak supervision and Black-Litterman
for automated ESG portfolio construction***
A. Sokolov et al. (2021)

Train a BERT classifier (on New York Times news – they are already tagged) to recognize ESG articles, and use it as a Black-Litterman view to tilt the portfolio away from companies with a lot of ESG press coverage (alternatively, use this ESG score to adjust your model’s alpha).

***A reinforcement learning approach
to optimal execution***
C.C. Moallemi and M. Wang (2021)

To decide when to trade (a single share), predict future prices with an RNN and trade, at time t , if the predicted price change on $[t, T]$ is negative – otherwise, wait.

The loss $\frac{1}{T} \sum_{i=1}^T (r_i - \text{RNN}_i(x_0))^2$ can be replaced with

$$(r_1 - \text{RNN}_1(x_0))^2 + \sum_{i=2}^T (\text{RNN}_{i-1}(x_1) - \text{RNN}_i(x_0))^2$$

or

$$\sum_{i=1}^m (r_i - \text{RNN}_i(x_0))^2 + \sum_{i=m}^T (\text{RNN}_{i-m}(x_m) - \text{RNN}_i(x_0))^2$$

(temporal difference supervised learning).

Instead of the (unconditional) predicted price change, reinforcement learning uses the *continuation value*

$$C_{[t,T]}(x) = \sup_{\pi} \mathbb{E}_{\pi} \left[\sum_{i=t}^{\tau_{\pi}} x_i = x \right],$$

i.e., it takes early stopping into account.

For the state x , use:

- Time of day;
- Spread, normalized by volatility, or price;
- Depth (level1, level5, imbalance $(1 - 5)/(1 + 5)$);
- Number of trades, number of price changes;
- Trade size (exponentially weighted).

Normalize the prices (and the price changes) by the spread.

The reinforcement learning approach is slightly better, but not much, and it is more data-hungry.

**Portfolio selection:
a target-distribution approach
N. Lassance and F. Vrms (2021)**

Replace the portfolio optimization problem

$$\begin{array}{ll} \text{Find} & w \\ \text{To maximize} & w' \mathbb{E}[X] - \frac{1}{2} \lambda w' \text{Var}[X] w \end{array}$$

with

$$\begin{array}{ll} \text{Find} & w \\ \text{To minimize} & \text{KL}(w'X \parallel \text{target}) \end{array}$$

where the target distribution has the same first two moments as an efficient portfolio, but with skewness and kurtosis reflecting the investor's preferences, e.g., a generalized Gaussian

$$f(x) \propto \exp -\frac{1}{2} \left(\frac{|x - \alpha|}{\beta} \right)^{\gamma}$$

or a shifted normal.

If the target distribution has a smaller support, use the “conditionnal KL divergence”

$$\text{CKL}(f \parallel g) = \mathbb{E}_{X \sim f} \left[\log \frac{f(X)}{g(X)} \mid X \in \text{Supp } g \right] + \frac{p}{1-p}$$

where $p = \mathbb{P}_{X \sim f}[X \notin \text{Supp } g]$.

When the asset returns are Gaussian (and the target mean and variances on or above the efficient frontier), then the optimal portfolio is mean efficient.

**Hidden errors in regression-based attribution
L. Sneddon**

If the return forecasts are a linear combination of “alphas”, $\mu = \sum \alpha_i$, the (unconstrained) optimal portfolio is

$$\begin{aligned} w &= \underset{w}{\text{Argmax}} w' \mu - \frac{1}{2} \lambda w' V w \\ &= (\lambda V)^{-1} \mu \\ &= \sum (\lambda V)^{-1} \alpha_i \end{aligned}$$

which gives an exact decomposition of the returns

$$r'w = \sum r'(\lambda V)^{-1} \alpha_i.$$

**Estimation of a high-dimensional
counting process without penalty
for high-frequency events
L. Mucciante and A. Sancetta (2021)**

The explanatory variances X_t for the intensity λ_t of a counting process N_t (here, high-frequency trades) often measure some form of “activity”: they are positive and have a positive impact on the number of events – use a sign constraint in the model.

$$\begin{array}{ll} \text{Find} & \beta \\ \text{To minimize} & -2 \int_0^T X'_t \beta dN_t + \int_0^T (X'_t \beta)^2 dt \\ \text{Such that} & \beta \geq 0 \\ \text{Where} & dN_t = \lambda_t dt \\ & \lambda_t = X'_t \beta \\ & X_t \geq 0 \\ & \lambda_t > 0 \end{array}$$

Predictors include:

- Volume imbalance, for levels 1 to 5,

$$\frac{\text{bid size} - \text{ask size}}{\text{bid size} + \text{ask size}};$$

- Trade imbalance;
- Spread;
- Duration.

and their exponentially weighted moving average.

**The calculus of M-estimation in R with geex
B.C. Saul and M.G. Hudgens (2020)**

Estimators defined by *estimating equations*

$$\sum \psi(y_i, \hat{\theta}) = 0$$

are asymptotically normal and their asymptotic variance can be computed with the sandwich estimator.

The **geex** package computes user-defined estimators and their asymptotic variance (with numerical derivatives, not automatic differentiation).

The calculus of M-estimation
L.A. Stefanski and D.D. Boos (2001)

M-estimators (or generalized estimating equations, GEE) are solutions of $\sum_i \psi(y_i, \theta) = 0$ or, more generally, $\sum_i \psi(y_i, \theta) = c_i$ with $c_n/\sqrt{n} \xrightarrow{p} 0$.

Examples include:

- Mean: $\psi(y, \theta) = y - \theta$;
- Mean and MAD:

$$\psi(y, \theta) = \begin{pmatrix} |y - \theta_2| - \theta_1 \\ y - \theta_2 \end{pmatrix};$$

- Any maximum likelihood estimator (MLE), with the score function

$$\psi(y, \theta) = \frac{\partial \log f_\theta(y)}{\partial \theta};$$

- Mean and variance:

$$\psi(y, \theta) = \begin{pmatrix} y - \theta_1 \\ (y - \theta_1)^2 - \theta_2 \end{pmatrix}$$

(it is not the same ψ function as for the MLE, but it gives the same estimator);

- Ratio \bar{Y}/\bar{X} :

$$\psi(y, \theta) = y - \theta x \quad \text{or} \quad \psi(y, \theta) = \begin{pmatrix} y - \theta_1 \\ x - \theta_2 \\ \theta_1 - \theta_3 \theta_2 \end{pmatrix};$$

- $\mu, \sigma^2, \sigma, \log \sigma$:

$$\psi(y, \theta) = \begin{pmatrix} y - \theta_1 \\ (y - \theta_1)^2 - \theta_2 \\ \sqrt{\theta_2} - \theta_3 \\ \log \theta_2 - \theta_4 \end{pmatrix};$$

- Instrumental variables $\beta_{IV} = \beta_{Y|T}/\beta_{W|T}$:

$$\psi(y, \theta) = \begin{pmatrix} \theta_1 - t \\ (y - \theta_2 w)(\theta_1 - t) \end{pmatrix}$$

$$\text{or } \psi(y, \theta) = \begin{pmatrix} \theta_1 - t \\ \theta_2 - w \\ (y - \theta_3 w)(\theta_2 - w) \\ (y - \theta_4 w)(\theta_1 - t) \end{pmatrix};$$

- Robust location $\psi(y, \theta) = h_k(y - \theta)$ where $h_k = \mathbf{V}$;
- Sample quantile: $\psi(y, \theta) = p - \mathbf{1}_{y \leq \theta}$
- Positive mean deviation from the median:

$$\psi(y, \theta) = \begin{pmatrix} 2(y - \theta_2)\mathbf{1}_{y > \theta_2} - \theta_1 \\ \frac{1}{2} - \mathbf{1}_{y \leq \theta_2} \end{pmatrix};$$

- Non-linear least squares, $y = g(x, \beta) + \varepsilon$:

$$\psi(y, x, \theta) = [y - g(x, \beta)]g'(x, \beta);$$

- Linear regression with robust loss (truncated L^1):

$$\psi(y, x, \theta) = h_k(y - x'\beta)x;$$

- Generalized linear models (GLM).

Under reasonable assumptions,

$$\hat{\theta} \sim \text{AMN}\left(\theta_0, \frac{V(\theta_0)}{n}\right)$$

(asymptotically multivariate normal), where

θ_0 : true parameter (unknown)

$\hat{\theta}$: estimator

$$A(\theta_0) = \mathbb{E}_{Y \sim F} \left[- \frac{\partial \psi(Y, \theta)}{\partial \theta} \Big|_{\theta=\theta_0} \right]$$

$$B(\theta_0) = \mathbb{E}_{Y \sim F} [\psi(Y, \theta_0) \psi(Y, \theta_0)']$$

$$V(\theta_0) = A(\theta_0)^{-1} B(\theta_0) A(\theta_0)^{-\top} \quad (\text{sandwich estimator})$$

For the MLE, $A = B = I$ is the information matrix and $V = I^{-1}$, but the general formula remains valid even under model misspecification. Use a CAS to compute the matrix products: often, you only want one of the diagonal elements of V (your estimator alone is not an M-estimator, but it is a component of one).

The variance matrix can also be used for Wald tests: $(\hat{\theta} - \theta_0)' V_n(\hat{\theta})^{-1} (\hat{\theta} - \theta_0)$.

For non-smooth functions, swap ∂_θ and \mathbb{E} :

$$A(\theta_0) = - \frac{\partial}{\partial \theta} \mathbb{E}_{Y \sim F} [\psi(Y, \theta)] \Big|_{\theta=\theta_0}.$$

An axiomatization of Λ -quantiles
F. Bellini and I. Peri (2021)

The Λ -quantiles of a distribution F are

$$\Lambda\text{-VaR}(R) = -\inf \{x \in \mathbf{R} : F(x) > \Lambda(x)\}$$

where $\Lambda : \mathbf{R} \rightarrow (0, 1)$ is non-decreasing; they are characterized by the *locality* property: changing F above or below $\Lambda\text{-VaR}(F)$ does not change $\Lambda\text{-VaR}(F)$.

Nonparametric extrema analysis
in time series for envelope extraction,
peak detection and clustering
K. Gokcesu and H. Gokcesu

To detect peaks (or bursts) in a signal $(x_t)_t$, compute its envelope: signals a, b , such that $\forall t \ a_t \leq x_t \leq b(t)$ and $\forall t \ x_t \in \{a_t, b_t\}$, minimizing

$$\sum |a_{t+1} - a_t| + \sum |b_{t+1} - b_t|.$$

If a and b are defined using constant interpolation,

$$a_t = s_t x_t + (1 - s_t) a_{t-1}$$

$$b_t = (1 - s_t) x_t + s_t b_{t-1}$$

$$s_t \in \{0, 1\}.$$

The problem can be solved efficiently, in $O(T \log T)$.

Iterated and exponentially weighted moving principal component analysis
P. Bilokon and D. Finkelstein (2021)

When computing principal components on an expanding or moving window, the principal components can flip sign: instead of recomputing them anew each time, use an iterative algorithm (Ogita-Aishima) to refine the previous ones.

To account for non-stationarity, use exponential weights.

(Python implementation available.)

Iterative refinement for symmetric eigenvalue decomposition
T. Ogita and K. Aishima (2018)

Principal component analysis: a review and recent developments
I.T. Jolliffe and J. Cadima (2016)

PCA can be computed from the eigendecomposition of the variance matrix $S = \text{Var } X$: the unit eigenvectors a satisfy $\text{Var } Xa = a'Sa = \lambda aa' = \lambda$, or from the SVD of the column-centered data matrix $X^* = ULA'$,

$$(n-1)S = X^*X^* = (ULA')'(ULA') = AL^2A',$$

which also gives the *biplot*: the rows of U represent the observations, those of AL the variables.

Variants include:

- Varimax: rotate the principal components to make the loadings more concentrated;
- Sparse PCA (SCoTLASS);
- Robust PCA,

$$\text{Minimize } \|L\|_* + \lambda \|S\|_1 \text{ such that } X = L + S;$$

- Functional PCA;
- Symbolic PCA (PCA for intervals, histograms, etc.).

Evaluation of the importance of criteria for the selection of cryptocurrencies
N.A. van Heerden et al.

To combine predictors x_1, \dots, x_m of y , use a linear combination with weights:

$$\begin{aligned} w_j &= 1/m \\ w_j &\propto \sigma_j \\ w_j &\propto \sigma_j \sum_i (1 - \rho_{ij}) \end{aligned}$$

$$w_j \propto H_j \text{ (entropy)}$$

$$w_j \propto \frac{d_j^-}{d_j^- + d_j^+}$$

$$\begin{aligned} \text{where } d_j^+ &= d(x_j, y) \\ d_j^- &= d(x_j, -y). \end{aligned}$$

Learning-based robust optimization: procedures and statistical guarantees
L.J. Hong et al. (2017)

The chance-constrained program

$$\begin{aligned} &\text{Find } x \\ &\text{To minimize } f(x) \\ &\text{Such that } \mathbb{P}_{\xi \sim P}[f(x, \xi) \in A] \geq 1 - \varepsilon \end{aligned}$$

can be relaxed to a robust optimization problem by replacing the constraint with

$$\forall \xi \in U \ g(x, \xi) \in A$$

for some set U (uncertainty set) such that

$$\mathbb{P}_{\xi \in P}[\xi \in U] \geq 1 - \varepsilon.$$

If P is only known from a sample, split the data in two:

- Use the first part to define the shape of U (ellipsoid, convex hull, union of ellipsoids or polytopes);
- Use the second to calibrate the size of U , such that

$$\mathbb{P}_{\text{data} \sim P^n} \left[\mathbb{P}_{\xi \sim P}[\xi \in U(\text{data})] \geq 1 - \varepsilon \right] \geq 1 - \delta.$$

From data to decisions: distributionally robust optimization is optimal
B.P.G. van Parys et al.

For the optimization problem

$$\begin{aligned} &\text{Find } x \\ &\text{To minimize } c(x, P) \\ &\text{Where } c(x, P) = \mathbb{E}_{\xi \sim P} \gamma(x, \xi) \end{aligned}$$

use the distributionally robust predictor

$$\hat{c}(c, \hat{P}) = \sup_{\text{KL}(\hat{P} \| P) \leq r} c(x, P)$$

where \hat{P} is the empirical distribution: the out-of-sample disappointment $P[c(x, P) > \hat{c}(x, \hat{P})]$ decays exponentially (uniformly) for all x .

Fractional growth portfolio investment
A.E. Brockwell (2021)

The Kelly portfolio, investing fractions $k = \Sigma^{-1}(\mu - r\mathbf{1})$ of the wealth in each asset, maximizes the expected log-return

$$L = \mathbb{E} \left[\delta^{-1} \log \frac{A_{t+\delta}}{A_t} \right],$$

but the variance

$$V = \text{Var} \left[\delta^{-1} \log \frac{A_{t+\delta}}{A_t} \right]$$

can be very high. The *fractional Kelly portfolio* invests a fraction αk , $\alpha \in [0, 1]$, and has log-return expectation and variance

$$\begin{aligned} L &= r + (\alpha + \frac{1}{2}\alpha^2)S^2 \\ V &= \alpha^2 S^2 \end{aligned}$$

where $S = \sqrt{(\mu - r\mathbf{1})'\Sigma^{-1}(\mu - r\mathbf{1})}$ is the Sharpe ratio of the Kelly portfolio.

Arbitrage-free implied volatility surface generation with variational autoencoders
B.X. Ning et al.

To generate arbitrage-free synthetic implied volatility (IV) surfaces:

- Fit a stochastic differential equation (SDE) to the volatility surface, for each day;
- Train a VAR on the SDE parameters;
- Sample from the VAE;
- Compute the IV surface from the corresponding SDE.

Regularization is all you need: simple neural nets can excel on tabular data
A. Kadra et al.

A simple MLP with a cocktail of regularizers, with suitable hyperparameter tuning (BOHB, 4 days), outperforms traditional machine learning (gradient boosted trees) on tabular data:

- Batchnorm;
- Stochastic weight averaging, *i.e.*, averaging the local optima encountered on the optimization path;
- Lookahead optimizer;
- Snapshot ensembles: ensembles of minima obtained after restarts;
- Weight decay (L^2);
- Dropout (various shapes);
- Skip connections (shakedrop, shake-shake);
- Mixup: data augmentation with convex combinations of training samples
- Cutout: mask subsets of the input;
- Cutmix: Mixup + Cutout;
- FGSM (adversarial training).

Examining the dynamic asset market linkages under the covid-19 global pandemic
A. Noda (2021)

To test for market efficiency (between 3 markets, S&P 500, Bitcoin, gold), estimate a VAR

$$x_t = \mu + A_1 x_{t-1} + \dots + A_q x_{t-q} + \varepsilon_t$$

with time-varying coefficients A_i , and compute the “joint degree of market efficiency” ζ

$$\Phi = (I - A_1 - \dots - A_q)^{-1}$$

$$\zeta = \text{Max} \sqrt{(\Phi - I)'(\Phi - I)}.$$

Under the efficient market hypothesis (EMH), $A_1 = \dots = A_q = 0$ and $\zeta = 0$.

Those markets are getting less efficient.

multimode: an R package for mode assessment
J. Ameijeiras-Alonso et al. (2021)

To visually assess the presence of several models in univariate data:

- The *mode tree* plots the modes versus the bandwidth of a kernel density estimator (kde);

- The *mode forest* is a set of bootstrapped mode trees;
- The significant zero (*SiZer*) map plots the significance of the sign of the slope of a kde (whether a confidence interval for $f'_h(x)$ is in \mathbf{R}_- , \mathbf{R}_+ or contains zero) as a function of x and the bandwidth h .

There are also statistical tests.

mosum: a package for moving sums in change-point analysis
A. Meier et al. (2021)

To detect changepoints (on the mean), compute the average on a window of size G before and after all potential breakpoints k

$$T_G(k) = \sqrt{\frac{G}{2}} \left(\text{Mean}_{k < t \leq t+G} X_t - \text{Mean}_{k-G < t \leq t} X_t \right)$$

and return $\text{Argmax}_k |T_G(k)| / \sigma_k$. You can try several (or asymmetric) bandwidths.

Conformal prediction with Orange
T. Hočevar et al. (2021)

A *conformal predictor* predicts a *set* of labels with low nonconformity, for some user-chosen nonconformity function such as:

- Distance to the closest neighbour with the same label;
- Predicted probability of the correct class; s
- Difference of predicted probabilities of the two most likely classes;
- (For regression) absolute error of the prediction.

Also check **conformal** (R), **nonconformist** (Python).

gdpc: an R package for generalized dynamic principal components
D. Peña et al. (2020)

The first *dynamic principal component* of a multivariate time series $(z_t)_t$ is the univariate time series $(f_t)_t$ such that (f_{t-k}, \dots, f_t) gives the best reconstruction of z_t :

$$z_{it} \approx \alpha_i + \sum_{j=0}^k \beta_{ij} f_{t-j}$$

(it is noisy at the ends of the sample and therefore not useful for forecasting); β can be computed from f with OLS and conversely. The loss can be a square loss, or a robust alternative. The original DPC was a linear combination (and convolution) of the observations.

**Dimension reduction for time series
in a blind source separation context using R**
K. Nordhausen et al. (2021)

Diagonalize, not just the covariance matrix, but (jointly) several cross-covariance matrices, for several lags.

Blind source separation of a multivariate time series $(z_t)_t$ assumes that the signals are autocorrelated, but that the noise is not:

$$x_t = \mu + \Omega z_t$$

$$\text{Cov}_\tau(z_t) = \text{E}[z_t z'_{t+\tau}] = \begin{pmatrix} \Lambda_\tau & 0 \\ 0 & 0 \end{pmatrix}.$$

AMUSE uses the eigendecomposition of the autocovariance matrix of the standardized time series $x_t^{\text{st}} = U\Lambda_\tau U'$, $UU' = I$. To allow the eigenvalues to be similar, SOBI approximately jointly diagonalizes several autocovariance matrices, maximizing

$$\sum_{\tau \in \mathcal{T}} \sum_i (u'_i \text{Cov}_\tau(x_t^{\text{st}}) u_i)^2, \quad U \text{ orthogonal.}$$

This can be generalized (gFOBI) to include 4th cross-moments $B_\tau = \text{E}[x_{t+\tau} x'_t x'_{t+\tau}]$ by maximizing

$$\sum_\tau \sum_i (u'_i B(x_t^{\text{st}}) u_i)^2$$

or by using a wider class of cumulants (gJADE).

$$\sum_\tau \sum_i \sum_{jk} (u'_i C_\tau^{jk}(x_t^{\text{st}}) u_i)^2$$

$$C_\tau^{jk} = \text{E}[x_{t+\tau} x'_t e_{jk} x'_{t+\tau}] - \text{Cov}_\tau(x_t)(e_{jk} + e_{kj}) \text{Cov}_\tau(x_t)' - \text{tr}(e_{jk}) I_p$$

$(e_{jk})_{jk}$: standard basis of $\mathbf{R}^{p \times p}$

or by inserting a nonlinear function g in the moment computations ($y \mapsto y^2$ or $y \mapsto \log \cosh y$)

$$\sum_{\tau, i} \text{E}[g(u'_i x_t^{\text{st}}) g(u'_i x_{t+\tau}^{\text{st}})^2] - \text{E}[g(u'_i x_t^{\text{st}})] \text{E}[g(u'_i x_{t+\tau}^{\text{st}})^2]$$

or by combining linear and quadratic parts

$$\lambda \sum_{i, \tau} (u'_i C_\tau u'_i)^2 + (1 - \lambda) \sum_{i, \tau} \text{E}[(u'_i x_t^{\text{st}})^2 (u'_i x_{t+\tau}^{\text{st}})^2].$$

For supervised dimension reduction (TSIR, TSAVE, TSSH), approximately jointly diagonalize

$$G_\tau(x_t^{\text{st}}, y_t) = \text{Cov} \text{E}[z_t | y_{t+\tau}]$$

or $G_\tau(x_t^{\text{st}}, y_t) = \text{E}[I_p - \text{Cov}(z_t | y_{t+\tau})]$

by maximizing

$$\sum_{\tau, i} (u'_i G_\tau u_i)^2.$$

Supervised dimension reduction of X given Y looks for a subspace $\text{Span } B$ such that the distributions

$$Y | X = x \quad \text{and} \quad Y | BX = Bx$$

coincide, by using the first eigenvectors of

$$M = \frac{1}{n} \sum_j \bar{z}_j \bar{z}'_j$$

$$M = \frac{1}{n} \sum_j (I - \text{Var}[Z | Y = j])^2$$

$$M = \sum_i y_i z_i z'_i$$

$$M = \sum \text{res}(y \sim x)_i z_i z'_i$$

(SIR (sliced inverse regression), SAVE (sliced average variance estimates), PHD (principal Hessian directions)) where

- z is the standardization of x ;
- y is discrete, with values $j = 1, \dots, h$ (slice it into equal-sized bins if needed);
- $z_j = \text{E}[Z | Y = j]$.

Implementation in `dr`.

**Principal component analysis
with sparse fused loading**
J. Guo et al. (2010)

Adding an L^1 penalty to PCA does not give enough sparsity: relax the orthogonality constraint by looking for A and B such that $X \approx XBB'$ (projection of X on $\text{Span } B$), $B \approx A$, A orthogonal:

Find A, B
To minimize $\|X - XBA'\|^2 + \lambda_1 \sum_k \|\beta_k\|_1 + \lambda_2 \sum_k \|\beta_k\|_2^2$
Such that $AA' = I$.

You can replace the second penalty with a *fusion penalty* to pull the coefficients together when the correlation is high.

$$\lambda_2 \sum_k \sum_{s < t} |\rho_{st}| |\beta_{sk} - \text{sign}(\rho_{st}) \beta_{tk}|$$

**SQUAREM: an R package
for off-the-shelf acceleration of EM, MM
and other EM-like monotone algorithms**
Y. Du and R. Varadhan (2020)

The square iterative method (SQUAREM) speeds up the convergence of EM-like monotone iterative algorithms

$$\theta_{n+1} = F(\theta_n)$$

$$L(\theta_{n+1}) \geq L(\theta_n)$$

by iterating:

$$\begin{aligned}
\theta_1 &= F(\theta_0) \\
\theta_2 &= F(\theta_1) \\
r &= \theta_1 - \theta_0 \\
v &= (\theta_2 - \theta_1) - r \\
\alpha &= -\|r\| / \|v\| \\
\theta_3 &= \theta_0 - 2\alpha r + \alpha^2 v \\
\text{if } L(\theta_3) &> L(\theta_2) - \eta : \\
\theta_0 &= F(\theta_3) \\
\text{else:} \\
\theta_0 &= \theta_2.
\end{aligned}$$

Examples include:

- Poisson mixtures;
- Ecdf estimation from interval-censored data;
- Admixture (estimating the proportion of each ancestral population in each individual, and the proportion of each allele in each ancestry);
- MM for logistic regression;
- Factor analysis

$$\begin{aligned}
Z &\sim N(0, I) && \text{latent} \\
Y &\sim N(\beta'Z, \Delta) && \text{observed.}
\end{aligned}$$

The R package smicd:
statistical methods for interval-censored data
P. Walter

Fully hyperbolic convolutional neural networks
K. Lensink et al.

Hyperbolic networks

$$Y_{j+1} = 2Y_j - Y_{j-1} + f_\theta(Y_j),$$

i.e., discretizations of $\ddot{y} = f_\theta(y)$ are invertible (we can recover Y_{j-1} from Y_j and Y_{j+1}). Combine them with learned discrete wavelet transforms to coarsen the state and increase the dimension without losing information.

Generative ODE modeling
with known unknowns
O. Linial et al. (2021)

To estimate the parameters θ of an ODE $\dot{z} = f_\theta(z)$ for which only an (unknown) transformation of the state $z = g(z)$ is observed, use an autoencoder

$$(x_t)_t \xrightarrow{\text{encoder}} \theta, z_0 \xrightarrow[\dot{z} = f_\theta(z)]{\text{known ODE}} (z_t)_t \xrightarrow{\text{decoder}} (x_t)_t$$

Exterior point operator splitting
for nonconvex learning
S. Das Gupta et al. (2021)

A closed set is *prox-regular* at a point if projection onto it is single-valued in the neighbourhood of this point.

Examples include sparsity and low rank:

$$\begin{aligned}
N &= \{x \in \mathbf{R}^d : \#x \leq k\} \\
N &= \{X \in \mathbf{R}^{m \times d} : \text{rank } X \leq k\}.
\end{aligned}$$

To solve the optimization problem

$$\begin{aligned}
&\text{Find } x \\
&\text{To minimize } f(x) + \frac{1}{2}\beta \|x\|^2 \\
&\text{Such that } x \in C \cap N
\end{aligned}$$

where f is convex, C is convex, N is non-convex but prox-regular around local minima, replace the constraint with an indicator function

$$\begin{aligned}
&\text{Find } x \\
&\text{To minimize } f(x) + \frac{1}{2}\beta \|x\|^2 + \iota(x) \\
&\text{Where } \iota(x) = \begin{cases} 0 & \text{if } x \in C \cap N \\ \infty & \text{otherwise,} \end{cases}
\end{aligned}$$

regularize it

$$\begin{aligned}
\iota_\mu(x) &= \min_y \iota(y) + \frac{1}{2\mu} \|y - x\|^2 \\
&= \frac{1}{2\mu} d(x, C \cap N)^2
\end{aligned}$$

and progressively decrease μ (e.g., from 1 to 10^{-4}).

To solve each subproblem

$$\text{Minimize}_x f(x) + \underbrace{\iota_\mu(x) + \frac{1}{2}\beta \|x\|^2}_{\iota(x)}$$

use ADMM (Douglas-Rachford)

$$\begin{aligned}
x &\leftarrow \text{prox}_{\gamma f} z \\
y &\leftarrow \text{prox}_{\gamma \iota}(2x - z) \\
z &\leftarrow z + y - x
\end{aligned}$$

where $\text{prox}_{\gamma f} z$ is the solution of a convex optimization problem, often known in closed form, and $\text{prox}_{\gamma \iota}$ can be computed from the projection onto $C \cap N$.

Implementation in NExOS.jl.

High frequency covariance: a Julia package
for estimating covariance matrices
using high-frequency financial data
S. Baumann and M. Klymak (2021)

To estimate volatility in presence of microstructure noise:

- Either use large intervals, so that the microstructure noise disappears;
- Or combine the sample volatility estimators at two different scales.

To estimate the covariance from asynchronous time series:

- Choose a grid of times and compute the correlation using the last available log-prices

$$\text{Cov}(X, Y) = \frac{1}{N} \sum_i (X_{\leq t_i} - \bar{X})(Y_{\leq t_i} - \bar{Y})$$

(but the correlations are biased downwards);

- *Refresh time sampling* (BNHLS) uses an adaptive grid where the next time is the time at which each asset has an updated price; you may want to put assets in blocks of similar trading frequencies;
- Pre-averaging averages returns on a moving window and multiplies the returns of two assets when the windows intersect;
- The spectral local method of moments is another estimator;
- The 2-scale volatility estimator can be used to compute covariances:

$$\text{Cov}(X, Y) = \frac{\text{Var}[\gamma X + (1-\gamma)Y] - \text{Var}[\gamma X - (1-\gamma)Y]}{4\gamma(1-\gamma)}$$

To make sure the covariance matrix is positive semi-definite:

- Linearly interpolate with the identity;
- Or replace eigenvalues below a threshold with the average of the (positive) eigenvalues thus discarded.

For the correlation matrix, iterate:

- Take the nearest positive semi-definite matrix;
- Take the nearest matrix with unit diagonal and off-diagonal elements in $[-1, +1]$.

On covariation estimation for multivariate continuous Itô semimartingales with noise in non-synchronous observation schemes
K. Christensen et al. (2011)

To estimate a covariance matrix from asynchronous data, in presence of microstructure noise, first average the returns, with some kernel function, pooling k consecutive ticks, $k \propto n$, then use the Hayashi-Yoshida estimator:

$$\rho_{\text{HY}} = \frac{\sum_{I_i^X \cap I_j^Y \neq \emptyset} \Delta X_i \Delta Y_j}{\sqrt{\sum (\Delta X_i)^2 \sum (\Delta Y_j)^2}}.$$

Estimating the quadratic covariation matrix from observations: local method of moments and efficiency
M. Bibinget et al. (2014)

Estimator of the variance matrix, from asynchronous data, in presence of microstructure noise, from the Fourier coefficients of the time series on subintervals of $[0, 1]$

$$S_{jkl} = \sum_i (Y_{i\ell} - Y_{i-1,\ell}) \Phi_{jk} \left(\frac{t_{i-1,\ell} + t_{i\ell}}{2} \right)$$

$$\Phi_{jk} = \frac{1}{kh} \int_{j \text{ periods}}^{(k+1)h} \cos\left(\frac{2\pi}{k} (t - jh)\right) dt$$

BayesNetBP: an R package for probabilistic reasoning in Bayesian networks
H. Yu et al. (2020)

To use a conditional Gaussian Bayesian network (CG-BN, *i.e.*, a PGM with a mixture of discrete and continuous nodes) estimated by `bnlearn`, `catnet`, `deal`, `pcalg`, or Hugin (commercial).

R0I: an extensible R optimization infrastructure
S. Theußl et al. (2020)

The R0I package provides a unified interface to most optimization packages (linear, mixed integer, conic, quadratic, nonlinear – there is a long list of supported solvers): specify the objective (linear, mixed integer, quadratic or nonlinear), the constraints (linear, second order, semi-definite, (dual) exponential, (dual) power cone, nonlinear), the bounds (and integrality constraints), and the solver (the package can provide a list of solvers suitable for the problem). Some problems can be automatically reformulated (e.g., binary QP to MILP).

Examples include:

- Best subset regression (linear regression with an ℓ_0 penalty);
- Relative risk regression (logistic regression for the relative risk instead of the odds ratio, *i.e.*, with a log link);
- Convex clustering (sum of norm (SON) clustering):

$$\text{Minimize}_M \sum_i \|M_{i\cdot} - X_{i\cdot}\|_2^2 + \lambda \sum_{i < j} \|M_{i\cdot} - M_{j\cdot}\|_1;$$

- Graphical lasso.

CVXR: an R package for disciplined convex optimization
A. Fu et al. (2020)

Long list of examples of convex optimization problems:

- Huber regression (L^2 for small residuals, L^1 for large ones);
- Quantile regression;
- Elastic net;
- Logistic regression ($z \mapsto \log(1 + e^z)$ is convex);
- Graphical lasso

$$\begin{array}{ll} \text{Find} & S \\ \text{To maximize} & \log \det S - \text{tr}(S\hat{\Sigma}) \\ \text{Such that} & S \succcurlyeq 0 \\ & \sum |S_{ij}| \leq \alpha \end{array}$$

- Saturating hinges (linear splines, constant beyond their boundaries)

$$\begin{array}{ll} \text{Find} & w_0, w \\ \text{To minimize} & \sum_k \ell(y_i, f(x_i)) + \lambda \|w\|_1 \\ \text{Such that} & \sum_{j=1}^k w_j = 0 \end{array}$$

- Log-concave distribution estimation on $[0, k]$.

- Survey calibration (changing the weights as little as possible so that the statistics of the sample match those of the population)
- Nearly isotonic fit: replace the constraints $\beta_{i+1} \geq \beta_i$ with a penalty on $(\beta_i - \beta_{i+1})_+$;
- Nearly convex fit: idem with $(\beta_i - 2\beta_{i+1} + \beta_{i+2})_+$
- Worst case risk of a portfolio with constraints on the asset variance matrix (e.g., known variances and correlation signs)

$$\begin{array}{ll}\text{Find} & \Sigma \\ \text{To maximize} & w' \Sigma w \\ \text{Such that} & \Sigma \succeq 0 \\ & \forall i, j \quad L_{ij} \leq \Sigma_{ij} \leq U_{ij}\end{array}$$

- Catenary (with a ground constraint);
- Portfolio optimization;
- Kelly gambling;
- Channel capacity (maximum mutual information);
- Fastest mixing Markov chain on a known directed graph: the rate of convergence is the second largest eigenvalue of P , i.e., $\sigma_{\max}(P - \frac{1}{n}\mathbf{1}\mathbf{1}')$.

cutpointr: improved estimation and validation of optimal cutpoints in R
C. Thiele and G. Hirschfeld (2021)

For more robust cutpoints for (logistic-regression-like) classification algorithms

$$\text{data} \mapsto \text{score} \mapsto \mathbf{1}_{\text{score} \geq \text{cutpoint}}$$

optimize the Youden index

$$\begin{aligned} J &= \text{sensitivity} + \text{specificity} - 1 \\ \text{sensitivity} &= \frac{\text{TP}}{\text{TP} + \text{FN}} \\ \text{specificity} &= \frac{\text{TN}}{\text{TN} + \text{FP}} \end{aligned}$$

or some other metric, not on the sample data, but:

- After bootstrap (average the optimal cutpoints);
- Or after smoothing the cutpoint \mapsto metric function (GAM, splines, loess);
- Or using a kde of the conditional distributions

$$\text{score} \mid P \quad \text{and} \quad \text{score} \mid N.$$

Colorspace: a toolbox for manipulating and assessing colors and palettes
A. Zeileis et al. (2020)

There are many colour spaces:

- RGB;
- sRGB (device-independent: fixed Gamma);
- HSV, whose dimensions are confounded: brightness changes dramatically with hue;
- HLS (very similar);
- XYZ (not perceptually uniform, unintuitive, but standardized);
- LUV: perceptually uniform, for emissive technologies, but the UV dimensions (red/green and yellow/blue) are unintuitive;

- LAB (similar, for pigments);
- polarLUV, aka HCL – that is the one you should use;
- polarLAB.

The package provides many predefined palettes, functions to evaluate a palette (`demoplot`, `hclplot`, `specplot`, `swatchplot`), some interactively (`hcl_wizard`, `hcl_color_picker`, `cvd_emulator`) and also desaturate, lighten, darken.

Many other packages provide colour palettes: `RColorBrewer`, `viridis`, `rcartocolor`, `scico`, `pals`, `paletteer`, `wesanderson`, `Polychrome`; also check `colorscience` (more complex algorithms), `roloc` (English colour names).

FastSHAP: real-time Shapley value estimation
N. Jethani et al.

The Shapley score is the solution of an optimization problem:

$$\begin{array}{ll}\text{Find} & \phi \\ \text{To minimize} & \mathbb{E}_{s \sim p} [v(s) - v(\mathbf{0}) - s' \phi] \\ \text{Such that} & \mathbf{1}' \phi = v(\mathbf{1}) - v(\mathbf{0})\end{array}$$

where p is the Shapley kernel; it can be solved by gradient descent.

If you want Shapley scores for many inputs to the same neural net, learn a function to compute the solution of that problem (for the constraint, either ignore it and modify the solution to satisfy it, or add it as a penalty).

Efficient estimation of bid-ask spreads from open, high, low and close prices
D. Aria et al. (2021)

Assuming that observed log-prices are the latent prices plus or minus half the spread,

$$\begin{aligned} \log P_t &= \log \tilde{P}_t + S \cdot (B_t - \frac{1}{2}) \\ B_t &\sim \text{Bernoulli} \end{aligned}$$

the spread is given by

$$\text{Cov}(\Delta \log P_t, \Delta \log P_{t-1}) = -\frac{1}{4} \text{Spread}^2$$

unless there are periods with no trades. More generally,

$$\text{Spread}^2 = -\frac{4 \text{Cov}(\Delta \log P_t, \Delta \log P_{t-1})}{(1 - P[P_t = P_{t-1}])^2}.$$

This can be extended to OHLC data.

A characterization of cross-impact kernels
M. Rosenbaum and M. Tomas (2021)

Model price impact as

$$P_t - P_0 = \int_0^t K(t-s)(dN_s^a - N_s^b)$$

where (N^a, N^b) is a multi-dimensional Hawkes process with intensity

$$\begin{pmatrix} \lambda_t^a \\ \lambda_t^b \end{pmatrix} = \begin{pmatrix} \mu \\ \mu \end{pmatrix} + \int_0^t \begin{pmatrix} \Phi^{aa}(t-s) & \Phi^{ab}(t-s) \\ \Phi^{ba}(t-s) & \Phi^{bb}(t-s) \end{pmatrix} \begin{pmatrix} dN_s^a \\ dN_s^b \end{pmatrix}$$

and $K : \mathbf{R}_+ \rightarrow \mathbf{R}^{d \times d}$ is the cross-impact kernel.

A martingale-admissible kernel is a kernel for which the prices are a martingale; this is the case if

$$P_t - P_0 = \text{long-term impact} \times \text{long-term order imbalance} \\ = \left(\lim_{s \rightarrow \infty} K(s) \right) \times \left(\lim_{s \rightarrow \infty} \mathbb{E}[N_s^a - N_s^b | \mathcal{F}_t] \right).$$

A no-arbitrage condition imposes constraints on $K(0)$ and $\lim_{s \rightarrow \infty} K(s)$; there is only one martingale-admissible kernel satisfying those (necessary) conditions; it need not ensure the absence of arbitrage, but fits the data well, and one can compute the closest no-arbitrage kernel.

DAGs with NO TEARS:
continuous optimization for structure learning
X. Zheng et al. (2018)

A graph is acyclic if its adjacency matrix satisfies $\text{tr } e^A = d$ – indeed,

$$\text{tr } e^A = \text{tr } I + \text{tr } A + \frac{1}{2!} \text{tr } A^2 + \dots \geq \text{tr } I = d$$

and $\text{tr } A^k$ counts cycles of length k .

For a weight matrix W , use $h(w) = \text{tr } e^{W \odot W} - d$ ($W \odot W$ has the same sparsity as W and nonnegative entries).

Dynotears:
structure learning from time series data
R. Pamfil et al. (2020)

Use the trace exponential function to enforce acyclicity of W in the SVAR model

$$\mathbf{x}_t = W\mathbf{x}_t + A_1\mathbf{x}_{t-1} + \dots + A_p\mathbf{x}_{t-p} + \varepsilon_t.$$

Beyond prediction in neural ODEs:
identification and interventions
H. Aliee et al.

Estimating an ODE from a single trajectory is an ill-posed problem: even in the linear case, the ODE is not uniquely determined:

$$(\forall t \ e^{tA} = e^{tB}) \not\Rightarrow A = B.$$

Adding a regularizer does not help but, in practice, this does not seem to matter, and a simple regularization

$$\|\theta\|_{\text{simple}} = \|W^{L+1}W^L \dots W^1\|_{1,1}$$

(the L^1 norm of the gradient of the neural network, if we remove the nonlinearities) correctly recovers causal relations.

Forecasting stock returns
with large dimensional factor models
A. Giovannelli and D. Massacci (2021)

Statistical factor models explain current stock returns from risk factors computed from current stock returns. Instead, explain *future* stock returns using risk factors computed from other time series.

y_{it} : trailing stock returns

x_{jt} : predictors, known at time t

f_{kt} : factors

$$y_{i,t+1} = \sum_k \beta_{ik} f_{kt} + \varepsilon_{i,t+1}$$

$$f_{kt} = \sum_j \gamma_{kj} x_{jt} + \eta_{kt}$$

Industrial forecasting with exponentially
smoothed recurrent neural networks
M. Dixon (2020)

An α -RNN is an RNN

$$h_t = \tanh(Wx_t + Uh_{t-1} + b)$$

$$y_t = Wh_t + b$$

with a smoothed hidden state

$$\tilde{h}_t = \tanh(Wx_t + Uh_{t-1} + b)$$

$$h_t = (1 - \alpha)h_{t-1} + \alpha\tilde{h}_t$$

$$y = Wh_t + b$$

(apply α coordinate-wise, and re-estimate it from time to time).

stratematch: prognostic score stratification
using a pilot design
R.C. Aikens et al.

Before (propensity score or Mahalanobis) matching, stratify the data (fit a model $y \sim x|T = 0$ on some of the controls – do not reuse these data).

Solving mixed integer programs
using neural networks
V. Nair et al.

Represent a mixed integer program (MIP) as a bipartite graph with variables and constraints as nodes, edges whenever a variable appears in a constraint, and node or edge features from the coefficients of the problem (and the solution of the relaxation) and learn two models (heuristics customized to a dataset):

- A branching model, using imitation learning to reproduce a known good (but expensive) branch-and-bound heuristic (“full strong branching”);
- A “diving” model, to generate good partial assignments.

Exact combinatorial optimization with graph convolutional neural networks

M. Gasse et al. (2019)

Imitation learning to reproduce known good heuristics; list of additional features, mostly from the solution of the relaxed problem.

A unified algorithm for the non-convex penalized estimation: the ncpen package

D. Kim et al. (2020)

Optimization of a convex loss with a non-convex penalty can be performed with the CCCP (convex concave procedure, or difference of convex (DC) algorithm): write the objective as a difference of convex functions

$$\begin{aligned} \text{Loss}(\beta) &= L(\beta) + \sum J(|\beta_i|) \\ &= \underbrace{L(\beta) + \kappa \sum |\beta_i|}_{\text{convex}} + \underbrace{\sum D(\beta_i)}_{\text{concave}} \\ \text{Loss}(\beta) &\leq L(\beta) + \kappa \sum |\beta_i| + \sum \nabla D(\bar{\beta}_i) \beta_i \\ &= U(\bar{\beta}, \beta) \end{aligned}$$

and iteratively minimize the upper bound obtained by linearizing the concave term

$$\bar{\beta} \leftarrow \underset{\beta}{\text{Argmin}} U(\bar{\beta}, \beta).$$

To minimize U , use a quadratic approximation of $L(\beta)$ around $\bar{\beta}$, combined with line search.

ROCnReg: an R package for receiver operating characteristic curve inference with and without covariates

M.X. Rodríguez-Álvarez and V. Inácio (2020)

The ROC curve plots the true and false positive fractions

$$\begin{aligned} x &= P[Y \geq c \mid D = 0] \\ y &= P[Y \geq c \mid D = 1]. \end{aligned}$$

The *partial area under the curve* (pAUC) is the area under the curve such that $x \in [0, u_1]$ (largest acceptable FPR) or $y \in [v_1, 1]$ (lowest acceptable TPR). The *Youden index* is

$$\text{YI} = \underset{p}{\text{Max}} |\text{ROC}(p) - p|.$$

One can also consider the *covariate-specific ROC* $\text{ROC}(p|x)$ and the *covariate-adjusted* one

$$\text{AROC}(p) = \int \text{ROC}(p|x) dP(x)$$

(it is different from the *pooled ROC*).

One can compute bootstrap estimates of the ROC curve (it can be considered as a cdf) and confidence intervals for the AUC; there are also frequentist and Bayesian approaches.

Precision-recall-gain curves: PR analysis done right
P.A. Flach and M. Kull

In case of class imbalance, if there are too many negative samples, ignore the true negatives and consider the precision-recall curve.

Rescale $1/\text{precision}$ and $1/\text{recall}$, linearly, so that they span $[0, 1]$, before making the precision-recall plot and computing its area under the curve (ignore the negative gains).

$$\begin{aligned} \text{precG} &= \frac{\text{prec} - \pi}{(1 - \pi)\text{prec}} = 1 - \frac{\pi}{1 - \pi} \frac{\text{FP}}{\text{TP}} \\ \text{recG} &= \frac{\text{rec} - \pi}{(1 - \pi)\text{rec}} = 1 - \frac{\pi}{1 - \pi} \frac{\text{FN}}{\text{TP}} \end{aligned}$$

NlinTS: an R package for causality detection in time series
Y. Hmamouche (2020)

Nonlinear generalizations of Granger causality include

- Nonlinear models, *i.e.*, comparing

$$\begin{aligned} Y_t &= f(Y_{<t}) + \varepsilon_t \\ \text{and } Y_t &= g(Y_{<t}, X_{<t}) + \varepsilon_t \end{aligned}$$

where f and g are neural networks;

- Transfer entropy

$$\begin{aligned} \text{TE}_{X \rightarrow Y} &= I(Y_t; X_{<t} \mid Y_{<t}) \\ &= H(Y_t \mid Y_{<t}) - H(Y_t \mid Y_{<t}, X_{<t}) \end{aligned}$$

which can be normalized by dividing by $H(Y_t \mid Y_{<t})$.

Estimators of transfer entropy often rely on discretization. Instead, one can use nearest neighbours.

$$\begin{aligned} H(X) &= - \underset{x \sim p}{\text{E}} [\log p(x)] \\ \hat{H}(X) &= - \frac{1}{n} \sum \log \hat{p}(x_i) \\ \hat{H}(X) &= \Gamma(n) - \Gamma(k) + \log c + \frac{m}{n} \sum d_i \end{aligned}$$

(assuming that \hat{p} is locally constant in balls around each x_i , where Γ is the gamma function, m the dimension, d_i twice the distance between x_i and its k th nearest neighbour, and c the volume of the unit ball. (The estimator can be improved by letting k vary with i .)

***tsmp: an R package for time series
with matrix profile***
F. Bischoff and P.P. Rodrigues (2020)

***Model-based clustering
of multivariate ordinal data
relying on a stochastic binary search algorithm***
C. Biernacki and J. Jacques (2015)

To sample from the BOS (binary ordinal search) model for ordinal data on $\llbracket 1, m \rrbracket$ with location μ and precision π , search μ in $\llbracket 1, m \rrbracket$ with stochastic binary search:

- Start with the interval of candidates $\llbracket 1, m \rrbracket$;
- Pick an element at random in the interval of candidates;
- Compare it with μ , with probability π ; if there is no comparison, select the result with probabilities proportional to the lengths of the intervals $e_{<}$, $e_{=}$, $e_{>}$;
- Reduce the interval accordingly;
- Continue until the interval is a singleton.

It can be estimated with the EM algorithm if $m \leq 8$ (the latent variables are the pivots chosen and whether the comparisons were performed). One can also consider mixtures and/or multivariate extensions.

***OneStep:
Le Cam's one-step estimation procedure***
A. Brouste et al. (2020)

Instead of computing the MLE:

- Start with a crude estimate, e.g., from moment matching, quantile matching, or the MLE on a small sample of the data;
- Do only one Newton step

$$\theta \leftarrow \theta - I_{\theta}^{-1} \frac{1}{n} \sum \dot{\ell}(\theta, x_i)$$

using the information matrix I_{θ} if known, or an estimator

$$\hat{I}_{\theta} = -\frac{1}{n} \sum \ddot{\ell}(\theta, x_i).$$

It is faster than the MLE, and still asymptotically efficient.

***Regularized transformation models:
the tramnet package***
L. Kook and T. Hothorn

Statistical models often estimate a conditional mean: they look for a function f such that

$$f(x) = \mathbb{E}[Y|X=x].$$

Instead, *transformation models* estimate the whole conditional distribution

$$Y|X=x \sim f(\cdot|X=x).$$

They can still be linear: $f(Y) - X'\beta \sim N(0, 1)$. The transformation can be parametrized with *Bernstein polynomials*

$$b_{n,k} = \binom{n}{k} x^k (1-x)^{n-k},$$

for which monotonicity is easy to enforce ($\sum_k \theta_k b_{k,n}$, $\theta_k \leq \theta_{k+1}$; cf the **basefun** package). The models can be stratified (a different transformation for each value of a categorical variable, but the same linear parameters β).

***Skew-t expected information matrix evaluation
and use for standard error calculations***
R.D. Martin et al. (2020)

The standard skew normal distribution has density $f(x) = 2\phi(x)\Phi(\alpha x)$. The standard T distribution is the distribution of $T = Z/(\chi_{\nu}^2/\nu)$, where $Z \sim N(0, 1)$ and χ_{ν}^2 are independent. The standard skew- T distribution is the distribution of $T = Z/(\chi_{\nu}^2/\nu)$, where $Z \sim \text{SN}(0, 1, \alpha)$.

***SimilaR:
R code clone and plagiarism detection***
M. Bartoszuk and M. Gagolewski (2020)

Detect plagiarism from the *program dependence graph*: a tree, indicating how statements are nested (like the AST, but with no ordering), with “data dependence edges” constraining the order in which the statements can be executed.

In addition, canonicalize statements (e.g., spurious braces), recognize duplicated variables, remove dead code, assume functions have no side effect (and can be memoized), rewrite map-like expressions (**apply***) as loops.

***ROBustness in network (robin):
an R package for comparison
and validation of communities***
V. Policastro et al. (2020)

To assess the significance of communities in a graph, check how much perturbation is needed to alter them (titration).

***AQuadtree: an R package for quadtree
anonymization of point data***
R. Lagonigro et al. (2020)

To preserve privacy, bin spatial data in a quadtree, putting isolated points in an “isolated” bin instead of discarding them.

RNGforGPD: an R package for generation of univariate generalized Poisson data
H. Li et al. (2020)

The generalized Poisson distribution (GPD)

$$P(y) = \begin{cases} \theta(\theta + \lambda y)^{y-1} e^{-\theta - \lambda y} \\ 0 \text{ if } \lambda < 0 \text{ and } y > \lfloor -\theta/\lambda \rfloor \end{cases}$$

allows for over- and under-dispersion in count data.

Its multivariate generalization is

$$\begin{aligned} X_i &\sim \text{GPD}(\theta_i, \lambda_i) & i \in \llbracket 0, m \rrbracket \\ Y_i &= X_i + X_0 & i \in \llbracket 1, m \rrbracket \end{aligned}$$

Package wsbacfit for smooth backfitting estimation of generalized structured models
J. Roca-Pardiñas et al. (2020)

Generalized structured models (GSM)

$$\Lambda(Y) = G(Z, \beta, g(X)) + S(T, \delta, s(U)),$$

with G, S, Λ known, β, g, δ, s unknown, generalize GAMs

$$Y = \sum g_i(X_i) + \varepsilon$$

and varying coefficient models

$$Y = \sum g_i(X_i) Z_i + \varepsilon.$$

gk: an R package for the g-and-k and generalized g-and-h distributions
D. Prangle (2020)

The g-and-k and g-and-h distributions are 4-parameter univariate distributions of the form

$$\begin{aligned} X &= A + BG(Z)H(Z) \\ Z &\sim N(0, 1) \end{aligned}$$

where A and B are location and scale parameters, G introduces asymmetry, and H fattens the tails.

$$\begin{aligned} G(z) &= 1 + c \tanh(gz/2) \\ H(z) &= z(1 + z^2)^k \\ H(z) &= z \exp(hz^2/2). \end{aligned}$$

(They are only defined from their quantiles: the density is not available in closed form.)

A new versatile discrete distribution
R. Turner (2020)

The *Beta-binomial distribution*

$$\begin{aligned} p &\sim \text{Beta}(\alpha, \beta) \\ X &\sim \text{Bin}(n, p) \end{aligned}$$

only allows for over-dispersion and its maximum likelihood estimation is unreliable. Instead, try the *discretized beta*

$$p(x) \propto \text{dbeta}_{\alpha, \beta} \left(\frac{x+1}{N+2} \right), \quad x \in \llbracket 0, N \rrbracket.$$

Linear fractional stable motion with the rlfsm R package
S. Mazur and D. Otryakhin (2020)

LFSM generalizes fractional Brownian motion (fBM):

$$X_t = \int [(t+s)_+^{H-1/\alpha} - (-s)_+^{H-1/\alpha}] dL_s,$$

where L is a symmetric α -stable Lévy motion.

IndexNumber: an R package for measuring the evolution of magnitudes
A. Saavedra-Nieves and P. Saavedra-Nieves (2020)

There are many ways of combining quantities and prices over time, in a CPI-like fashion: Paasche, Marshall-Edgeworth, Laspeyres, Fisher indices.

The Lambert way to Gaussianize heavy-tailed data with the inverse of Tukey's h transformation as a special case
G.M. Goerg (2014)

Tukey's h distribution

$$\begin{aligned} U &\sim N(0, 1) \\ Z &= U \exp(\tfrac{1}{2} h U^2), \end{aligned}$$

which can be generalized to $Y = \sigma Z + \mu$, has fat tails. Conversely, one can use the inverse transformation (expressible with the Lamber W function, *i.e.*, the inverse of $u \mapsto ue^u$) to remove fat tails.

Finding optimal normalizing transformations via bestNormalize
R.A. Peterson (2020)

To make your data more Gaussian, try \log , $\sqrt{\cdot}$, \exp , Argsinh , Box-Cox (power transformation), Yeo-Johnson (Box-Cox, separately for positive and negative inputs), Lambert $W \times F$, and ordered quantiles.

R Journal (2020)

The **crqa** package (recurrence quantification analysis, RQA) extracts features from a recurrence (or cross-recurrence) plot.

For fast topological data analysis (TDA), prefer Ghudi in TDA in dimension 2, and Ripser in TDAstats in higher dimensions.

The **biglasso** package provides out-of-code lasso, with memory-mapped files and *feature screening rules*.

The **DChaos** package provides several estimators of the Lyapunov exponent.

The **ProjectManagement** package designs Gantt charts, identifies critical activities, computes early and last times of each activity, manages resources and costs – e.g., to allocate delay costs using Shapley values.

The futures API

```
f <- future(expr)
v <- value(f)
r <- resolved(f)
```

enables asynchronous and parallel processing. Also check `future.apply`, `furrr`, `doFuture`; `parallel`, `foreach`, `doMC` (Unix), `doParallel` (Windows); `parallelly`, `globals`, `listenv`.

The KSPM package provides kernel regression.

The `gofCopula` package provide all the goodness-of-fit tests you can think of, for the most common copulas.

The `ari` package generates videos from a presentation and a script, using `ffmpeg` (`tuneR`) and (paid) text-to-speech APIs (AWS Polly, Microsoft or Google).

The R-Docker ecosystem has become very large.

Seeded CCA is CCA after dimension reduction (when $p > n$, it is faster than penalized CCA).

When reshaping data (normalizing a data-frame), one may use regular expressions, e.g., `(.*)[.](.*)`; the capture groups can be named (`?<part>.*`)[.](`?<dim>.*`); named argument can simplify this syntax: `part='.*'`, `'[.]'`, `dim='.*'`. Alternatives include `reshape2`, `data.table`, `tidyr`, `tidyfast`, `tidyfst`, etc.

The TULIP package provides (six) sparse generalizations of LDA; it uses `tenstr` for tensor computations.

The NTS package provides non-linear time series models, such as threshold AR (TAR), functional AR

$$X_t = \sum_i \phi_i * X_{t-i} + \varepsilon_t,$$

where X_t , ε_t , ϕ_i are functions, and non-linear non-Gaussian state space models (sequential Monte Carlo, SMC).

The `cran2copr` package uses Redhat's `copr` buildsystem to turn CRAN packages requiring compilation into (rpm-installable) binary packages. Also check `bspm` for cross-distribution binary packages.

***Deep matrix tri-factorization:
mining vertex-wise interactions
in multi-space attributed graphs***
Y. He (2020)

Given the incidence matrix of a graph, $G \in \{0, 1\}^{n \times n}$, and node features $S \in \mathbf{R}^{n \times s}$, $O \in \mathbf{R}^{n \times o}$, matrix tri-factorization approximates the graph by finding \hat{S} , \hat{O} , W minimizing

$$\|G - \hat{S}W\hat{O}'\|^2 + \lambda_1 \|S - \hat{S}\| + \lambda_2 \|O - \hat{O}\|$$

and can help predict missing edges. The matrix W “harmonizes” the two feature spaces, linearly: instead, replace the bilinear mapping $(S, O) \mapsto SWO'$ with a neural net; this generalizes to more than two feature spaces.

***Fast nonnegative matrix tri-factorization
for large-scale data co-clustering***
H. Wang et al.

The fast nonnegative matrix factorization

$$\begin{array}{ll} \text{Find} & F \in \mathbf{R}^{d \times m} \\ & S \in \mathbf{R}^{m \times c} \\ & G \in \mathbf{R}^{n \times c} \\ \text{To minimize} & \|X - FSG'\|^2 \\ \text{Such that} & F, S, G \geq 0 \\ & F, G \in \Psi \end{array}$$

where Ψ is the set of cluster indicator matrices (*i.e.*, boolean object \times cluster matrices: $g_{ij} = 1$ if x_i belongs to cluster j). It generalizes k -means but clusters both rows and columns.

Regularize by adding terms $\text{tr}(G'L_dG)$ and $\text{tr}(F'L_fF)$ where $L = I - D^{-1/2}WD^{1/2}$ is the normalized graph Laplacian.

Scalable non-negative matrix tri-factorization
A. Čopar et al. (2017)

Matrix trifactorization

$$\text{Minimize}_{U, S, V} \|X - USV'\|^2,$$

estimated by gradient descent

$$\begin{array}{l} U \leftarrow U \odot \frac{XVS'}{USV'VS'} \\ V \leftarrow V \odot \frac{X'US}{VS'U'US} \\ S \leftarrow S \odot \frac{U'XV}{U'USV'V} \end{array}$$

possibly with orthogonality constraints $U'U = I$, $V'V = I$,

$$\begin{array}{l} U \leftarrow U \odot \sqrt{\frac{XVS'}{U'U'XVS'}} \\ V \leftarrow V \odot \sqrt{\frac{X'US}{V'V'S'US}} \\ S \leftarrow S \odot \sqrt{\frac{U'XV}{U'USV'V}} \end{array}$$

can be computed blockwise.

***Constant function market makers:
multi-asset trades via convex optimization***
G. Angeris et al. (2021)

Decentralized (crypto-currency) exchanges (DES) do not use a limit order book (LOB) but a constant function market maker (CFMM), an automated market maker implemented as a smart contract, and to which anyone can contribute liquidity (as with an ETF). Its reserves are $R \in \mathbf{R}_+^n$ (for n assets) and it maintains a vector of weights $v \in \mathbf{R}_+^n$, $\mathbf{1}'v = 1$ for the stakes of the liquidity providers. A trade (Δ, Λ) (“I give $\Delta \in \mathbf{R}_+^n$ and want $\Lambda \in R\mathbf{R}_+^n$) is accepted if $\phi(R + \Delta - \Lambda) = \phi(R)$ (or $R + \gamma\Delta - \Lambda$, $\gamma < 1$, to account for a trading fee),

for some concave, increasing, differentiable function ϕ , such as

$$\phi(R) = p'R \quad (\text{pegged: constant prices})$$

$$\phi(R) = \prod R_i^{w_i}$$

$$\phi(R) = (1 - \alpha)\mathbf{1}'R + \alpha \prod R_i^{w_i}$$

$$\phi(R) = \mathbf{1}'R - \alpha \prod R_i^{-1}.$$

The unscaled prices are

$$p_i = \frac{\partial \phi(R)}{\partial R_i};$$

the prices are p_i/p_n if asset n is the numéraire.

Inverse options on a Black-Scholes world

C. Alexander and A. Imeraj (2021)

Options on Deribit, an unregulated bitcoin exchange, are *inverse option*: options to buy or sell bitcoin, priced, margined and settled in bitcoin, which avoids the use of USD.

$$\text{Payoff}_{\text{Call}}(S) = K \cdot \text{Max}(K^{-1} - S^{-1}, 0)$$

S : price of BTC in USD

K : strike in USD

They chose not to tell you

B. Knuteson (2021)

Overnight returns are less volatile, and higher, than intraday returns.

A sparsity algorithm

with applications to corporate credit rating

D. Wang et al. (2021)

When looking for a counterfactual explanation of the output of a black-box model, *i.e.*, the minimum change to the input to change the output, add a sparsifying penalty to the optimization problem, to make the explanation more actionable.

Financial return distributions:

past, present and covid-19

M. Wątorrek et al. (2021)

To model distribution tails:

$$f(x) \sim |x|^{-(1+\alpha)} \quad 0 < \alpha < 2 \quad \alpha\text{-stable}$$

$$f(x) \sim |x|^{-(1+\alpha)} e^{-\gamma|x|} \quad \gamma > 0 \quad \text{truncated } \alpha\text{-stable}$$

$$f(x) \sim |\exp|(x^{-\beta}) \quad 0 < \beta < 1 \quad \text{stretched exponential}$$

$$f(x) \sim e_q(-\beta x^2) \quad q\text{-Gaussian}$$

where the q -Gaussian distribution maximizes the Tsallis entropy if the first and second moments are fixed, and the q -exponential is

$$e_q(x) = [1 + (1 - q)x]_+^{1/(1-q)}.$$

End-to-end risk budgeting portfolio optimization with neural networks

A.S. Uysal et al. (2021)

Do not use risk budgeting blindly: use it end-to-end, to maximize the information ratio (with `cvxpylayers`):

- Start with features (returns and volatility for 7 ETFs);
- Use a neural network to compute the risk budgeting parameters, b , c ;
- Solve the risk budgeting problem

$$\begin{aligned} \text{Find} \quad & y \geq 0 \\ \text{To minimize} \quad & y' \Sigma y \\ \text{Such that} \quad & \sum b_i \log y_i \geq c \end{aligned}$$

- Compute the weights, $w = y / \|y\|_1$;
- Compute the information ratio.

The unreasonable effectiveness of optimal transport in economics

A. Galichon (2021)

Applications of optimal transport in economics include many 2-player situations, such as *matching problems*

x : worker

y : job

α_{xy} : job satisfaction

γ_{xy} : output

w_{xy} : wage

$$u_x = \text{Max}_y (\alpha_{xy} + w_{xy})_+$$

$$v_y = \text{Max}_x (\gamma_{xy} + w_{xy})_+$$

Maximize u_x and v_y

or hedonic models

x : producer
 y : consumer
 z : quality
 P_z : price
 C_{xz} : production cost
 U_{yz} : utility
 Maximize $P_z - C_{xz}$ and $U_{yz} - P_z$.

If P (resp. Q) is the martingale measure for options on X (resp. Y), the price of an option with payoff $u(X)$, resp. $v(Y)$, is $E_P u(X)$, resp. $E_Q v(Y)$. If the market is incomplete and there is no unique martingale measure for (X, Y) , the price of an option with payoff $\Phi(X, Y)$ is at most

$$\max_{\pi \in \mathcal{M}(P, Q)} E_\pi \Phi(X, Y).$$

If $P = \text{Unif}(0, 1)$, the solution of the optimal transport problem is the graph of the cdf of Q – it defines quantiles. Replacing $[0, 1]$ with $[0, 1]^n$ gives *multivariate quantiles*.

Inverse optimal transport tries to recover the transport cost Φ_{xy} from the optimal transport plan π_{xy} , often from covariates ϕ_{xyk}

$$\pi_{xy} = \exp \left[\sum_k \lambda_k \phi_{xyk} - u_x - v_y \right]$$

(λ , u , v unknown), for instance, to link import-exports π to several measures of country similarity ϕ_{xyk} .

Stock price prediction using BERT and GAN **P. Sonkiya et al. (2021)**

Use a GAN to forecast returns (e.g., from technical indicators): you get a distribution of plausible returns (as with a Bayesian model) – or an ensemble of forecasts.

Deep risk models: a deep learning solution for mining latent risk factors to improve covariance matrix estimation **H. Lin et al.**

Feed stock returns to:

- A GRU, then a FC layer;
- A GAT (graph attention network), then a GRU and a FC layer

to generate risk factor returns, which are then used linearly, to reproduce stock returns (the loss is the explained variance, and, to stabilize the model, the explained forward variance), with a penalty for multicollinearity (VIF).

Correlation scenarios and correlation stress testing **N. Packham and F. Woebbecking (2021)**

Model the correlation matrix as

$$c_{ij} = \tanh \left[\eta + \sum_k \lambda_k \mathbf{1}_{\text{only one of } i \text{ and } j \text{ is exposed to } k} + \sum_k \nu_k \mathbf{1}_{\text{both } i \text{ and } j \text{ are exposed to } k} \right]$$

where i and j are the assets, and k the risk factors.

Malliavin calculus in finance **E. Alós and D.G. Lorite (2021)**

1. The implied volatility surface is the relation

$$\sigma \sim \log(F/K) + T$$

where F is the forward price. For T fixed, it exhibits a smile, a skew; as $T \rightarrow \infty$, it becomes more symmetric and flatter; empirically, the slope is proportional to $1/\sqrt{T}$.

In incomplete markets, delta hedging can be replaced by gamma hedging (hedging Δ and Γ using bond, underlying and vanilla options) or vega hedging (hedging Δ and vega).

The implied volatility can be expressed as a weighted average of future volatilities.

$$I_0 = \frac{\int_0^T e^{rt} \sigma_t^2 \frac{\partial^2 \text{BS}}{\partial x^2} S^2 dt}{\int_0^T e^{rt} \frac{\partial^2 \text{BS}}{\partial x^2} S^2 dt}$$

2. The realized variance is an estimator of the integrated variance,

$$\int_s^t \sigma_u^2 du \approx \sum r_{t_i, t_{i+1}} \quad (\text{log-returns}),$$

but it is contaminated by microstructure noise.

Prefer the Fourier estimator of volatility

$$\sum_j (\Delta_j X)^2 + \sum_{j \neq \ell} \left(\sum_{-N}^N e^{ik(t_j - t_\ell)} \right) \Delta_j X \Delta_\ell X.$$

Spot volatility exhibits jumps, clustering, roughness and long memory (there is evidence for and against both short and long memory – one could have both, e.g., with the sum of a long-memory process and a short-memory one).

Under reasonable assumptions, a *local volatility model*

$$\frac{dS}{S} = rdt + \sigma(t, S)dW$$

consistent with observed prices exists (*i.e.*, it has the correct marginals, but unrealistic dynamics), from Gyöngi's lemma and Dupire's formula

$$\sigma^2(T, K) = \frac{\partial_T C + rK \partial_K C}{\frac{1}{2} K^2 \partial_K^2 C}.$$

For instance, the CEV (constant elasticity of variance) model

$$dS = \mu S dy + \sigma S^\gamma dW,$$

for $\gamma < 1$, ensures $\text{Cor}(S, \sigma) < 0$ and produces a downward sloping skew.

Stochastic volatility models have two sources of randomness,

$$\begin{aligned} dS &= rSdt + \sigma SdW \\ \sigma &= f(Y) \\ dY &= a(t, Y)dy + b(t, Y)dB; \end{aligned}$$

the function f can be exponential, square root, absolute value; the process Y can be log-normal, Ornstein-Uhlenbeck or CIR.

For instance, the Heston model uses the square root of a CIR process,

$$\begin{aligned} \sigma &= \sqrt{v} \\ dv &= k(\theta - v)dt + \nu\sqrt{v}dB, \end{aligned}$$

where ν is the vol-of-vol.

The SABR (stochastic alpha beta rho) model is

$$\begin{aligned} dF &= \sigma F^\beta dW & \beta \in [0, 1] \text{ (often, } \beta = 1) \\ d\sigma &= \alpha \sigma dB & \alpha > 0 \\ \rho &= \frac{d\langle W, B \rangle_t}{dt}. \end{aligned}$$

Stochastic-local volatility models combine both ideas

$$\frac{dS}{S} = rdt + \sigma_t \lambda(t, S) dW,$$

where σ is a diffusion.

Rough volatility models are stochastic volatility models driven by a fractional Brownian motion, such as the rough Bergomi model.

$$\begin{aligned} dS &= rSdt + \sigma SdW \\ \log \frac{\sigma_t^2}{\sigma_0^2} &= \nu\sqrt{2H}Z_t - \frac{1}{2}\nu^2 t^{2H} \\ Z_t &= \int_0^t (t-s)^{H-\frac{1}{2}} dB, \quad H < \frac{1}{2}. \end{aligned}$$

The variance swap payoff is

$$\sum \log \frac{S_i}{S_{i-1}} - K,$$

where K (fair price) is chosen so that the initial contract price be zero. The fair price of its continuous analogue is

$$\mathbb{E} \int_0^T \sigma_t^2 dt = 2 \mathbb{E} \log \frac{S_T}{S_0}.$$

The volatility swap payoff is

$$\sqrt{\sum \log \frac{S_i}{S_{i-1}}} - K;$$

the fair price of its continuous analogue

$$\mathbb{E} \sqrt{\int_0^T \sigma_t^2 dt}$$

is more difficult to compute.

The gamma swap is a weighted variance swap

$$\int_0^T a(u) \sigma_u^2 du$$

with $a(u) = S_u/S_0$; it can be replicated with a European option with payoff

$$\frac{S_T}{S_0} \log \frac{S_T}{S_0}.$$

For arithmetic variance swaps, $a(u) = S_u^2$.

3. Malliavin calculus is a calculus of variations for stochastic processes.

The **Malliavin derivative** is an inverse D of the operator

$$h \mapsto W(h) = \int_0^T h(s) dW_s$$

satisfying $DW(h) = h$ and $Df(A) = f'(A)DA$.

If $F = f(W(h_1), \dots, W(h_n))$, it is defined as

$$DF = \sum \partial_i f(W(h_1), \dots, W(h_n)) h_i;$$

it is then extended to the closure of the set of such functions.

For instance, for Brownian motion, $D_s W_t = \mathbf{1}_{[0,t]}(s)$.

For exponential Brownian motion, $D_r S_t = \sigma S_t \mathbf{1}_{[0,t]}(r)$.

It satisfies the following properties.

$$\begin{aligned} \mathbb{E}\langle DF, h \rangle &= \mathbb{E}[FW(h)] \\ D\psi(F_1, \dots, F_n) &= \sum \partial_i \psi DF_i \\ D(FG) &= (DF)G + F(DG) \\ \mathbb{E}[G\langle DF, h \rangle] + \mathbb{E}[F\langle DG, h \rangle] &= \mathbb{E}[FGW(h)] \\ D_r A_t &= 0 \text{ for } r > t \text{ if } A \text{ is adapted} \\ D_s \mathbb{E}_t[A] &= \mathbb{E}[D_s A] \mathbf{1}_{[0,t]}(s) \end{aligned}$$

The **divergence operator**, or **Skorohod integral**, is the adjoint of the Malliavin derivative.

$$\mathbb{E}\langle DF, u \rangle = \mathbb{E}[F\delta(u)]$$

It generalizes the Ito integral to non-adapted processes.

$$\delta(u) = \int_0^T u(s) dW(s)$$

For processes of the form $u(s) = \sum A_i h_i(s)$.

$$\delta(u) = \sum_i A_i W(h_i) - \langle DA_i, h_i \rangle.$$

In particular

$$\begin{aligned} \delta \left[\sum A_i \mathbf{1}_{[t_i, t_{i+1}]}(s) \right] &= \\ \sum A_i (W_{t_{i+1}} - W_{t_i}) - \sum \int_{t_i}^{t_{i+1}} D_s A_i ds \end{aligned}$$

where the second term is zero if the A_i are adapted (Ito integral).

For a diffusion

$$dX = \mu ds + \sigma dW$$

the Malliavin derivative is

$$DX_t = \int_0^t D\mu_s ds + \sigma \mathbf{1}_{[0,t]} + \int_0^t D\sigma_s dW_s;$$

it can be computed as the solution of a SDE or, after a change of variable, an ODE. It is easy to compute for most volatility models.

4. If F is \mathcal{F}_T -measurable, it can be expressed as (*martingale representation theorem*)

$$F = E[F] + \int_0^T m(T, s) dW_s.$$

The **Clark-Ocone-Haussman formula** gives an explicit martingale representation,

$$F = E[F] + \int_0^T E_r[D_r F] dW_r.$$

It can be used to build hedging strategies (apply it to the final value of the replicating portfolio, $V_T = \alpha_T S_T + \beta_T e^{rT}$) or price VIX options (apply it to σ_t^2).

The **integration by parts formula**

$$E[f'(F)G] = E\left[f(F)\delta\left(\frac{Gu}{\langle DF, u \rangle}\right)\right]$$

can be used to compute the expectation of a derivative (Greeks), with Monte Carlo simulations.

The **anticipating Ito formula** generalizes Ito's formula to non-adapted processes.

5. **Fractional Brownian motion** (fBM) is a Gaussian process with covariance function

$$E[B_t B_s] = \frac{1}{2}(t^{2H} + s^{2H} - |t - s|^{2H});$$

in particular, $B_t - B_s \sim N(0, |t - s|^{2H})$. For $H \neq \frac{1}{2}$, it is not Markovian, it is not a martingale, nor a semi-martingale, and the increments are correlated: $E[(B_t - B_s)(B_u - B_r)] = \dots \neq 0$. It is self-similar, $(B_{at})_t \stackrel{d}{=} (a^H B_t)_t$, and λ -Hölder continuous for $\lambda < H$.

Since it is not a semi-martingale, we cannot use Ito calculus to define stochastic integration.

It has a representation as

$$B_t = \int_0^t K(t, s) dW_s$$

$$K(t, s) \propto (t - s)^{H - \frac{1}{2}} +$$

$$\left(\frac{1}{2} - H\right) \int_s^t (u - s)^{H - \frac{3}{2}} \left(1 - \left(\frac{s}{u}\right)^{\frac{1}{2} - H}\right) du$$

The **Riemann-Liouville fractional Brownian motion** (RLfBM) truncates this kernel and only keeps the first term,

$$B_t \propto \int_0^t (t - s)^{H - \frac{1}{2}} dW_s.$$

The Malliavin derivative is $D_s B_t = K(s, t)$; one can also compute the Malliavin derivative of most rough volatility models.

Python for algorithmic trading

Y. Hilpisch (2020)

For readers not very familiar with Python.

**Artificial intelligence in finance:
a Python-based guide**

Y. Hilpisch (2020)

For readers who have not been exposed to deep learning yet (with a chapter on reinforcement learning).

**Introducing localgauss, an R package
for estimating and visualizing
local Gaussian correlation**

G.D. Berensten et al. (2014)

To assess local changes in correlation, look at:

– The correlation curve, $x \mapsto \rho(x)$,

$$\rho = \beta \frac{\sigma_X}{\sigma_Y} = \frac{\beta \sigma_X}{\sqrt{(\beta \sigma_X)^2 + \sigma_\varepsilon^2}}$$

$$\beta(x) = \frac{d}{dx} E[Y|X = x]$$

$$\sigma_\varepsilon^2(x) = \text{Var}[Y|X = x];$$

– The conditional correlation (exceedance correlation)
– but, for a Gaussian distribution it tends to 0 in the tails (unless $|\rho| = 0$);
– The Holland-Wang dependence

$$\gamma(x, y) = \frac{\partial^2}{\partial x \partial y} \log f_{X,Y}(x, y),$$

but it is not in $[-1, +1]$ – in the Gaussian case,

$$\gamma = \frac{\rho}{1 - \rho^2} \frac{1}{\sigma_X \sigma_Y};$$

– The *local Gaussian correlation*, obtained by maximizing the *local likelihood*

f : density

ϕ_θ : Gaussian density with parameter θ

$$\text{Minimize}_{\theta_x} \int k_h(v - x) [\phi_{\theta_x}(v) - \log \phi_{\theta_x}(v) f(v)] dv$$

$$\text{i.e. } \int k_h(v - x) \nabla_\theta \log \phi_\theta(v) [f(v) - \phi_\theta(v)] dv = 0.$$

Recognizing and visualizing copulas: an approach using local Gaussian approximation
G.D. Berentsen et al. (2014)

Use Gaussian pseudo-observations to compute the local Gaussian correlations.

Dynamic copula methods in finance
U. Cherubini et al. (2012)

0. Given the joint distribution of (X, Y) , we want to describe the joint distribution (copula and margins) of $(X, Y, X + Y)$. Applications include credit risk (sum of non-Gaussian, dependent risks) and market dynamics (non-independent increments – with the added requirement that the resulting process be Markov and a martingale).

1. Correlation trading (resp. correlation risk) exploits (resp. measures the impact of) changes in correlation. Copula-based models should not introduce any spurious arbitrage, e.g., when pricing derivatives with different expiry dates, or when aggregating risk (VaR).

2. The price of a bivariate digital put, MDP (receive \$1 if $S_A \leq K_A$ and $S_B \leq K_B$) is related to the price of the univariate digital puts, DP_A, DP_B , via the copula C :

$$\begin{aligned} \text{MDP} &= vP[S_A \leq K_A, S_B \leq K_B] \\ &= vC(Q_A(K_A), Q_B(K_B)) \\ &= vC\left(\frac{DP_A}{v}, \frac{DP_B}{v}\right) \end{aligned}$$

where v is the discount factor. Other examples include: bivariate digital corridor, digital best-of, first-to-default, nth-to-default.

The *Fréchet* copulas are mixtures of the mix, max and independence copulas.

The *Kendall function* of an Archimedean copula

$$k(t) = P[C(U, V) \leq t] = t - \frac{\phi(t)}{\phi'(t)}$$

is useful to derive closed-form formulas for Archimedean copulas.

The following bivariate copula is not exchangeable:

$$(u, v) \mapsto u^\alpha v^\beta C(u^{1-\alpha}, v^{1-\beta}), \quad \alpha, \beta \in [0, 1].$$

Archimedean copulas can be made hierarchical, by replacing $C(\dots) = \phi^{-1}[\phi(\cdot) + \phi(\cdot) + \phi(\cdot) + \phi(\cdot)]$ with $\phi_3^{-1}[\phi_3 \phi_1^{-1}(\phi_1(\cdot) + \phi_1(\cdot)) + \phi_3 \phi_2^{-1}(\phi_2(\cdot) + \phi_2(\cdot))]$.

The conditional probabilities are

$$\begin{aligned} P[X \leq x | Y = y] &= \frac{\partial C(F_X(s), v)}{\partial v} \Big|_{v=F_Y(y)} \\ P[X \leq x | Y \leq y] &= \int_0^{F_Y(y)} \partial_2 C(F_X(x), w) dw. \end{aligned}$$

In particular, for a *1-factor copula*, i.e., if the X_i 's are independent given X_1 ,

$$\begin{aligned} P[U_2 \leq u_2, \dots, U_n \leq u_n | U_1 = u_1] &= \prod_{i>1} \partial_1 C(u_1, u_i) \\ C(u_1, \dots, u_n) &= \int_0^{u_1} \prod_{i>1} \partial_1 C(u, u_i) du. \end{aligned}$$

This can be generalized to more factors.

3. Copulas can be used to describe, not only cross-sectional data, but also time dependence – but we need to impose a few constraints on the result:

- The Markov property, which results from the efficient market hypothesis – the price should contain all the information;
- The martingale property: the time series should be unpredictable.

Given a Markov process $(U_t)_t$ with uniform margins, we have, for $s \leq r \leq t$,

$$\begin{aligned} P(U_s \leq u_s, U_t \leq u_t) &= \int P[U_s \leq u_s, U_t \leq u_t | U_r \leq u] du \\ &= \int P[U_s \leq u_s | U_r = u] \cdot P[U_t \leq u_t | U_r \leq u] du \\ &= \int \partial_2 C_{sr}(u_s, u) \cdot \partial_1 C_{rt}(u, u_t) du \end{aligned}$$

We can define a product a bivariate copulas:

$$A * B(u, v) = \int_0^1 \partial_2 A(u, t) \partial_1 B(t, v) dt.$$

It is associative, non-commutative, and satisfies

$$\begin{aligned} C * \Pi &= \Pi * C = \Pi && \text{(zero)} \\ C * M &= M * C = C && \text{(one)} \\ W * W &= M && \text{(minus one)} \\ W * C * W &= \hat{C} && \text{survival copula} \end{aligned}$$

More generally, $A * B(x, y) = A \star B(x, 1, y)$, where

$$A \star B(u_1, \dots, u_{m+n-1}) = \int_0^1 \partial_m A(u_1, \dots, u_{m-1}, \xi) \partial_1 B(\xi, u_{m+1}, \dots, u_{m+n-1}) d\xi.$$

A stochastic process is Markov if its copulas satisfy

$$C_{t_1, \dots, t_n} = C_{t_1, t_2} \star C_{t_2, t_3} \star \dots \star C_{t_{n-1}, t_n}.$$

It is mixing if $\lim_{k \rightarrow \infty} C_{i, i+1} = \Pi$.

It is right-continuous if $\lim_{k \rightarrow 0^+} C_{i, i+k} = M$.

Brownian dynamics are defined by $C_{st} = C_{\rho^{t-s}}^{\text{Gauss}}$.

Farlie-Gumbel-Morgenstern dynamics can only produce very low correlations.

$$\begin{aligned} C(u, v) &= uv + \theta uv(1-u)(1-v) \quad \theta \in [-1, 1] \\ \theta_{st} &= \frac{1}{3} \theta_{sr} \theta_{rt} \\ \theta_n &= 3 \left(\frac{\theta}{3} \right)^n \end{aligned}$$

Time-changed Brownian copulas are more flexible: every semi-martingale is a time-changed Brownian motion (with the quadratic variation for martingales and, more generally, Lévy subordinators or other increasing processes, such as cumulated volatility or cumulated jump intensity).

The C -convolution of F_X and F_Y is the copula of $(X, X + Y)$:

$$\begin{aligned} F_X \overset{C}{*} F_Y(u, v) &= C_{X, X+Y}(u, v) \\ &= \int_0^u \partial_1 C[w, F_Y(F_{X+Y}^{-1}(v) + F_X^{-1}(w))] dw \\ F_{X+Y}(t) &= \int_0^1 \partial_1 C[w, F_Y(t - F_X^{-1}(w))] dw. \end{aligned}$$

A Markov process $(X_t)_t$ is a martingale iff

- (i) The increments $X_t - X_s$ have finite mean;
- (ii) $\forall s, t \forall u \in [0, 1]$ almost everywhere

$$\int_0^1 F_{X_t - X_s}^{-1}(v) \partial_1 C_{X_s, X_t - X_s}(u, dv) = 0.$$

This is the case, for instance, if the increments and the copula are symmetric: $\tilde{C}(u, v) := u - C(u, 1 - v) = C(u, v)$.

4. The c -quantile curve of y conditioned on x , $q(x, p)$, is the value of y such that

$$p = F(y|x) = \partial_1 C(F_X(x), F_Y(y)).$$

A *stationary copula-based Markov process* is defined by its invariant distribution G^* and the copula C of (C_{t-1}, X_t) . To estimate it, use the empirical distribution for G^* , and the MLE for the copula C .

The α -mixing coefficients are

$$\alpha_k = \sup_{m \in \mathbf{Z}} \sup_{\substack{A \in \mathcal{F}_{-\infty}^m \\ B \in \mathcal{F}_{m+k}^\infty}} |P(A \cap B) - P(A)P(B)|.$$

The β -mixing coefficients are similar, but use partitions $\{A_1, \dots, A_I\}$, $\{B_1, \dots, B_J\}$ of Ω and $\sum_{ij} |P(A_i \cap B_j) - P(A_i)P(B_j)|$.

The ρ -mixing coefficients are

$$\rho_k = \sup_{m \in \mathbf{Z}} \sup_{\substack{f \in L^2(\mathcal{F}_{-\infty}^m) \\ g \in L^2(\mathcal{F}_{m+k}^\infty)}} \text{Cor}(f, g).$$

The maximum correlation of a copula C is

$$\rho_C = \sup_{\substack{f, g \in L^2(0,1) \\ \int f = \int g = 0 \\ \int f^2 = \int g^2 = 1}} \iint f(u)g(v)C(du, dv).$$

if $\rho_C < 1$, then a stationary Markov process defined from C is α - and ρ -mixing, i.e., $\alpha_k \rightarrow 0$, $\rho_k \rightarrow 0$ when $k \rightarrow \infty$. This is the case for the Student and Marshall-Olkin copulas.

A process $(X_t)_t$ has long memory if $H(t, h) \sim_{h \rightarrow \infty} Ah^{-p}$, $A > 0$, $p > 0$, and short memory if $H(t, h) = O(e^{-Ah})$, $A > 0$, where the Hellinger measure of dependence between X_t and X_{t+h} is

$$H(t, h) = 1 - \iint f_{X_t X_{t+h}}^{1/2}(x, y) f_{X_t}^{1/2}(x) f_{X_{t+h}}^{1/2}(y) dx dy.$$

It can be computed from the copulas $\frac{1}{2} \iint (c^{1/2} - 1)^2 - 1$ and replaced by other measures of dependence: $\iint c^2 - 1$, $\iint c \log c$, $\iint C(u, v) - uv$, $\iint (C(u, v) - uv)^2$, $\sup |C(u, v) - uv|$.

We can also define non-parametric Markov processes (i.e., processes with functional parameters), for instance,

$$X_t = \begin{cases} X_{t-1} + \varepsilon_t & \text{with probability } \eta(X_{t-1}) \\ \varepsilon_t & \text{otherwise.} \end{cases}$$

Analyzing dependent data with vine copulas: a practical guide with R C. Czado (2019)

1. Distribution F , density f , copula C , copula density c , conditional density and h -functions are related as follows.

$$\begin{aligned} F(x_1, \dots, x_d) &= C(F_1(x_1), \dots, F_d(x_d)) \\ f(x_1, \dots, x_d) &= f(F_1(x_1), \dots, F_d(x_d)) f_1(x_1) \cdots f_d(x_d) \\ c(u_1, \dots, u_d) &= \frac{\partial^d C(u_1, \dots, u_d)}{\partial u_1 \cdots \partial u_d} \\ f(x_1|x_2) &= c_{12}(F_1(x_1), F_2(x_2)) f(x_2) \\ F(x_1|x_2) &= \frac{\partial C(F_1(x_1), u_2)}{\partial u_2} \Big|_{u_1=F_2(x_2)} \\ h_{1|2}(u_1|u_2) &= \frac{\partial C(u_1, u_2)}{\partial u_2} \end{aligned}$$

2. Some dependence measures can be computed from the copula.

$$\begin{aligned} \rho &= 12 \iint_{[0,1]^2} uv dC(u, v) - 3 \\ \tau &= 4 \iint_{[0,1]^2} C(u, v) dC(u, v) - 1 \\ \lambda_L &= \lim_{t \rightarrow 0^+} \frac{C(t, t)}{t} \end{aligned}$$

3. Bivariate copula classes include: elliptical (Gaussian, Student), Archimedian (defined from a generator function, $C(u, v) = \phi^{-1}(\phi(u) + \phi(v))$, Clayton, Gumbel, Frank, Joe, a few 2-parameter families (Clayton-Gumbel (BB1), Joe-Gumbel (BB6), Joe-Clayton (BB7), Joe-Frank (BB8)), Tawn (3 parameters, with shapes not symmetric along the diagonal), Marshall-Olkin, etc.

Extreme value copulas are the limiting copulas of $(\text{Max}_{1 \leq i \leq n} X_i, \text{Max}_{1 \leq i \leq n} Y_i)$; they are the copulas satisfying

$$\forall m \in \mathbf{N}^\times \quad \forall u, v \in [0, 1] \quad C(u, v) = C(u^{1/m}, v^{1/m})^m.$$

They are the copulas of the form

$$C(u, v) = \exp \left[\log(uv) A \left(\frac{\log v}{\log(uv)} \right) \right]$$

where $A : [0, 1] \rightarrow [\frac{1}{2}, 1]$ is called the *Pickands dependence function*.

Copulas can be plotted in x -scale (original), u -scale (uniform margins) or z -scale (Gaussian margins).

To sample from a bivariate copula:

$$\begin{cases} u \sim \text{Unif} \\ v \sim h_{2|1}(\cdot|u) \end{cases} \quad i.e. \quad \begin{cases} u \sim \text{Unif} \\ \varepsilon \sim \text{Unif} \\ v = h_{2|1}^{-1}(\varepsilon|u). \end{cases}$$

To estimate copula parameters, first process the margins (parametrically or not – this may involve regression or time series modeling) and invert the formula giving Kendall's τ from the ccopula parameter.

Let $C_{12|3}$ be the conditional distribution of U_1, U_2 given U_3 . The margins are no longer uniform: it is not a copula. The margins are $C_{1|3}$ and $C_{2|3}$: the *conditional bivariate copula* is

$$C_{12;3}(u_1, u_2|v_3) = C_{12|3}(C_{1|3}^{-1}(u_1|v_3), C_{2|3}^{-1}(u_2|v_3)).$$

Conditional copulas depend on the conditioning value, but it can be averaged out:

$$C_{12;3}^A(u_1, u_2) = \int C_{12;3}(u_1, u_2|v_3) dv_3.$$

It is a copula, which can also be obtained as the *partial copula*, i.e., the distribution of (these are uniform)

$$\begin{aligned} V_{1|3} &= C_{2|3}(U_2|U_3) \\ V_{2|3} &= C_{1|3}(U_1|U_3). \end{aligned}$$

4. A 3-variate copula can be decomposed using bivariate copula (pair copula construction, PCC) by repeatedly using $f_{1|2} = c_{12}f_1$:

$$\begin{aligned} f_{123} &= f_{1|23}f_{2|3}f_3 \\ f_{2|3} &= c_{23}f_2 \\ f_{1|23} &= c_{12;3}f_{1|3} \\ &= c_{12;3}c_{13}f_1 \\ f_{123} &= c_{12;3}c_{13}c_{23}f_1f_2f_3. \end{aligned}$$

The conditional copula $c_{12;3}$ depends on x_3 , but we will assume it does not (*simplified PCC*).

$$\begin{aligned} f_{123}(x_1, x_2, x_3) &= c_{12;3}(F_{1|3}(x_1|x_3), F_{2|3}(x_2|x_3); x_3) \cdot \\ &\quad c_{13}(F_1(x_1), F_3(x_3)) \cdot \\ &\quad c_{23}(F_2(x_2), F_3(x_3)) \cdot \\ &\quad f_1(x_1)f_2(x_2)f_3(x_3) \end{aligned}$$

Conversely, we can define a 3-variate copula density as

$$\begin{aligned} c(u_1, u_2, u_3) &= c_{12;3}(C_{1|3}(u_1|u_3), C_{2|3}(u_2|u_3)) \cdot \\ &\quad c_{13}(u_1, u_3)c_{23}(u_2, u_3) \end{aligned}$$

where $C_{1|2}(u_1|u_2) = \partial C_{12}/\partial u_2$. The copula c_{12} can be computed by integration.

In dimension d , there are many possible decompositions.

$$\begin{aligned} c_{1\dots d} &= \prod_{i < j} c_{ij:i+1, \dots, j-1} & \text{D-vine} & \quad \text{Diagram: A chain of nodes connected sequentially.} \\ c_{1\dots d} &= \prod_{i < j} c_{ij:1, \dots, i-1} & \text{C-vine} & \quad \text{Diagram: A central node connected to multiple other nodes.} \end{aligned}$$

5. A **regular vine** (R-vine) is a sequence of trees T_1, \dots, T_{d-1} such that

- (i) $V(T_1) = \llbracket 1, d \rrbracket$;
- (ii) $V(T_i) = E(T_{i-1})$;
- (iii) $\{a, b\} \in E(T_i) \implies |a \cap b| = 1$.

To simplify the notations, let $A_e = \text{union}(\text{flatten}(e))$ be the complete union and $D_{\{a,b\}} = A_a \cap A_b$ the conditioning set.

A *D-vine* is a vine whose trees are chains.

A *C-vine* is a vine whose trees are stars.

Regular vines can model multivariate Gaussian or Student distributions, with the partial correlations as parameters.

Regular vines can be encoded in triangular matrices.

6. To sample from a multivariate distribution:

$$\begin{aligned} w_1 &\stackrel{\text{iid}}{\sim} U(0, 1) \\ x_1 &= F_1^{-1}(w_1) \\ x_2 &= F_2^{-1}(w_2|x_1) \\ &\vdots \\ x_d &= F_d^{-1}(w_d|x_1, \dots, x_{d-1}) \end{aligned}$$

7. To find a good starting point for the optimization, start to estimate the parameters sequentially. For instance, for $c_{123} = c_{12|3}c_{13}c_{12}$, first estimate c_{12} , c_{13} , then estimate $c_{12|3}$ from the *pseudo-observations* $C_{1|3}(u_{k1}|u_{k3}), C_{2|3}(u_{k2}|u_{k3})$ (for observation k).

8. If the vine structure is known, but not the copula families, select them with the AIC, sequentially or not.

If the vine structure is not known, use a greedy approach (Dißmann algorithm), with a minimum spanning tree for each tree, computed from $|\tau|$, AIC, a copula gof p -value, etc. For C-vines, it suffices to choose

the root of the tree. For D-vines, it suffices to choose the order of the nodes (a Hamiltonian path, with a TSP solver).

9. To compare models, use the AIC, BIC, KLIC (KL criterion – log-likelihood) or the likelihood ratio test (with correction for model complexity).

10. With stock return data: fit univariate GARCH(1,1) models with Student innovations and use the residuals; find a representative stock in each sector (high $\sum_i |\tau_{ij}|$); fit a C-vine copula to each sector (`VineCopula::RVineStructSelect`); use it for portfolio VaR computation (you need parametric margins).

11. Recent developments in vine copula based modeling include:

- Bayesian vine copulas: they provide credible intervals;
- Intependence tests, for the pair copulas, to simplify the models (you can also truncate them);
- Factor vine copulas (?);
- Non-parametric pair copulas;
- Non-simplified vines (with covariates);
- Tests for constant conditional correlation, to select the vine structure violating the simplifying assumption as little as possible;
- Goodness-of-fit (gof) tests;
- Approximate KL divergence between vine copulas;
- Relation between graphical models and vine copulas (conditional independences correspond to independence copulas);
- Conversely, vine copulas inside graphical models;
- Discrete variables;
- D-vine-copula-based quantile regression;
- Factor structure for vine copulas.

Applications include:

- Copulas with a time-varying dependence structure;
- D-vines for longitudinal data;
- Modeling the relations between the entries of realized variance matrices (parametrized with the logarithm of the Cholesky decomposition);
- Medical diagnostic test accuracy (copula of TP, TN, P);
- Survival data;
- Copulas with zero inflation (in insurance).

For software implementations, check `VineCopula` (supercedes `CDVine`) and `vinecopulib` (C++/R/Python).

Simulating copulas: stochastic models, sampling algorithms and applications J.F. Mai and M. Scherer (2017)

1. Bivariate copulas can be sampled as $(C_{1|2}^{-1}(U_1|U_2), U_2)$, where $U_1, U_2 \sim U(0, 1)$ and $C_{1|2}(u_1|u_2) = \partial C / \partial u_2$.

Measures of dependence can be computed from the copula:

$$\tau = 1 - 4 \iint \frac{\partial C}{\partial u_1} \frac{\partial C}{\partial u_2}$$

$$\rho = \frac{\iint C - \iint \Pi}{\iint M - \iint \Pi}$$

where $\Pi(\mathbf{u}) = \prod u_i$ is the independence copula and $M(\mathbf{u}) = \min_i u_i$ the comonotonicity copula.

For an *exchangeable copula*, the correlation (the same for all pairs) satisfies $\rho \geq -1/(d-1)$.

An **extendible** sequence of random variables is part of an infinite exchangeable sequence: the correlation is then nonnegative, but it need not have positive orthant dependency,

$$P[\forall i \ X_i \geq x_i] \geq \prod_i P[X_i \geq x_i].$$

Homogeneous mixtures, $\theta \sim F$, $X_i \stackrel{\text{iid}}{\sim} F_\theta$, are exactly the extendible sequences (DeFinetti).

Heterogeneous mixtures partition the dimensions and use a different distribution for each part.

Extreme value distributions $C(u_1^t, \dots, u_d^t) =$

$C(u_1, \dots, u_d)^t$ have a Pickand representation

δ : measure on the simplex Δ_d

$$P(w_1, \dots, w_d) = \int_{\Delta_d} \text{Max}\{w_1 u_1, \dots, w_d u_d\} \delta(du)$$

$$C(u_1, \dots, u_d) = \left(\prod u_i \right)^{P(\log \mathbf{u} / \mathbf{1}' \log \mathbf{u})}.$$

2. With the sampling procedure

$$M \sim F$$

$$X_1, \dots, X_d \sim \text{Exp}(M),$$

the cdf of the margins is $\phi(x) = E[e^{-xM}]$, i.e., the Laplace transform of F , and the survival copula of (X_1, \dots, X_d) is $C(u_1, \dots, u_d) = \phi(\phi^{-1}u_1 + \dots + \phi^{-1}u_d)$ (archimedean copula). If ϕ is not completely monotonic, the same formula may still define a copula for small values of d , but it may not be extendible, just exchangeable.

Archimedean copulas can be rescaled:

- An α -stable Lévy subordinator Λ_m stopped at M , defines a new random variable $\tilde{M} = \Lambda_M$ with Laplace transform $\phi(x^\alpha)$ (the Laplace transform of a Lévy subordinator is $\psi(x) = x^\alpha$);
- The Laplace transform of $M_1 + \dots + M_\beta$ is $\phi(x)^\beta$.

Hierarchical (**H-extendible**) archimedean copulas are defined as

$$C_{\phi_0}(C_{\phi_1}(u_{11}, \dots, u_{1d_1}), \dots, C_{\phi_J}(u_{J1}, \dots, u_{Jd_J})),$$

provided the generators are compatible: ϕ_j and $(\phi_0^{-1} \circ \phi_j)'$ completely monotonic. They can be sampled as

$$E_{ji} \sim \text{Exp}(1)$$

M with Laplace transform ϕ

$\Lambda^{(1)}, \dots, \Lambda^{(J)}$ Lévy subordinators with exponents ψ_j

$$U_{ji} = (\phi_0 \circ \psi_j)(E_{ji} / \Lambda_M^{(j)}).$$

Archimedean copulas can be made asymmetric, e.g.,

$$V \sim C_\phi$$

$$\tilde{U} \sim \Pi$$

$$U_k = \text{Max}\{V_k^{1/\alpha_k}, \tilde{U}_k^{1/\alpha_k}\}$$

3. The lack of memory characterizing exponential distributions, $P[X \geq x + y | X \geq y] = P[X \geq x]$, generalizes, in dimension d , to the *Marshall-Olkin distribution*

$$\begin{aligned} \bar{F}(x_1, \dots, x_n) &= P[\forall i \ X_i \geq x_i] \\ &= \exp \left[- \sum_{\substack{I \subset \llbracket 1, d \rrbracket \\ I \neq \emptyset}} \lambda_I \cdot \text{Max}_i x_i \right]. \end{aligned}$$

There are $2^d - 1$ parameters. It can be interpreted as the time-to-failure, when the failure of a group of items $I \subset \llbracket 1, d \rrbracket$ has a different cause for each I .

To sample from it:

$$E_I \sim \text{Exp}(\lambda_I) \text{ for each } I \subset \llbracket 1, d \rrbracket, \ I \neq \emptyset$$

$$X_k = \text{Min}\{E_I : I \ni k\}.$$

The corresponding survival copula is

$$\hat{C}(u_1, \dots, u_d) = \prod_I \text{Min}_{k \in I} u_k^{\lambda_I / \sum_{j \ni k} \lambda_j}.$$

They can be sampled as

$$Y_i \sim \text{Cat}(\mathcal{P}(\llbracket 1, d \rrbracket) \setminus \{\emptyset\})$$

$$P(Y_i = I) = \lambda_I / \sum \lambda_J$$

$$\varepsilon_i \sim \text{Exp}(\sum \lambda_J)$$

$$X_k = \varepsilon_1 + \varepsilon_2 + \dots + \varepsilon_{\text{Min}\{i : k \in Y_i\}}.$$

The MO copula is an extreme value copula (but the MO distribution is not an extreme value distribution), has a singular component, has an interpretation in terms of shocks (insurance, credit risk), and positive upper tail dependence (but lower tail independence).

For an exchangeable Marshall-Olkin copula, $|I| = |J| \Rightarrow \lambda_I = \lambda_J$ and

$$C(u_1, \dots, u_d) = \prod u_{(k)}^{a_k - 1}$$

where $\forall i, j \ (-1)^i \Delta^i a_j \geq 0$ (d-monotone sequence).

To sample from it:

- Sample the time until the first shock (the minimum of exponential variables is still exponential);
- Sample the number of components affected;
- Iterate.

If the sequence $(a_k)_k$ can be extended to an infinite completely monotone sequence (with $a_0 = 1$, this is the case iff $a_k = E[X]$, for some random variable X with values in $[0, 1]$; equivalently, the Hankel determinants are nonnegative), this is an extendible MO copula.

A completely monotone sequence defines a Lévy subordinator with $\psi(1) = 1$ and a *Lévy-frailty copula* $C_\psi(u_1, \dots, u_d) = \prod u_{(i)}^{\psi(i) - \psi(i-1)}$.

To sample from it:

$$E_k \sim \text{Exp}(1)$$

$$\Lambda_t \sim \text{Lévy}(\psi)$$

$$X_k = \inf\{t > 0 : \Lambda_t > E_k\}$$

$$U_k = \exp(-X_k).$$

There is an h-extendible variant.

4. Spherical distributions can be recognized from their characteristic function $\phi_X(t) = E[e^{it'X}] = \varphi(\|t\|^2)$ (but not all univariate functions define a characteristic function: there are fewer as the dimension increases). Extendible spherical distributions are mixtures of Gaussians, $\sqrt{W}Z$, $Z \sim N(0, I)$.

For elliptical distributions $X \sim E_d(\mu, \Sigma, \phi)$, $\phi(t) = e^{it'\mu}\phi(t'\Sigma t)$; they are extendible if $\mu = \mu_1 \mathbf{1}$ and

$$\Sigma = \sigma^2 \begin{pmatrix} 1 & \rho \\ \rho & 1 \end{pmatrix}$$

h-extendible elliptic copulas have a block correlation matrix.

7. Variance can be reduced with antithetic variables ($\mathbf{u} \mapsto 1 - \mathbf{u}$), control variates (e.g., from an independence structure – it may not work well), or importance sampling (e.g., by increasing the dependence).

8. Exchangeable Marshall-Olkin copulas

$$C(u_1, \dots, u_d) = \prod u_{(k)}^{a_k - 1}$$

can be generalized to *Shock copulas*

$$C(u_1, \dots, u_d) = \prod g_k(u_{(k)}).$$

A random vector (X_1, \dots, X_d) has a *min-stable exponential distribution*, i.e., $\text{Min}\{c_1 X_1, \dots, c_d X_d\}$ have univariate exponential distributions for all $c_1, \dots, c_d \in [0, \infty]$, iff the margins are exponential and the copula is an extreme value copula.

Extendible extreme value copulas are characterized by

$$C(u_1, \dots, u_d) = \mathbb{E} \left[\exp - \sum_{k=1}^d \Lambda_{-\log(u_k)} \right]$$

for a strong IDT subordinator Λ with $\psi(1) = 1$.

A. A Lévy subordinator is a càdlàg stochastic process $(\Lambda_t)_{t \geq 0}$ with $\Lambda_0 = 0$ satisfying:

(i) Stochastic continuity (no deterministic jumps)

$$\forall t \geq 0 \forall \varepsilon > 0 \lim_{t \rightarrow 0} P[|\Lambda_{t+h} - \Lambda_t| \geq \varepsilon] = 0$$

(ii) Independent increments;

(iii) Stationary increments: $\Lambda_{t+h} - \Lambda_t \stackrel{d}{=} \Lambda_h$;

(iv) $t \mapsto \Lambda_t$ is a.s. non-decreasing.

Λ_t is infinitely divisible.

The Laplace transform of a Lévy subordinator is $\mathbb{E}[e^{-x\Lambda_t}] = e^{-t\psi(x)}$ (Lévy-Khinchin) where $\psi(x) = \mu x + \int_{[0, \infty]} (1 + e^{-tx}) \nu(dt)$ (ψ is the Laplace exponent, μ the drift, ν the Lévy measure).

Examples include:

- Poisson: $\psi(x) = \lambda(1 - e^{-x})$, $\nu(B) = \lambda \mathbf{1}_{1 \in B}$ (number of jumps of size in B per unit of time);
- Compound Poisson: $\Lambda_t = \mu t + \sum_{i=1}^{N_t} J_i$;
- Gamma: $\mu = 0$, $\nu(dt) = \beta(e^{-\eta t}/t) \mathbf{1}_{t > 0} dt$, $\psi(x) = \beta \log(1 + x/\eta)$, $\Lambda_t \sim \Gamma(\beta t + \eta)$;
- Inverse Gaussian

$$\Lambda_t \sim \text{IG}(\beta t, \eta)$$

$$\Lambda_t = \inf\{s > 0 : \eta s + X_s = \beta t\}$$

X_t standard Brownian motion

$$\alpha\text{-stable: } \nu(dt) = \frac{\alpha}{\Gamma(1-\alpha)} \frac{1}{t^{1+\alpha}} \mathbf{1}_{t > 0} dt.$$

An *additive subordinator* has independent, but not necessary stationary, increments.

A *strong IDT subordinator* is a non-decreasing càdlàg stochastic process $(\Lambda_t)_t$ with $\Lambda_0 = 0$, strongly infinitely divisible such that

$$(\Lambda_t)_{t \geq 0} = (\Lambda_{t/n}^{(1)} + \dots + \Lambda_{t/n}^{(n)})_{t \geq 0}$$

where $\Lambda^{(i)}$ are iid copies of Λ .

A partial correlation vine based approach for modeling and forecasting multivariate volatility time series N. Barthel et al. (2018)

Partial correlations on the edges of a vine provide an unconstrained parametrization of a correlation matrix.

Model volarilities and partial correlations with a HAR (heterogeneous AR, e.g., 1-, 5- and 22-day lags) or VARFIMA model.

Pair copula construction for financial applications: a review K. Aast (2016)

Applications of the pair copula construction (PCC) include:

- VaR and CVaR of a portfolio;
- Probability of default;
- Liquidity risk (bid and ask spread of several assets);
- Systemic risk (CDS of financial institutions, stock market indices);
- (Scenario-based) CVaR portfolio optimization (C-vine with skewed Student margins)
- Option pricing.

kdecopula: an R package for the kernel estimation of bivariate copula densities T. Nagler (2017)

To reduce the boundary effect when estimating a non-parametric copula density:

- Reflect the data over the sides of the square;
- Use kernels supported on the square, e.g., Beta;
- Transform the margins to make them Gaussian.

Evading the curse of dimensionality in nonparametric density estimation with simplified vine copulas T. Nagler and C. Czado (2016)

(Truncated, simplified) vine copulas provide scalable high-dimensional density estimators, by reducing the problem to a sequence of bivariate density estimations.

Implementation: `rvinecopulib`, `kde1d`.

ESG, risk and (tail) dependence
R. Bax et al. (2021)

For assets j , in sector S , in ESG category $k \in \{A, B, C, D\}$, estimate a vine copula with fixed first and second-level trees

$$\begin{array}{c} \diagup \diagdown \\ A \\ | \\ \geq B - S - D \leq \\ | \\ C \\ \diagup \diagdown \\ j \end{array} \quad \begin{array}{cccc} A, S - B, S - C, S - D, S \\ \diagup \diagdown & \diagup \diagdown & \diagup \diagdown & \diagup \diagdown \\ & j, C & & \end{array}$$

and aggregate measures of dependence (Kendall's τ) or tail dependence (tail dependence coefficient λ) as

$$\frac{|\tau_{j,k}|}{\sum_{\{j,k\} \subset i} |\tau_i|}.$$

Market making via reinforcement learning
T. Spooner et al. (2018)

Define the reward as P&L penalized against speculation (inventory \times change in price). For the state, use the inventory, the spread, the price change, the book imbalance, the signed volume, the volatility, and the RSI, with *tile coding* – combine several discretizations of the state space, e.g., from grids with different offsets. Use TD (SARSA) with eligibility traces; train on market data. The actions are

$$\begin{array}{ccccccccc} _ & _ & _ & _ & _ & _ & _ & _ & _ \\ | & | & | & | & | & | & | & | & | \\ _ & _ & _ & _ & _ & _ & _ & _ & _ \end{array}$$

and an inventory-clearing order.

**Reinforcement learning
for optimized trade execution**
Y. Nevmyvaka et al. (2006)

**Risk-sensitive compact decision trees
for autonomous execution
in presence of simulated market response**
S. Vyetenko and S. Xu (2021)

Do not maximize $E[G]$ but $E[G] - \lambda \text{Var}[G]$.

**Persistent clustering
and a theorem of J. Kleinberg**
G. Carlsson and F. Mémoli (2008)

Single linkage clustering is the only functor from the category of finite metric spaces and non-decreasing maps to the category of persistent sets (multiscale clusterings (X, θ) , there $\theta(r)$ is interpreted as the partition of X at scale r) that

- Preserves the underlying set
- Gives the expected persistent set for 2-point spaces $\Delta_2(\delta)$: $\theta(r)$ is $\{\{*\}, \{*\}\}$ is $r < \delta$ and $\{\{*, *\}\}$ otherwise;
- Gives the discrete partition for $r \ll 1$.

Coarser categories allow more such multiscale clustering functors:

- Increasing monic maps: density-based clustering;
- Isometries: anything (too general).

Classifying clustering schemes
G. Carlsson and F. Mémoli (2010)

There is no clustering scheme $(X, d) \mapsto P \in \text{Partitions}(X)$ satisfying Kleinberg's axioms: scale invariance, surjectivity (all clusterings are possible, if we change the metric), consistence (reducing/increasing intra/inter-cluster distances does not change the clustering) – we need multi-scale clusterings.

Single-linkage clustering can be defined from 2-simplices $\Delta_2(\delta)$, $\delta > 0$, and morphisms $\Delta_2(\delta) \rightarrow X$. The 2-simplex $\Delta_2(\delta)$ can be replaced by other simplices ($\Delta_m(\delta)$ is very similar to DBSCAN) or an arbitrary family of metric spaces.

**Characterization, stability and convergence
of hierarchical clustering methods**
G. Carlsson and F. Mémoli (2010)

A dendrogram (X, θ) defines an ultrametric $(x, y) \mapsto \text{Min}\{r \geq 0 : x \text{ and } y \text{ belong to the same component of } \theta(r)\}$. Conversely, an ultrametric defines a dendrogram. Single linkage clustering corresponds to the maximal subdominant ultrametric.

The distortion of a map of metric spaces $f : (X, d) \rightarrow (Y, d)$ is

$$\text{dis}(f) = \text{Max}_{x, x' \in X} |d(x, x') - d(fx, fx')|.$$

The joint distortion of $f : X \rightarrow Y$ and $g : Y \rightarrow X$ measures the degree to which they are inverses,

$$\text{dis}(f, g) = \text{Max}_{\substack{x \in X \\ y \in Y}} |d(x, gy) - d(fx, y)|.$$

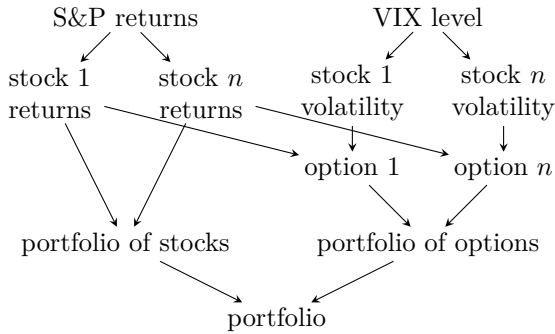

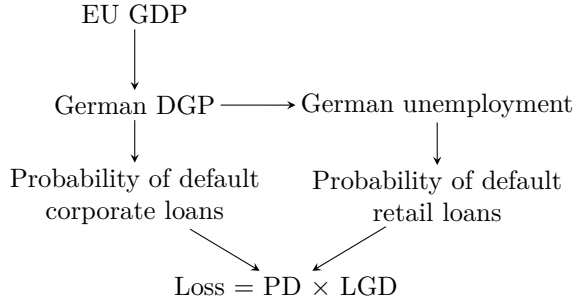

The *Gromov-Hausdorff distance* between (X, d) and (Y, d) is

$$\frac{1}{2} \text{Min}_{f, g} \text{Max}\{\text{dis } f, \text{dis } g, \text{dis}(f, g)\}.$$

Single linkage hierarchical clustering $(X, d) \rightarrow (X, u)$ is a contraction for the Gromov-Hausdorff distance. Average linkage and complete linkage are not continuous.

**A probabilistic graphical model approach
to model interconnectedness**
A. Denev et al. (2017)

The output of a model is often used as input to another: PGMs can account for those dependencies – they are not needed if you just want expectations, but the probability distributions contain more information.

Building probabilistic causal models using collective intelligence O. Laudy et al. (2021)

CausalityLink (commercial) extracts data from text:

- Numeric indicators (GDP, etc.), from a large ontology, with timestamps and duration;
- Trends: changes in those indicators over some time span;
- Events, with start and end date;
- Causal links: indicator/trend/event \rightarrow indicator/trend.

Use those links to build a Bayesian network:

- Start with the nodes you are interested in;
- Add edges between them, starting with the strongest ones, but only if you do not introduce a cycle.

Use two states (up, down); estimate the root node probabilities from the past 90 days (with a 14-day half-life); estimate the single-cause probabilities $P(B|A)$ from count data. For multiple causes, combine $P(B|A_i)$ into $P(B|A_1, \dots, A_k)$ using a log-linear model

$$P(A_1, \dots, A_k, B) \propto \exp \left[\mu + \sum \lambda_{A_\ell=i_\ell} + \lambda_{B=j} + \sum_{B=j} \lambda_{A_\ell-i_\ell} \right],$$

where $i_\ell, j \in \{\text{UP}, \text{DOWN}\}$.

Foundations of reinforcement learning with applications in finance A. Rao and T. Jelvis (2021)

Reinforcement learning (RL), or *stochastic control* is the study of sequential optimal decisions under uncertainty. The environment is described by a *Markov decision process* (MDP), *i.e.*, the conditional distribution of reward r and next state s' given current state s and action a ,

$$P(r, s'|s, a);$$

we want to find the *policy* $\pi(a|s)$ maximizing the (expected) return, *i.e.*, the discounted sum of future rewards $G_t = \sum_{s \geq t} \gamma^{s-t} R_t$.

One can distinguish between

- *Prediction*: Computing the value function $V^\pi(s) = E[G_0|S_0 = s]$, for a given policy π ;
- *Control*: computing the optimal value function V^* , and the corresponding optimal policy π^* ;
- *Planning*: solving a known MDP (often, with dynamic programming);
- *Learning*: solving an unknown MDP.

1. *Inventory management* can be modeled as an MDP:

- State: number of items on inventory, constrained to be at most N ;
- Action: number of items to order (there might be a (fixed) delivery delay);
- Stochastics: demand $\sim \text{Poisson}(\lambda)$.

Dynamic pricing for end-of-season products can also be modeled as an MDP” assume the demand is $\text{Poisson}(\lambda)$, with λ a known function of price.

3. The *Bellman policy operator* $B^\pi : V \mapsto R + \gamma PV$ is a contraction: it has a fixed point. *Policy iteration* iterates it to compute V^π . *Value iteration* iterates the *Bellman optimality operator* $B^* : V \mapsto \text{Max}_a(R + \gamma PV)$: it alternates two steps,

$$\begin{aligned} V &\leftarrow V^\pi && \text{policy evaluation} \\ \pi &\leftarrow \text{greedy}(\pi) && \text{policy improvement.} \end{aligned}$$

6. *Merton’s portfolio problem* is an analytic solution to the dynamic asset allocation and consumption problem.

7. The *optimal exercise* of an American option in the binomial tree model can be computed with dynamic programming; this generalizes to more general *optimal stopping* problems.

In a (no-arbitrage) incomplete market, option prices are not uniquely defined. *Superhedging* computes upper and lower bounds, but they are often too far apart. Instead, one can compute the price maximizing some expected utility, *e.g.*, CARA (expected utility *indifference pricing*).

8. *Optimal execution* can be modeled as an MDP:

- State: price, number of shares left to sell, time left;
- Action: number of shares sold;
- Reward: utility of the sales proceeds, after correcting the price with the temporary price impact (“eating into the book”);
- Stochastics: the price follows a random walk, corrected with the permanent price impact.

For (unrealistic) linear price impacts, we can solve the Bellman equation.

8. *Optimal market making* can be modeled as an MDP:

- State: mid-price, current P&L, inventory;
- Actions: bid and ask prices and quantities;
- Reward: utility of P&L and inventory value;
- Stochastics: random walk for the mid-price; random number of shares bought and sold.

9. Many RL prediction algorithms are based on the update rule

$$V(S_t) \leftarrow V(S_t) + \alpha(\text{target} - V(S_t))$$

for different targets:

- Monte Carlo: G_t ;
- TD (temporal difference): $R_{t+1} + \gamma V(S_{t+1})$;
- n -step TD, $G_{t,2} = R_{t+1} + \gamma R_{t+2} + \gamma^2 V(S_{t+2})$, or, more generally, $G_{t,k}$;
- TD(λ), an exponentially-weighted average of the $G_{t,k}$, which can be efficiently computed (without waiting for the end of the episode) with *eligibility traces*.

10. For control, if the MDP is unknown, we need to replace the state value function V with the state-action value function Q , and alternate policy evaluation (Monte Carlo, TD, TD(λ) – for Q , TD is called SARSA), and policy improvement (ϵ -greedy rather than greedy, to explore enough).

But this is *on-policy*. If the target and behaviour policies, π and μ are different (*off-policy*):

- Q-learning uses $R_{t+1} + \gamma \text{Max}_a Q(S_{t+1}, a)$ as target;
- Importance sampling multiplies the SARSA updates with $\pi(S_t, A_t) / \mu(S_t, A_t)$ (for one step).

Convergence is not guaranteed if we combine bootstrapping (using V itself in the target), off-policy learning, and function approximation.

Which trading agent is best? Using a threaded parallel simulation of a financial market changes the pecking order

M. Rollins and D. Cliff (2020)

Automated trading algorithms (AA, GDX, ZIP, ZIC)) are often compared in market (LOB) simulators (e.g., BSE, the Bristol Stock Exchange), but which comes ahead depends on the mix of strategies they compete with. The computation time, and the resulting delay of those algorithms, may change the rankings.

Parametrized response zero-intelligence (PRZI) traders
D. Cliff (2021)

In the *zero-intelligence constrained* (ZIC) strategy, each trader has a side (buy or sell), a limit price λ , only trades one share, and samples their bid or ask uniformly in $[p_{\min}, \lambda]$ or $[\lambda, p_{\max}]$.

The SHVR strategy bids one tick above the current best bid (if below λ).

The GVWY strategy bids at the trader's limit price (no profit, unless the trade crosses the spread).

Those strategies can be blended.

Strategic bidding in continuous double auctions
P. Vyteling et al. (2018)

The AA (adaptive aggressiveness) strategy tunes its aggressivity (eager to trade, even for lower profits, vs eager to profit, even for a lower probability of trade). Prior algorithms include:

- ZIP (zero-intelligence plus), a variant of ZIC which progressively updates its profit margin;
- GD, which estimates the probability that a bid will be accepted;
- GDX, which also uses dynamic programming, and may delay trading, waiting for better market conditions.

BSE: a minimal simulation of a limit-order-book stock exchange
D. Cliff (2018)

Reinforcement learning with expert trajectory for quantitative trading
S. Chen et al. (2021)

Reinforcement learning with expert trajectories uses (some variant of Q -learning with) a reward of 1 for the expert and 0 for the other agent's actions.

An empirical assessment of characteristics and optimal portfolios
C.G. Lamoureux and H. Zhang (2021)

Do not optimize a sum of squared residuals, but a utility function.

$$\sum_t \frac{(1 + r_{\text{port},t})^{1-\gamma}}{1-\gamma} \quad \text{utility}$$

$$r_{\text{port},t} = \sum w_{i,t-1} r_{i,t} \quad \text{portfolio returns}$$

$$w_{i,t} = f_{\theta}(x_{i,t}) \quad \text{portfolio weights}$$

$$x_{i,t} \quad \text{stock characteristics}$$

Constructing long-short stock portfolios with a new listwise learn-to-rank algorithm
X. Zhang et al. (2021)

Learning-to-rank models for information retrieval

$$\text{Loss} = \sum_{\text{relevance}} f_k \cdot \frac{1}{\underset{\substack{\text{discount} \\ \text{factor}}}{\log(1+k)}}$$

focus on best-ranked items: adapt them for stock selection by focusing on both the top and bottom items by generalizing the Plackett–Luce probability distribution on \mathcal{S}_n (ListMLE)

$$P[\sigma] = \prod_i \frac{\theta_{\sigma^{-1}(i)}}{\sum_{k \geq i} \theta_{\sigma^{-1}(k)}}$$

to consider long-short pairs (instead of long-only items)
 $\theta_i \rightsquigarrow \theta_{2n+1-i}$.

***Imputation, estimation
and missing data in finance***
G. DiCesare (2006)

Comparisons of estimators of the parameters of a partially-observed multivariate Brownian motion:

- EM algorithm;
- Impute-solve:
 - Simulate $X_{\text{mis}}|X_{\text{obs}}, \theta_k$;
 - Estimate $\hat{\theta}$ from the completed dataset;
 - Update $\theta_{k+1} = \theta_k + \gamma_k(\hat{\theta} - \theta_k)$;
- Impute-posterior:
 - Sample $X_{\text{mis}}|X_{\text{obs}}, \theta_k$;
 - Sample $\theta|X_{\text{obs}}, X_{\text{mis}}$.

The EM algorithm can be implemented with the *sweep operator*

$$\text{sweep}_k : \begin{cases} \mathbf{R}^{p \times p} & \longrightarrow \mathbf{R}^{p \times p} \\ G & \longmapsto H : h_{kk} = -1/g_{kk} \\ & h_{jk} = h_{kj} = g_{jk}/g_{kk} \\ & h_{j\ell} = h_{\ell j} = g_{j\ell} - \frac{g_{jk}g_{j\ell}}{g_{kk}} \end{cases}$$

$$\text{sweep}_1 \cdots \text{sweep}_p G = -G^{-1} \det G$$

on the sufficient statistic

$$T = \begin{pmatrix} 1 & \mathbf{1}'Y \\ Y'\mathbf{1} & Y'Y \end{pmatrix} \quad \Theta = \begin{pmatrix} -1 & \mu \\ \mu\Sigma & \end{pmatrix}.$$

Some of those computations can be generalized to SDEs: for instance, after Euler discretization, one can sample from $X_i|X_{i-1}, X_{i+1}$ with Metropolis-Hastings.

From the Markovian property, we can cut the data into blocks along dates for which all the variables are observed.

Dynamic style analysis and applications
M. Markov et al. (2004)

Return-based style analysis is a constrained regression of a fund's returns against benchmarks,

$$R_t = \alpha + \sum_i \beta_i r_{it} + \varepsilon_t, \quad \beta \geq 0, \quad \beta'\mathbf{1} = 1.$$

Allow for time-changing exposures β_{it} and add a “smoothness” penalty on $\sum \|\beta_{it} - \beta_{i,t-1}\|^2$ (smoothness would be a penalty on $\Delta^2\beta$, not $\Delta\beta$; one could also use a Kalman filter).

Choose the scale of the penalty to maximize R^2 .

To find the position of the most likely breakpoint, compare all the models with a penalty on

$$\sum_{\substack{i,t \\ t \neq t_0}} \|\beta_{i,t} - \beta_{i,t-1}\|^2,$$

for all values of t_0 (one could try the fused lasso instead).

Conditional distribution in portfolio theory
E. Qian and S. Gorman (2001)

The simplified Black-Litterman framework can be generalized for views on returns, volatilities and correlations. In the case of two assets, r_1, r_2 , and views $\tilde{\mu}_2 = E[r_2]$ and $\tilde{\sigma}_2^2 = \text{Var}[r_2]$, regress $r_1 \sim r_2$:

$$r_1 = \mu_1 + \rho \frac{\sigma_1}{\sigma_2} (r_2 - \mu_2) + \varepsilon$$

$$\varepsilon \sim N(0, \sigma_2^2(1 - \rho^2))$$

and compute $E[r_1]$, $\text{Var}[r_1]$, $\text{Cov}[r_1, r_2]$ as a function of $\rho, \mu_1, \mu_2, \sigma_1, \sigma_2, \tilde{\mu}_2, \tilde{\sigma}_2$.

For a view on $d = r_1 - r_2$, regress r_1 and r_2 against d .

In the general case $r \sim N(\mu, \Sigma)$ with views on $v = Pr$, regress $r \sim v$:

$$r = \mu + \Sigma P' \Sigma_v^{-1} (r - \mu_v) + \varepsilon$$

$$\varepsilon \sim N(0, \Sigma - \Sigma P' \Sigma_v^{-1} P \Sigma)$$

$$\mu_v = P \mu$$

$$\Sigma_v = P \Sigma P'.$$

The posterior is then

$$\tilde{\mu} = \mu + \Sigma P' \Sigma_v^{-1} (\tilde{\mu}_v - \mu_v)$$

$$\tilde{\Sigma} = \Sigma + \Sigma P' (\Sigma_v^{-1} \tilde{\Sigma}_v \Sigma_v^{-1} - \Sigma_v^{-1}) P \Sigma.$$

Global portfolio optimization revisited: a least discrimination alternative to Black-Litterman
J. P  zier (2007)

Given a prior distribution p (e.g., $X \sim N(\mu, \Sigma)$) and constraints on a posterior distribution \tilde{p} (e.g., $E[PX] = v$, as in Black-Litterman, or $PX = v$, or $\text{Var}[PX] = V$), look for the posterior distribution \tilde{p} , satisfying those constraints, and minimizing the difference in certainty equivalent of the optimal (dynamic) strategy (Black-Litterman only considers static strategies, *i.e.*, portfolios)

$$\text{CE}(f_{\tilde{p}}(x) | \tilde{p}) - \text{CE}(f_p(X) | p).$$

For a payoff (random variable) Y and a utility function u , the certainty equivalent is defined as $E[u(Y)] = u(\text{CE}[Y])$.

Fully flexible views: theory and practice

A. Meucci (2008)

Given a prior distribution on asset returns (and/or risk factors), and views, *i.e.*, constraints on some of the generalized moments, blend them:

- Take N samples from the prior; see them as a uniform distribution p (you could also use importance sampling);
- Solve the optimization problem

Find q , probability distribution on the samples

To minimize the relative entropy $\mathcal{E}(q, p) = \int q \log \frac{q}{p}$

Such that the constraints be satisfied

- If there are confidence levels on the views, use the mixture $(1 - c)p + cq$ (or $\sum c_i q_i$ if there are several views);
- Use for portfolio construction.

In the Gaussian case:

$$X \sim N(\mu, \Sigma)$$

$$E[QX] = \tilde{\mu}$$

$$\text{Var}[GX] = \tilde{\Sigma}$$

$$X \sim N(\bar{\mu}, \bar{\Sigma})$$

$$\bar{\mu} = \mu + \Sigma Q' (Q \Sigma Q')^{-1} (\tilde{\mu} - Q \mu)$$

$$\bar{\Sigma} = \Sigma G' [(Q \Sigma Q')^{-1} \tilde{\Sigma} (Q \Sigma Q')^{-1} - (Q \Sigma Q')^{-1}] G \Sigma.$$

In the general case, to impose constraints on expectations, volatilities and correlations, use

$$\begin{aligned} \sum_j q_j X_{jk} &= m_k \\ \sum_j q_j X_{jk}^2 &= \hat{m}_k^2 + \sigma_k^2 \\ \sum_j q_j X_{jk} X_{j\ell} &= \hat{m}_k \hat{m}_\ell + \hat{\sigma}_k \hat{\sigma}_\ell c_{k\ell} \end{aligned}$$

(this is not quite right, because we use \hat{m} and $\hat{\sigma}$ from the prior, but it makes the constraints linear and the problem convex).

Deep learning for portfolio optimization

Z. Zhang et al. (2020)

Neural net (LSTM), fed past prices and returns to directly compute the weights maximizing the information ratio (for 4 assets).

Enhancing time series momentum strategies using deep neural networks

B. Lim et al. (2019)

Time series momentum strategies require both a trend estimator and position sizing (*volatility scaling*), to

keep the volatility constant), e.g.,

$$\text{trend} = \text{past returns} \quad \text{trend} = \text{MACD}/\sigma$$

$$\text{position} = \text{sign}(\text{trend}) \quad \text{position} = \phi(\text{trend})$$

$$\phi(y) = ye^{-y^2} = \sqrt{\lambda}$$

Instead, use a neural net (WaveNet, fed the past 5 days of returns) to directly find the position size maximizing the information ratio.

Deep reinforcement learning for trading

Z. Zhang et al. (2020)

Comparison of 3 reinforcement learning algorithms, critic-only (DQN), actor-only (policy gradient) and actor-critic, to maximize the (after-transaction-cost) P&L of a (volatility-adjusted) strategy using 1m, 2m, 3m, 1y normalized returns, price, MACD(63,252), RSI(30): DQN works better.

Macroeconomic forecasting with statistically validated knowledge graphs

S. Tilly and G. Livan (2021)

To forecast/nowcast industrial production:

- Use the *global database of events, language and tone* (GDELT, available via Google BigQuery) to build theme co-occurrence graphs;
- Filter the themes relevant to economic growth with an LSTM, trained on 1000 manually labeled events (4000 nodes, 1 million edges);
- Compute its backbone using a *disparity filter*: normalize the weights of the edges connected to a given node so they sum up to 1 and apply the Benjamini-Hochberg (BH) procedure;
- Compute the *portrait divergence* to compare the graph with the previous month's;
- Compute the eigenvector centralities of all the nodes;
- Reduce the dimension of the centralities with PLS;
- Add the Baltic Dry index (a shipping index) and crude oil price to the predictors;
- Conclude with Granger causality, and a factor-augmented AR model.

An information-theoretic, all-scales approach to comparing networks

J.P. Bagrow and E.M. Bollt (2019)

The **network portrait** of a graph is a matrix $B_{\ell,k}$ = number of nodes having k nodes at distance ℓ . The 0th row contains the number of nodes; the first row is the degree distribution; each row defines a probability distribution.

```
## Error in count(.): Argument 'x' is not a vector: list
```

```
## Error in count(.): Argument 'x' is not a vector: list
```

```
## Error in count(.): Argument 'x' is not a vector: list
```

For weighted graphs, compute all shortest paths and bin their lengths

The *network portrait divergence* compares graphs using the Jensen-Shanon divergence between the distributions $P(k, \ell) \propto k B_{\ell, k}$.

Portraits of complex networks
J.P. Bagrow et al. (2007)

Comparing methods for comparing networks
T. Tantardini et al. (2019)

Distances between networks include:

- Distance between the similarity matrices $S = (I + \varepsilon^2 D - \varepsilon A)^{-1}$, where A is the adjacency matrix and D the degree;
- Distances between graphlet counts; one can also compute them on each egonet, aggregate them (Net-Dis), and use PCA;
- Distance between the graphlet correlation matrices, obtained by counting, for each node, in how many graphlets of each type it is, and computing the correlation matrix between those counts;
- Distance between the spectra of the Laplacians, e.g., via the heat signature trace $h(t) = \sum_i e^{-\lambda_i t}$;
- Graph kernels, TDA, portrait divergence, etc.

The graphlet correlation distance (GCD) gives the best results.

Open-source cross-sectional asset pricing
A.Y. Chen and T. Zimmerman (2021)

List of 300+ investment signals. Unusable code (Stata) and data (commercial).

The most general methodology to create a valid correlation matrix for risk management and option pricing
R. Rebonato and P. Jäckel (1999)

Correlation matrices can be parametrized as $C = BB'$, where the rows of B are on the sphere \mathbf{S}^{n-1} .

$$b_{ij} = \cos \theta_{ij} \prod_{k=1}^{j-1} \sin \theta_{ik} \quad 1 \leq j \leq n-1$$

$$b_{in} = \prod_{k=1}^{n-1} \sin \theta_{ik}$$

$$\theta \in \mathbf{R}^{n \times (n-1)}$$

The closest correlation matrix can be obtained by solving

$$\text{Minimize } \left\| \hat{C} - C \right\|_F^2.$$

As a starting point for the optimization:

- Eigenvalue decomposition $C = SAS'$;
- Zero out the negative eigenvalues: Λ_+ ;
- Compute $B_0 = S\sqrt{\Lambda_+}$;

- Normalize the rows of B_0 : B .

If C was a valid correlation, we have $C = BB'$.

Unconstrained parametrization for variance covariance matrices
J.C. Pinheiro and D.M. Bates (1996)

Generating realistic stock market order streams
J. Li et al. (2020)

WGAN whose generator uses an LSTM to condense past orders and a (pretrained) neural net to differentially approximate the continuous double auction (CDA) mechanism.

Style transfer with time series: generating synthetic financial data
B. da Silva and S.S. Shi (2019)

Generate high frequency data with a denoising autoencoder (?) rather than a GAN or VAE; then use style transfer to get daily data.

Time series generative adversarial networks
J. Yoon et al. (2019)

Jointly learn a latent representation and a GAN.

On unbiased simulations of stochastic bridges conditional on extrema
A. Schaug and H. Chandra (2019)

The promises and pitfalls of machine learning for predicting stock returns
E. Leung et al. (2021)

Nonlinear models, e.g., GBM, have better predictive power on future returns than linear models, but their advantage almost disappears if we account for transaction costs, microcaps, multiple testing, non-synchronous implementation, risk constraints.

Matrix evolutions: synthetic correlations and explainable machine learning for constructing robust investment portfolios
J. Papenbrock et al. (2021)

Financial correlation matrices have the following properties:

- The distribution of correlations is positively skewed;
- Eigenvalues follow the Marchenko-Pastur distribution but for a very large eigenvalue (market) and a couple of large eigenvalues (industries);
- The first eigenvector has positive entries (Perron-Frobenius);

- The correlation has a “hierarchical structure”, *i.e.*, the distances from the correlation $\sqrt{1 - c_{ij}}$ are very close to the distances on the (single linkage) dendrogram d_{ij} ; this can be measured by the *cophenetic correlation* $\text{Cor}(\sqrt{1 - c}, d)$;
- The minimum-spanning tree is scale-free, *i.e.*, it has a power law degree distribution.

To generate real-looking correlation matrices, pick matrices at random in some neighbourhood of the empirical correlation and use multiobjective optimization (why?) to match

- The average correlation;
- The Gini coefficient of the eigenvalues;
- The single-linkage cophenetic correlation;
- The sum of the negative coefficients of the first eigenvector.

Those matrices can then be used to compare investment strategies, *e.g.*, risk parity and hierarchical risk parity.

MOEA/D: A multi-objective evolutionary algorithm based on decomposition
Q. Zhang and H. Li (2007)

To solve the multiobjective optimization problem

$$\text{Maximize}_{x \in \Omega} f_1(x), \dots, f_n(x),$$

reduce it to a set of 1-dimensional problems

$$\text{Maximize}_{x \in \Omega} \sum_i \lambda_i f_i(x)$$

(where λ is fixed) and solve them sequentially, starting each optimization with the solution of the closest λ .

Instead, MOEA/D solves the problems simultaneously:

- P_j : Maximize $\sum_{x \in \Omega} \lambda_{ij} f_i(x)$ subproblems;
- $x_{j,t}$: best solution to P_j after t steps;
- $x_{j,t+1}$: computed from the $x_{j',t}$ for the subproblems where $\lambda_{j'}$ is close to λ_j

Contrary to domination-based multiobjective optimization, decomposition-based algorithms can deal with higher-dimensional problems (if there are many objectives, most candidate solutions are non-dominated).

History, shocks and drifts: a new approach to portfolio formation
M. Kritzman and D. Turkington (2021)

Generate scenarios by changing low-frequency components (shocks, trend) and keeping the high-frequency part.

Spectral temporal graph neural network for multivariate time series forecasting
D. Cao et al. (2021)

To forecast multivariate time series, stack the following layers:

- GRU: $X \mapsto R$;
- *Correlation layer*, *i.e.*, self-attention

$$W = \text{Softmax}\left(\frac{QK'}{\sqrt{d}}\right), \quad Q = RW_1, \quad K = RW_2;$$

use the attention matrix W as a graph incidence (or weight) matrix in the next layer;

- Graph Fourier transform, independently for each component;
- 1-dimensional convolution;
- Gated linear unit: $\text{GLU}(a, b) = a \odot \sigma(b)$;
- (Repeat several times)
- Fully-connected layer.

Fast ES-RNN: a GPU implementation of the ES-RNN algorithm
A. Redd et al. (2019)

ES-RNN uses an LSTM to compute the parameters of a Holt-Winters exponential smoothing model; it won the M4 competition – Theta, another exponential smoothing variant, won the previous one.

COIN: Compression with implicit neural representation
E. Dupont et al. (2021)

To compress an image, overfit a neural net (pixel coordinates \mapsto RGB) to it and store the quantized weights; it is competitive with JPEG at low rates.

Learning continuous image representation with local implicit image function
Y. Chen et al. (2020)

From an image $H \times W \times 3$, compute features $H \times W \times D$. In the neighbourhood of a pixel (h, w) , use the features $M_{h,w,\cdot}$ of that pixel and those $M_{h \pm 1, w \pm 1, \cdot}$ of its neighbours to forecast RGB values. Since a point is in several neighbourhoods, ensemble their forecasts, using areas as weights.

Learning neural network subspaces
M. Wortsman et al. (2021)

Do not look for a point in weight space but a subspace (segment, Bézier curve, simplex): in each epoch, pick a random point in the subspace to train, and force the endpoints to be orthogonal; at test time, use the mid-point.

A unified approach to measurement error and missing data: overview and applications
M. Blackwell et al. (2017)

Multiple overimputation generalizes multiple imputation to noisy observations – a missing observation is an observation with infinite noise.

imputeTS:
time series missing value imputation in R
S. Moritz and T. Batrz-Beielstein (2017)

Missing values in univariate time series can be imputed by a Kalman filter (ARIMA or structural models), interpolation, or seasonal decomposition (or lof, mean, median, mode, moving average, constant value, random value).

Comparison of different methods for univariate time series imputation in R
S. Moritz et al. (2015)

The zoo and forecast packages provide several `na.*`; also check `Amelia`, `mtsdi`, `VIM`, `mice`, `imputeR` (they deal with multivariate non-time-series data: add polynomials of time, lags and leads).

Imputation of multivariate time series data: performance benchmark for multiple imputation and spectral techniques
J. Bauer et al. (2013)

First look for missingness patterns: proportion of missing data, run lengths, etc. (CDS data, 1000 tickers, 10 maturities).

Data imputation with empirical orthogonal functions (DINEOF – EOF is another term for left and right singular vectors) uses the SVD to recover the missing data, progressively increasing the number of singular values retained.

Singular spectrum analysis (SSA) adds lags

$$\begin{pmatrix} x_1 & x_2 & \cdots & \\ \vdots & \vdots & & \vdots \\ x_L & x_{L+1} & \cdots & x_N \end{pmatrix}$$

and reconstructs the signal by averaging over the anti-diagonals. It can be generalized to multivariate SSA (MSSA).

Temporal regularized matrix factorization for high-dimensional time series prediction
H.F. Yu and N. Rao (2016)

Matrix completion can be used to model time series, in high dimension, with missing values: $Y \approx FX$.

$$\text{Minimize}_{F,X} \sum_{int} (y_{it} - f'_i x_t)^2 + \lambda_1 R(F) + \lambda_2 R(X)$$

The regularizer $R(X)$ could come from a graph

$$R(X) = \sum_t \|x_t\|^2 + \sum_{s,t} w_{st} \|x_t - x_s\|^2$$

if the weights are chosen beforehand. Instead, use the negative log-likelihood of some time series model

$$R(X) = -\log P(x_1, \dots, x_T | \theta),$$

e.g., an AR model

$$R(X) = \sum_{t>L} \left\| x_t - \sum_{\ell=1}^L \theta_\ell x_{t-\ell} \right\|^2 + \sum_t \|x_t\|^2$$

and a penalty (prior) for θ .

Applications include missing value imputation and forecasting.

Probabilistic sequential matrix factorization
O.D. Akyildiz et al. (2019)

In the matrix factorization problem

$$\text{Minimize}_{C,X} \|Y - CX\|,$$

add a prior on C (matrix variate Gaussian) and X (nonlinear state space model).

$$s \sim \text{IG}$$

$$C \sim \text{MN}(C_0, I, sV_0)$$

$$x_0 \sim N(\mu_0, sP_0)$$

$$x_k \sim N(f_\theta(x_{k-1}), sQ_0)$$

$$y_k \sim N(Cx_k, sR_0)$$

(For s constant, it is Gaussian, but if we marginalize it, we get more robust Student distributions.)

Mixtures, EM and missing data
B. Stewart (2017)

We want to estimate $\mu = E[X]$ and $\Sigma = \text{Var}[X]$ in presence of missing data.

0. Start with initial estimates, e.g, means and variances (diagonal Σ) from available observations.

1. For each missingness pattern, estimate a regression $X_{\text{mis}} = X_{\text{obs}}\beta + \varepsilon$. We can compute β and $\sigma^2 = \text{Var} \varepsilon$ from μ, Σ . We this replace each missing value with a distribution $X_{\text{mis},i} \sim N(X_{\text{obs},i}\beta, \sigma^2)$. More precisely, we will need the expectations $E[X_{\text{mis},i}]$ and $E[X_{\text{mis},i}X'_{\text{mis},i}]$ (E-step).

2. Using the expectations $E[X]$ and $E[XX']$, re-estimate μ, Σ , with MLE (M-step).

3. Iterate until convergence.

Amelia II: a program for missing data
J. Honaker et al. (2011)

To impute missing data, the EMB (EM with bootstrap) algorithm:

- Bootstraps missing data $m = 5$ times
- Models each bootstrap dataset as a Gaussian $N(\mu, \Sigma)$, using the EM algorithm for MLE with missing values;
- Imputes the missing values with their conditional expectation (m times).

***What to do about missing values
in time series cross-section data***
J. Honaker and G. King (2010)

To allow smooth interpolation when needed, add basis functions to the data (e.g., with cubic splines); also add lags and leads of the variables. Implementation in *Amelia*.

mice:
multiple imputation by chained equations in R
S. van Buuren and K. Groothuis-Oudshoorn (2011)

Iterate T times:

- Sample θ_1 from $\theta_1|Y_1^{\text{obs}}, Y_2, \dots, Y_p$;
- Sample Y_1^{mis} from $Y_1^{\text{mis}}|\theta_1, Y_1^{\text{obs}}, Y_2, \dots, Y_p$;
- ...
- Sample θ_p ;
- Sample Y_p^{mis} .

Those conditional models (often, regression or GLMs) need not be compatible: they may not come from a well-defined joint distribution – this does not seem to be a problem. Generate 5 such implied datasets; fit your model on each of them; pool those models. The *VIM* package provides a few more plots.

***Gaussian process imputation
of multiple financial time series***
T. de Wolff et al. (2020)

Missing data in time series (4 to 10 time series) can be imputed with a multi-output Gaussian process (MOGP), with a multioutput spectral mixture (MOSM) kernel.

***MOGPTK:
the multioutput Gaussian process toolkit***
T. de Wolff et al. (2020)

Built with PyTorch (formerly Tensorflow/GPflow).

***Spectral mixture kernels
for multioutput Gaussian processes***
G. Parra and F. Tobar (2017)

$$k_{ij}(\tau) = \sum_q \alpha_{ij}^q \exp\left[-\frac{1}{2}(\tau + \theta_{ij}^q)' \Sigma_{ij}^q (\tau + \theta_{ij}^q)\right] \cdot \cos[(\tau + \theta_{ij}^q)' \mu_{ij}^q + \phi_{ij}^q]$$

***GP-VAE:
deep probabilistic time series imputation***
V. Fortuin et al. (2019)

VAE with a low-dimensional GP prior on the latent space, with a Cauchy kernel (it can be seen as a Gamma mixture of RBF kernels at different scales). When computing the ELBO, only include terms with data. To generate data, replace the missing values with 0 (this introduces bias).

***BRITS: bidirectional recurrent imputation
for time series***
W. Cao et al. (2018)

Use an RNN (BiLSTM) to impute missing values; the loss is delayed until we have the next observation

One can add cross-sectional features.

***Recurrent neural networks for multivariate
time series with missing values***
Z. Che et al. (2017)

To deal with missing values in a RNN (GRU), use the last available value and add to the input: a missingness indicator, and the time since the last observation

***NAOMI: Non-autoregressive multiresolution
sequence imputation***
Y. Liu et al. (2019)

Deep generative models for sequences are autoregressive: errors compound. Instead, use a multi-resolution approach: feed the time series (with the missing values zeroed out) and the mask to a BiLSTM, predict $x_{n/2}$ from h_0 and h_n , feed that new value to the network, and proceed recursively.

***Multivariate time series imputation
with generative adversarial networks***
Y. Luo et al. (2018)

Train a GAN to generate complete data that looks like real data (assuming you have several/many similar time series); find a point in latent space (noise) that gives a time series close to the actual data; use it to generate a complete time series.

***E² GAN: end-to-end
generative adversarial network***
Y. Luo et al. (2019)

Use a denoising autoencoder as generator.

***Estimating missing data
in temporal data streams using
multidirectional recurrent neural networks***
J. Yoon et al. (2017)

First interpolate within streams (BiRNN), then impute across streams (AE with dropout).

**Time series imputation and prediction with
bidirectional generative adversarial networks**
M. Gupta and R. Beheshti (2020)

Given many similar time series, train a GAN whose generator fills in the missing values, and whose discriminator distinguishes between real and imputed values.

**Panning for gold: Model-X knockoffs for
high-dimensional controlled variable selection**
E. Candès et al. (2017)

To select relevant variables in a model $Y \sim X$ while controlling the false discovery rate (FDR), one could use *conditional randomization*, i.e., repeatedly sample X_i^* from $X_i|X_{-i}$, compute test statistics T_i and T_i^* , compare them, and use

$$P = \frac{1 + \sum_k \mathbf{1}_{T_i > T_i^*}}{1 + K}.$$

This can be done with a single sample ($K = 1$) with a *knockoff distribution*, i.e., a distribution (X, \tilde{X}) such that

- (i) $(X, \tilde{X}) \stackrel{d}{=} (X, \tilde{X})_{\text{swap}(S)}$, where $S \subset \llbracket 1, p \rrbracket$ and $\text{swap}(S)$ swaps X_j and \tilde{X}_j for all $j \in S$
- (ii) $\tilde{X} \perp\!\!\!\perp X | Y$ (e.g., \tilde{X} is constructed without looking at Y)

For a Gaussian distribution, $X \sim N(0, \Sigma)$, we can use

$$(X, \tilde{X}) \sim N\left(0, \begin{pmatrix} \Sigma & \Sigma - \text{diag}(s) \\ \Sigma - \text{diag}(s) & \Sigma \end{pmatrix}\right)$$

and sample from $\tilde{X}|X$, where s is chosen so that the matrix be positive semi-definite; we then have $\text{Cor}(X_j, \tilde{X}_j) = 1 - s_j$.

- Choose $\Sigma_{\text{approx}} \approx \Sigma$, e.g., I or block-diagonal;
- $\hat{s} = \underset{s}{\text{Argmin}} \sum |1 - s_j|$ st $s \geq 0$, $\text{diag}(s) \preceq 2\Sigma_{\text{approx}}$;
- $\gamma = \underset{\gamma}{\text{Argmax}} \gamma$ st $\text{diag}(\gamma\hat{s}) \preceq 2\Sigma$;
- $s = \gamma\hat{s}$.

Use a statistic $W_j = w_j(X, \tilde{X}, y)$ such that

$$w_j((X, \tilde{X})_{\text{swap}(S)}, y) = \begin{cases} +w_j(X, \tilde{X}, y) & \text{if } j \notin S \\ -w_j(X, \tilde{X}, y) & \text{if } j \in S \end{cases}$$

for instance, a difference of lasso coefficients

$$Z_j = b_j(\lambda) \\ W_j = |Z_j| - |\tilde{Z}_j|$$

or

$$Z_j = \text{Max}\{\lambda : b_j(\lambda) \neq 0\} \\ W_j = \text{sign}(|Z_j| - |\tilde{Z}_j|) \text{Max}\{|Z_j|, |\tilde{Z}_j|\}.$$

Conditional on $|W_1|, \dots, |W_p|$, the signs of the null (i.e., irrelevant) W_j are iid coin flips. Estimate the false discovery proportion as

$$\widehat{\text{FDP}}(t) = \frac{\#\{j : W_j \leq -t\}}{\#\{j : W_j \geq t\}};$$

set the threshold to

$$\tau = \text{Min}\{t > 0 : \widehat{\text{FDP}}(t) \leq q\}$$

and select the variables $\hat{S} = \{j : W_j \geq \tau\}$: this controls the modified FDR

$$\text{mFDR} = \mathbb{E} \left[\frac{|\hat{S} \cap H_0|}{|\hat{S}| + 1/q} \right] \leq q$$

(add 1 to the $\widehat{\text{FDR}}$ numerator to control the FDR). R implementation: `knockoff`.

**Detection of accounting anomalies
in the latent space using
adversarial autoencoder neural nets**
M. Schreyer et al. (2019)

To add an arbitrary prior to the latent space of an autoencoder, e.g., a Gaussian mixture, use a discriminator.

**Learning sampling in financial statement
audits using VQ autoencoding neural networks**
M. Schreyer (2020)

The VQ-VAE

$$x \xrightarrow{q_\theta} z_e \mapsto z_q \xrightarrow{p_\phi} \tilde{x}$$

adds a “quantize” operation to the autoencoder, which maps the latent representation z_e to the closest vector z_q among a (learned) codebook e_ψ . The loss has 4 terms:

- Reconstruction from z_q [depends on ψ, ϕ];
- Reconstruction from z_e , skipping the reconstruction step $[\theta, \phi]$;
- $\|z_e - \tilde{z}_q\|$ to move the latent representation towards the codebook vectors $[\theta]$;
- $\|\tilde{z}_e - z_q\|$ to move the codebook vectors towards the latent representation $[\psi]$;

where $\bar{\cdot}$ is the *stop-gradient* operation: identity in the forward pass, zero in the backward pass – i.e., the quantity is considered constant.

**Counterexample-guided learning
of monotonic neural networks**
A. Sivaraman et al. (2020)

To ensure that a trained model is monotonic, compute its (upper and lower) *monotonic envelope*: $\bar{f}(x_0)$ comes from the maximum monotonic violation for $x \leq x_0$ and can be computed with an SMT solver – more precisely, an *OMT* (optimization modulo theories) solver such as OptiMathSAT proprietary.

One can also include those examples at training time, adding (to the next batch) counterexamples for each sample in the current batch, and assigning them the average label.

**Automatically learning compact quality aware
surrogates for optimization problems**
K. Wang et al. (2020)

In the *predict-then-optimize* framework

$$\xi \mapsto \theta \mapsto \underset{x}{\operatorname{Argmin}} f_{\theta}(x)$$

simplify the optimization layer by replacing $x \in \mathbf{R}^n$ with $x = Py$, $y \in \mathbf{R}^m$, $m \ll n$, where P is *learned* (rather than random).

[Implementation with `cvxpylayers` – `qpth` is older and limited to quadratic programming.]

**Generative minimization networks:
training GANs without competition**
P. Grnarova et al. (2021)

To find the Nash equilibria of a min-max game

$$\text{Player 1 : } \underset{u}{\operatorname{Min}} \underset{v}{\operatorname{Max}} M(u, v)$$

$$\text{Player 2 : } \underset{v}{\operatorname{Max}} \underset{u}{\operatorname{Min}} M(u, v)$$

the often-used gradient descent ascent (GDA) need not converge. Instead, minimize the *duality gap*

$$\operatorname{DG}(u, v) = \underset{v'}{\operatorname{Max}} M(u, v') - \underset{u'}{\operatorname{Min}} M(u', v).$$

For GANs,

$$M(u, v) = \underset{\substack{z_1 \sim \text{data} \\ z_2 \sim \text{noise}}}{\operatorname{E}} [\log D_v(z_1) + \log(1 + D_v G_u z_2)].$$

To estimate the duality gap, run k steps of gradient descent to find u_{worst} and v_{worst} .

**Ultra data-efficient GAN training: drawing
a lottery ticket first, then training it toughly**
T. Chen et al. (2021)

To train a GAN with little data:

- Look for a lottery ticket, with *iterative magnitude pruning* (train for t epochs and 100 samples, prune the smallest weights rewind);
- Train with adversarial augmentation: perturbations to the intermediate features.

**Bootstrap your own latent:
a new approach to self-supervised learning**
J.B. Grill (2020)

BYOL performs self-supervised learning (SSL) without negative pairs by training two networks:

- An online network, which predicts the target representation of an augmented version of the input;
- A target network, moving average of the online network.

**Exploring simple Siamese
representation learning**
X. Chen and K. He (2020)

To learn a latent representation, use simple siamese networks (SimSiam): feed two augmentations of the same image to two copies of the same network, keeping one frozen (“stop-gradient”) and use the latent representation of one to predict that of the frozen one (that is BYOL without the moving average).

**Understanding self-supervised learning
dynamics without contrastive pairs**
Y. Tian

In BYOL/SimSiam, the stop gradient and the predictor are important; the moving average, weight decay, predictor optimality, less so.

DirectPred does not train the predictor, but sets its weights using the PCA of its input.

Non-additive measures
V. Torra et al. (2014)

A **non-additive measure** (or *capacity*, or fuzzy measure) satisfies

$$A \subset B \Rightarrow \mu(A) \leq \mu(B).$$

It can model negative and positive interactions,

$$\begin{aligned} \mu(A \sqcup B) &< \mu(A) + \mu(B) \\ \mu(A \sqcup B) &> \mu(A) + \mu(B). \end{aligned}$$

For instance, a 2-book set $\{x_1, x_2\}$ may be more valuable than the individual books,

$$v(\{x_1, x_2\}) > v(\{x_1\}) + v(\{x_2\}).$$

In a workshop, if $\mu(A)$ is the number of widgets produced by the workers in A , we have $\mu(A \sqcup B) = \mu(A) + \mu(B)$ if they work independently, $\mu(A \sqcup B) > \mu(A) + \mu(B)$ if they cooperate, $\mu(A \sqcup B) < \mu(A) + \mu(B)$ if they interfere.

Examples include

- Sugeno λ -measures,

$$\mu(A \sqcup B) = \mu(A) + \mu(B) + \lambda\mu(A)\mu(B);$$

- Distorted probabilities $\mu(A) = f(P(A))$, with f non-decreasing and P a probability;
- \perp -decomposable non-additive measures, $\mu(A \sqcup B) = \mu(A) \perp \mu(B)$, where \perp is a t -conorm,

$$a \perp b = b \perp a$$

$$a \leq c, b \leq d \Rightarrow a \perp b \leq c \perp d$$

$$a \perp (b \perp c) = (a \perp b) \perp c$$

$$a \perp 0 = a$$

The *Möbius transform* of μ is

$$m(A) = \sum_{B \subset A} (-1)^{|A|-|B|} \mu(B)$$

and satisfies

$$\mu(A) = \sum_{B \subset A} m(B).$$

The **Choquet integral** is

$$\begin{aligned} C_\mu(f) &= \int_0^\infty \mu_f(r) dr \\ \mu_f(r) &= \mu\{x : f(x) > r\} \\ C_\mu(f) &= \sum (f(x_{s(i)}) - f(x_{s(i-1)})) \mu(A_{s(i)}) \\ A_{s(i)} &= \{x_{s(i)}, \dots, x_{s(N)}\} \end{aligned}$$

where the $f(x_{s(i)})$ are in increasing order. (In the book example, $C_v(n)$ is the value of n_1 copies of volume 1 and n_2 copies of volume 2, if we sell $n_1 \wedge n_2$ 2-book sets and the rest as individual volumes.) The *Sugeno integral* is

$$\begin{aligned} S_\mu(f) &= \sum_{r \in [0,1]} r \wedge \mu_f(r) \\ &= \text{Max}_i \text{Min}\{f(x_{s(i)}), \mu(A_{s(i)})\}. \end{aligned}$$

The *generalized fuzzy integral* of a simple function

$$f = \bigoplus_{i=1}^n a_i \mathbf{1}_{A_i} \quad A_1 \supseteq \dots \supseteq A_n$$

is

$$\text{GF}_\mu(f) = \bigoplus a_i \boxdot \mu(A_i).$$

The Choquet integral is obtained with $\oplus = +$ and $\boxdot = \cdot$, the Sugeno integral with $\oplus = \max$ and $\boxdot = \min$.

There are several notions of *entropy* for non-additive measures.

$$\begin{aligned} H_Y(v) &= \sum_i h\left(\sum_{\substack{A \subset N \\ i \notin A}} \gamma_{|A|}^n (v(A \cup \{i\}) - v(A))\right) \\ H_{MR}(v) &= \sum_i \sum_{\substack{A \subset N \\ i \notin A}} \gamma_{|A|}^n h(v(A \cup \{i\}) - v(A)) \\ h(x) &= -x \log x \\ \gamma_k^n &= \frac{(n-k-1)! k!}{n!}. \end{aligned}$$

A maximal chain $\emptyset = C_0 \subsetneq \dots \subsetneq C_n = \llbracket 1, n \rrbracket$ defines a probability distribution

$$p_C = (v(C_1) - v(C_0), \dots, v(C_n) - v(C_{n-1}))$$

and yet another entropy

$$M_{\min}(v) = \text{Min}_C H(p_C).$$

5a. The von Neumann-Morgenstern theorem states that a preference order on subsets of a convex set X satisfies

- (i) $p \succ q \Rightarrow \lambda p(1-\lambda)r \succ \lambda q + (1-\lambda)r$
- (ii) $p \succ q$ and $q \succ r \Rightarrow \exists \alpha, \beta \in (0, 1)$

$$\alpha p + (1-\alpha)r \prec q \prec \beta p + (1-\beta)r$$

iff there exists $u : \mathcal{P}(X) \rightarrow \mathbf{R}$ such that

- $p \succ q \Leftrightarrow u(p) \geq u(q)$
- (affine) $\forall p, q \in \mathcal{P}(X) \forall \lambda \in [0, 1]$

$$u(\lambda p + (1-\lambda)q) = \lambda u(p) + (1-\lambda)u(q)$$

Such a u is unique up to a positive affine transformation. This result can be generalized to *mixture spaces* (replace $\lambda p + (1-\lambda)q$ with $h_\lambda(p, q)$), *subjective probabilities*, i.e., preference orders such that

$$E \cap G = F \cap G = \emptyset \Rightarrow (E \succ F \Leftrightarrow E \cup G \succ F \cup G),$$

and *Savage acts*, i.e., maps $f : S \rightarrow X$.

5b. An urn contains 30 red balls and 60 black-or-yellow balls; you are presented with four lotteries:

- Get \$100 if you pick a red ball;
- Get \$100 if you pick a black ball;
- Get \$100 if you pick a red or yellow ball;
- Get \$100 if you pick a black or yellow ball;

For most people, $R \succ B$, but $RY \prec BY$: this cannot be formalized by expected utility theory (**Ellsberg's paradox**), but can be with the Choquet integral utility model, which accounts for both uncertainty (probability theory) and imprecision (or knightian uncertainty – fuzzy sets).

5c. The Choquet integral can be generalized to functions taking negative values,

$$\int a dv = \int_{-\infty}^0 [v(a \geq y) - v(S)] dy + \int_0^\infty v(a \geq y) dy.$$

If v is *convex* (supermodular), i.e.,

$$\forall A, B \quad v(A \cup B) + v(A \cap B) \geq v(A) + v(B),$$

its core $\{p : \forall A \ p(A) \geq v(A)\}$ is non-empty and

$$\int a dv = \text{Min}_{p \in \text{Core}(v)} \int a dp.$$

6. The *Möbius transform* can be defined for a function on a poset $f : (P, \leq) \rightarrow \mathbf{R}$.

$$\begin{aligned} \mu(x, y) &= \begin{cases} 1 & \text{if } x = y \\ -\sum_{y \leq z < x} \mu(y, z) & \text{if } y < x \\ 0 & \text{otherwise} \end{cases} \\ \Delta^f(x) &= \sum_{y \leq x} \mu(x, y) f(y) \\ f(x) &= \sum_{y \leq x} \Delta^f(y) \end{aligned}$$

It measures the extra contribution not achieved by smaller coalitions.

Let \bar{v} be the multilinear extension of the non-additive measure $v : \{0, 1\}^n \rightarrow \mathbf{R}$. The **Shapley value** is

$$\begin{aligned} \phi_i(v) &= \sum_{S \ni i} \frac{1}{|S|} \Delta^v(S) \\ &= \int_0^1 \frac{\partial}{\partial x_i} \bar{v}(t, \dots, t) dt. \end{aligned}$$

It is characterized by:

- Symmetry: $\phi_{\sigma(i)}(\sigma v) = \phi_i(v)$;
- Efficiency: $v(X) = \sum \phi_i(v)$;
- Null-zero: $(\forall S \ v(S \cup i) = v(S)) \Rightarrow \phi_i(v) = 0$;
- Additivity: $\phi(v + w) = \phi(v) + \phi(w)$.

It can be generalized

- From singletons $\{i\}$ to arbitrary subsets;
- To bi-cooperative games, where $v(S, T)$ is the value if voters in S vote +1, those in T vote -1, and the rest abstain;
- To a subset of $\mathcal{P}(X)$ (feasible coalitions), described by a graph.

***Understanding machine learning
for diversified portfolio construction
by explainable AI***
M. Jaeger et al. (2020)

Block-bootstrap the investment universe (16 assets, 20 years, daily, 1- or 3-month blocks), build HRP and ERC portfolios (monthly rebalancing), forecast Calmar(HRP) – Calmar(ERC) from bootstrap features (presence of trend, stability of this trend, dispersion, how good an approximation the hierarchy-filtered correlation matrix is, etc.) with xgboost, and explain with Shapley values.

The Shapley vs feature plot is an alternative to partial dependency plots.

Return attribution
C.R. Bacon and M.A. Wright (2012)

(Textbook material)

Performance attribution: history and progress
C.R. Bacon (2019)

(Review)

***Geometric attribution
and the interaction effect***
A.E. Weber (2018)

There are many variants of Brinson attribution: arithmetic or geometric, with or without interaction.

$$\begin{aligned} r &= \sum w_i w_i \\ \bar{r} &= \sum \bar{w}_i \bar{r}_i \\ A &= \sum w_i \bar{r}_i \\ S &= \sum \bar{w}_i r_i \end{aligned}$$

$$\begin{aligned} r - \bar{r} &= \sum (w_i - \bar{w}_i)(\bar{r}_i - \bar{r}) + \sum \bar{w}_i(r_i - \bar{r}_i) + \sum I_i \\ r = \bar{r} &= \sum (w_i - \bar{w}_i)(\bar{r}_i - \bar{r}) + \sum w_i(r_i - \bar{r}_i) \\ \frac{1+r}{1+\bar{r}} &= \frac{1+r_A}{1+\bar{r}} \cdot \frac{1+r}{1+r_A} \\ \frac{1+r}{1+\bar{r}} &= \frac{1+r_A}{1+\bar{r}} \cdot \frac{1+r}{1+r_S} \cdot \frac{(1+\bar{r})(1+r)}{(1+r_A)(1+r_S)} \end{aligned}$$

(For the geometric ones, write each factor as 1+contribution.)

Risk-adjusted performance attribution
J.D. Fisher and J. D'Alessandro (2018)

The CAPM $R_P = \alpha + \beta R_M = \alpha + R_B + (1 - \beta)R_B$ suggests adding a risk term to Brinson analysis (it is easier to outperform by taking on more risk):

$$R_P - R_B = \alpha + (1 - \beta)R_B.$$

Risk-adjusted performance attribution
D. Spaulding (2016)

Brinson analysis can be adjusted for risk: replace the returns μ with

$$MM = \frac{\sigma_{\text{Benchmark}}}{\sigma_{\text{Portfolio}}} \cdot \mu.$$

Attribution hears a Who!
A. Muralidhar (2016)

Replace MM with

$$M^3 = \sqrt{T} \frac{(\mu_P - \frac{1}{2}\sigma_P^2) - (\mu_B - \frac{1}{2}\sigma_B^2)}{\sqrt{\sigma_P^2 - \sigma_B^2 - 2\sigma_P\sigma_B\rho}}$$

where T is the number of years of data.

***Dynamic segment timing and the predictability
of actively managed mutual fund returns***
J.C. Hsu et al. (2016)

The Hsu-Kalesnik-Myers (HKM) model generalizes the multi-period Brinson model by decomposing the returns into static, dynamic and stock-specific components.

***Performance attribution:
measuring dynamic allocation skill***
J.C. Hsu et al. (2010)

HKM model

***Absolute return equity risk attribution
and forecasting***
R.A. Cooper and T. Li (2012)

Return attribution $\mu = \sum \mu_i$ defines a volatility and information ratio attribution:

$$\begin{aligned} \sigma &= \frac{\sigma^2}{\sigma} = \frac{\text{Var} \sum X_i}{\sigma} = \frac{\sum \text{Cov}(X_i, X)}{\sigma} = \sum \rho_i \sigma_i \\ IR &= \frac{\mu}{\sigma} = \frac{\sum \mu_i}{\sigma} = \sum \frac{\rho_i \sigma_i}{\sigma} \cdot \frac{\mu_i}{\rho_i \sigma_i} = \sum \rho_i \frac{\sigma_i}{\sigma} IR_i \end{aligned}$$

Effective return: a breakthrough in cumulative performance attribution
R. Surz (2010)

For multi-period return attribution:

- Replace the time-changing returns r_{ijt} with constant returns r_{ij} leading to the same cumulated returns;
- weak them ever so slightly so that r_i , \bar{r}_i and \bar{r} have the correct values;
- Then, use 1-period Brinson analysis.

Conditional benchmarks and predictors of mutual fund performance
S. Cederburg (2018)

Managerial skill can be measured from the residuals of a Cahart 4-factor regression. Allow non-constant regression coefficients by estimating them (with the generalized method of moments, GMM) from some covariate, e.g., the 3-month lagged factor loadings (computed from portfolio weights and (constant) constituent factor exposure).

[One could also use a Kalman filter.]

Non-linear factor attribution
S. De Boer (2019)

B : exposures

$$X = Bf + \varepsilon$$

P : factor-mimicking portfolios

$$w = Bp + \eta$$

η : residual weights

$$\omega = \frac{\Omega\eta}{\eta'\Omega\eta}$$

$$C_{ik} = \frac{\omega_{ik}^2}{\sum_{\ell} \omega_{i\ell}^2}$$

$$\Delta = \varepsilon' \text{diag}(\eta)C$$

Characteristics-based factors
Z. Chen et al. (2018)

There is a difference between stock characteristics (e.g., momentum) and stock exposures (e.g., beta to a momentum portfolio): only the former explain returns – using the latter to adjust returns (residuals of a regression against the factor portfolio) is a bad idea.

Arbitrage portfolios
Z. Chen et al. (2018)

Look at double-sorted portfolios, wrt both stock characteristics and beta (for this characteristic).

Smart beta multifactor methodology: mixing vs integrating
T. Chow et al. (2017)

To combine investment factors, one could invest in stocks with a good overall score, or combine single factor portfolios – the former has better performance, but higher turnover and concentration.

Downsampling time series for visual representation
S. Steinarsson (2013)

Split the data into (equal-size) buckets, with the first and last points alone in their bucket.

- Keeping only the median (or the mode) in each bucket tends to remove local extrema.
- The longest line algorithm picks a point in each bucket to maximize the length of the resulting line (dynamic programming).
- The **Douglas-Peucker** algorithm picks the point farthest away from the line from the first to the last point, and iterates until the points are sufficiently close.
- The *Visvalingam-Whyatt* algorithm measures the importance of a point as the area of the triangle it forms with its adjacent points.
- The *largest triangle* algorithm picks the point in each bucket with the largest area with the point selected in the previous bucket and the average point in the next one.

We can use dynamic bucket sizes (to keep outliers):

- Start with equal-sized buckets;
- Fit a linear regression in each bucket (also include one point before and one point after);
- Split the bucket with the largest residuals, and merge the pair with the smallest residuals.

A Bayesian graphical approach for large-scale portfolio management with fewer historical data
S. Oya (2021)

The L^1 penalty in the graphical lasso can be seen as a Laplace prior; the posterior can be sampled with Gibbs sampling (positive definiteness complicates matters).

The Shapley decomposition for portfolio risk
S. Mussard and V. Terraza (2008)

The variance of a portfolio is $w'Vw = \sum w_i\sigma_i^2 + 2\sum_{i<j} w_iw_j\rho_{ij}\sigma_i\sigma_j$; the second term, the “between security risk”, can be decomposed into individual asset contributions with Shapley values.

Portfolio performance attribution via Shapley value
N. Moehle et al. (2021)

Use Shapley values to decompose any performance measure into the contribution of features that can be turned on or off, e.g., inputs (used or not), constraints, terms in the optimization objective, etc.

Variance allocation and Shapley value

R. Colini-Baldeschi et al. (2017)

The Shapley decomposition of a variance game is

$$\text{Var}\left[\sum X_i\right] = \sum_i \text{Cov}\left(X_i, \sum_j X_j\right).$$

The Shapley value decomposition of optimal portfolios

H. Shalit (2017)

Use Shapley values to decompose the risk (volatility) of the mean-variance and the *mean-Gini* portfolio built on a set of assets.

The *Gini mean difference* is

$$\text{GMD}(X) = \frac{1}{2} \mathbb{E}_{X_1, X_2} |X_1 - X_2| = 2 \text{Cov}(X, F_X(X)).$$

Deep learning for portfolio

Z. Zhang et al. (2020)

LSTM on prices, for 4 assets (ETFs on equities, bonds, commodities and VIX), to compute portfolio weights (softmax) maximizing the Sharpe ratio.

Portfolio construction as linearly constrained separable optimization

N. Moehle et al. (2021)

The portfolio optimization problem

$$\begin{array}{ll} \text{Find} & h \\ \text{To minimize} & \alpha'h - \gamma h'Vh - \phi(h) \\ \text{Such that} & \ell \leq \mathbf{1}'h \leq u \\ \text{Where} & V = X\Sigma X' + D \end{array}$$

where ϕ models transaction costs, minimum trade size, tax liability, position limits, minimum holdings size, integer share constraints, can be formulated as a *separable affine problem*

$$\begin{array}{ll} \text{Find} & h, y \in \mathbf{R}^n, c \in \mathbf{R} \\ \text{To maximize} & \alpha'h - \gamma(y'y + h'Dh) \\ \text{Such that} & y = CXh \\ & c + \mathbf{1}'h = 1 \\ & 1 - u \leq c \leq 1 - \ell \\ \text{Where} & \Sigma = CC' \text{ Cholesky} \end{array}$$

i.e., of the form (after introducing slack variables to remove the inequalities)

$$\begin{array}{ll} \text{Find} & x \\ \text{To minimize} & \sum f(x_i) \\ \text{Such that} & Ax = b. \end{array}$$

For a lower bound, solve the convex problem

$$\text{Minimize}_x \sum f_i^{**}(x_i) \text{ such that } Ax = b$$

where f^{**} is the *convex envelope* of f .

The problem

$$\begin{array}{ll} \text{Find} & x, z \in \mathbf{R}^n \\ \text{To minimize} & I_A(z) + \sum f_i(x_i) \\ \text{Such that} & x = z \\ \text{Where} & I_A(z) = \begin{cases} 0 & \text{if } Az = b \\ \infty & \text{otherwise} \end{cases} \end{array}$$

can be solved with ADMM:

$$\begin{array}{l} L(x, z, \lambda) = f(x) + I_A(z) + \frac{1}{2} \|x - z + \lambda\|^2 \\ x \leftarrow \underset{x}{\text{Argmin}} L(x, z, \lambda) \\ z \leftarrow \underset{z}{\text{Argmin}} L(x, z, \lambda) \\ \lambda \leftarrow \lambda + x - z. \end{array}$$

The z update reduces to solving a linear system, and the x updates are univariate $x_i \leftarrow \text{prox}_{f_i}(z_i - \lambda_i)$, with f_i piecewise quadratic. ADMM is guaranteed to converge for convex problems: since it is non-convex, initialize with the relaxed problem.

Scaling may help

$$\begin{array}{ll} \text{Find} & x \\ \text{To minimize} & \sum f_i(x_i) \\ \text{Such that} & Ax = b \end{array} \rightsquigarrow \begin{array}{ll} \text{Find} & \tilde{x} \\ \text{To minimize} & \sum f_i(E_{ii}\tilde{x}_i) \\ \text{Such that} & DAE\tilde{x} = Db \\ \text{Where} & \tilde{x} = E^{-1}x \\ & E \text{ diagonal} \\ & D \text{ invertible} \end{array}$$

Exploring the factor zoo with a machine-learning portfolio

H. Sak et al. (2019)

Train an ensemble of models, for 100 stocks, on a moving window; only use predictors with a significant Fama-French alpha in the training window.

Deep fundamental factor models

M.F. Dixon and N.G. Polson (2020)

Fit a neural network on a moving window, to predict the returns of 3000 assets from 50 factors. Use the gradient and the Hessian (of the output wrt the input) to find the most important factors and interactions.

Deep factor model
K. Nakagawa et al. (2018)

Deep factor models (17 factors to predict the returns of 2000 Topix stocks with a fully-connected neural net) can be interpreted with *layerwise relevance propagation* (LRP) [yes, this ignores the nonlinearity].

$$\begin{aligned} \ell &: \text{layer} \\ i, j &: \text{neurons} \\ x &: \text{activations (before non-linearity)} \\ z &: \text{activations (after)} \\ g &: \text{non-linearity} \\ R_i^\ell &: \text{contribution of neuron } i \\ R^n &: \text{output} \\ R_i^\ell &= \sum_j \frac{z_{ij}}{z_{\bullet j}} R_j^{\ell+1} \\ z_{ij} &= w_{ij}^\ell x_i^\ell \\ x_i^{\ell+1} &= g(z_{i\bullet}) = g\left(\sum s_{ij}^\ell x_i^\ell\right) \end{aligned}$$

To improve numeric stability, replace $z_{ij}/z_{\bullet j}$ with

$$\frac{z_{ij}}{z_{\bullet j} + \varepsilon \text{sign}(z_{\bullet j})} \text{ or } \frac{z_{ij}^+}{z_{\bullet j}^+} - \frac{z_{ij}^-}{z_{\bullet j}^-}$$

**Deep recurrent factor model:
interpretable non-linear
and time-varying multi-factor model**
K. Nakagawa et al. (2019)

Layerwise relevance propagation to interpret LSTM-based factor models (500 stocks, 17 factors); the contributions are comparable to those of a linear model.

**Interpreting deep learning models
with marginal attribution
by conditioning on quantiles**
M. Merz et al. (2021)

The first- and second-order *marginal attribution by conditioning on quantiles* (MACQ) of a model $x \mapsto \mu(x)$ are

$$\begin{aligned} S_j &= \mathbb{E} \left[X_j \frac{\partial \mu(X)}{\partial X_j} \middle| \mu(X) = \mu_\alpha \right] \\ T_{ij} &= \mathbb{E} \left[X_i X_j \frac{\partial^2 \mu(X)}{\partial X_i \partial X_j} \middle| \mu(X) = \mu_\alpha \right] \end{aligned}$$

where μ_α is the α quantile of $\mu(X)$. If the origin 0 is chosen in the middle of the data,

$$\mu_\alpha \approx \mu(0) + \sum_i S_i - \frac{1}{2} \sum_{ij} T_{ij}.$$

Monotone and partially monotone neural nets
H. Daniels and M. Velikova (2010)

Neural networks with just one hidden layer cannot approximate arbitrary monotonic functions, but with two, they can, for instance, with a *min-max network* (but it will not work well in practice).

$$x \mapsto \min_i \max_j \sigma \left(\sum w_{ijk} x_k \right)$$

Certified monotonic neural networks
X. Liu et al. (2020)

Add a penalty

$$\mathbb{E}_{x \sim \text{Unif}} \sum_i \text{Max} \{b, -\partial_{x_i} f(x)\}^2$$

to ensure that the derivatives of f are at least $b \geq 0$.

Proving that a ReLU network is monotonic can be formulated as a mixed integer program. To speed up computations, enforce and test monotonicity for pairs of consecutive layers (instead of the whole network).

One can also look for monotonicity violations around a given observation.

**A biclustering method
for time series data analysis**
J. Lee et al. (2009)

The **plaid model** for biclustering is

$$Z_{ij} = \mu_0 + \sum_k (\mu_k + \alpha_{ik} + \beta_{kj}) \rho_{ik} \kappa_{kj} + \varepsilon_{ij},$$

where ρ, κ are binary variables indicating cluster membership (of cluster k , for row i and column j), and $\mu_k + \alpha_{ik} + \beta_{kj}$ describes cluster k . The *layers* (biclusters) can be extracted one by one, by alternately estimating and (ρ, κ) .

For time series, ensure that the clusters in the time dimension are convex by filling in gaps of size at most C , and only keeping the largest convex component (there is also a pruning step, limited to the interval extremities in the time dimension).

**Improved biclustering
of microarray data demonstrated through
systematic performance tests**
H. Turner et al. (2005)

The original plaid algorithm used alternating least squares (3 steps: ρ , κ and $\mu + \alpha + \beta$); instead, use *binary least squares*

$$\rho = \text{Argmin}_{\rho \in \{0,1\}^n} \sum_{ij} (z_{ij} - \rho_i x_j)^2$$

(the objective is separable).

Plaid models for gene expression data
L. Lazzeroni and A. Owen (2002)

(First paper on the plaid model.)

Biclustering of expression data
Y. Cheng and G.M. Church (2000)

To find a δ -bicluster, *i.e.*, a short subset of rows I and columns J such that the *mean square residue*

$$H(I, J) = \text{Mean}_{i \in I} (a_{ij} - a_{iJ} - a_{IJ} + a_{IJ})^2$$

be below δ , one could start with the full matrix and greedily remove the row or column reducing $H(I, J)$ the most, until we reach δ (or no row or column reduces H). Instead,

- Remove the rows (resp. columns) with

$$d(i) = \text{Mean}_{j \in J} (a_{ij} - a_{iJ} - a_{IJ} + a_{IJ})^2 > \alpha H(I, J);$$

- Remove the rows (columns) with the largest $d(i)$;
- Add back rows (columns) with $d(i) \geq H(I, J)$.

(Also look at the row variance

$$V(I, J) = \text{Mean}_{j \in J} (a_{ij} - a_{IJ})^2$$

to reject trivial clusters.)

The Gibbs-plaid biclustering model
T. Chekouo et al. (2015)

Plaid model with a prior on the gene labels ρ_{ik} and the condition labels κ_{jk} , from similarities from the gene ontology (GO) annotations and proximity in time respectively.

Extracting conserved gene expression motifs from gene expression data
T.M. Murali and S. Kasif (2003)

A conserved motif (*xMotif*) is a pair (I, J) of genes and samples such that $\forall i \in I \quad \forall j \in J \quad a_i \leq x_j b_i$. To find them:

- Pick k samples at random (seed);
- Find the genes on which they agree;
- Find the samples on which those genes agree;
- Discard if unsatisfactory;
- Start again.

Spectral biclustering of microarray data: coclustering genes and conditions
Y. Kuger et al. (2003)

SVD to uncover checkerboard patterns.

QuBic: a qualitative biclustering algorithm for gene expression data
G. Lie et al. (2009)

The QuBic qualitative clustering algorithm

- Starts with a graph, with genes as vertices, and gene similarity as edge weights;
- Picks the heaviest edge;
- Builds a cluster around it, progressively adding genes, such that the proportion of samples with the same gene expression (terciles) remains above 95%.

A systematic comparison and evaluation of clustering methods for gene expression data
A. Prelić et al. (2006)

The *bimax* algorithm, for binary data:

- Picks a row as a template, and divides the columns into two groups: 1s in the template, and 0s in the template;
- Divides the rows into three groups:
 - With 0s where there are 0s in the template;
 - With 0s where there are 1s in the template;
 - The rest;
- Proceeds recursively (the two blocks of zeroes can be ignored).

A linear time biclustering algorithm for time series gene expression data
S.C. Madeira and A.L. Oliveira (2005)

Discretize the data and look for biclusters with the same value in each column (date), from the *suffix tree* (Ukkonen) of the rows.

D1 U2 D3 U4 D5
N1 N2 N3 U4 N5
U1 U2 D3 U4 U5

```

Biclustering gene expression using factor graphs and the max-sum algorithm
M. Denitto et al. (2015)

The biclustering problem can be solved iteratively, by looking for the largest bicluster, replacing with with noise, and iterating. The problem of finding the largest bicluster can be modeled with a *factor graph* and binary variables x_{ij} for cluster membership:

- $a_{ij}x_{ij}$ to promote high-value clusters (high gene expression);
- $d(a_{ij}, a_{kl})x_{ij}x_{kl}$ to promote coherent clusters;
- A factor for each pair of rows i, k (resp. columns), zero if either is zero or if they have the same (column) pattern

$$I \left\{ \sum_j x_{ij} = 0 \text{ or } \sum_\ell x_{k\ell} = 0 \text{ or } \sum_j (x_{ij} - x_{kj})^2 = 0 \right\}$$

to get submatrices

(Prior approaches used exemplars and had a quartic number of factors.) The problem can be efficiently solved with the MaxSum message passing algorithm (the messages can be computed explicitly).

A biclustering approach based on factor graphs and the max-sum algorithm
M. Denitto et al. (2017)

More detailed version of the same paper.

**Biclustering of time series data
using factor graphs**
M. Denitto et al. (2017)

**HOP-MAP: efficient message passing
with high-order potentials**
D. Tarlow et al. (2010)

In a factor graph (with binary variables), with high-order potentials such as

- Cardinality: $\theta(h_1, \dots, h_N) = f(h_1 + \dots + h_N)$,
- Convexity: $\theta(h_1, \dots, h_N) = \mathbf{1}_{\{i : h_i=1\} \text{ convex}}$,
- Ordering: $\theta(h_x, h_y) = 1$ if exactly one coordinate, i , of h_x is 1, exactly one coordinate, j , of h_y , is 1, and $i < j$,

the messages can be computed efficiently with dynamic programming.

**Factor graphs, message passing,
loopy belief propagation**

A **factor graph** is a factorization of an (unnormalized) probability distribution as $p(x) \propto \prod_f \phi_f(x_f)$, where each ϕ_f only depends on a subset x_f of the variables x_1, \dots, x_N . It can be represented as a bipartite graph, with nodes for variables x_i and factors ϕ_f , and edges whenever a variable is used in a factor.

$$p(x_1, x_2, x_3, x_4) \propto \phi(x_1, x_2, x_3) \phi(x_3, x_4)$$

In the case of trees, the probability can be maximized by *message passing*, i.e., exchanging messages between nodes (each message to/from a variable is a function of its possible values – for a discrete variable with k values, it is a dimension- k vector).

$$\mu_{x \rightarrow f}(x) = 0$$

$$\mu_{f \rightarrow x}(x) = \log f(x)$$

$$\mu_{f \rightarrow x}(x) = \max_{x_1, \dots, x_M} \log f(x, x_1, \dots, x_M) + \sum_m \mu_{x_m \rightarrow f}(x_m)$$

$$\mu_{x \rightarrow f}(x) = \sum_{\ell \in \mathcal{N}(x)} \mu_{f_\ell \rightarrow x}(x).$$

Empirically, the **max-sum** algorithm still gives good results for non-trees (loopy belief propagation).

**Simultaneous supervised clustering
and feature selection over a graph**
X. Shen et al. (2012)

The *fused lasso*, a penalty on $\sum |\beta_{i+1} - \beta_i|$, clusters the predictors of a linear regression when there is an ordering on them. This ordering can be represented by a graph $\bullet \cdots \bullet$: the fused lasso can be generalized to an arbitrary (e.g., complete) graph. The L^1 norm in the penalties $\sum |\beta_i|$ (for irrelevant predictors) and

$\sum |\beta_i - \beta_j|$ can be replaced with $\text{Min}\{|\beta|, 1\}$: the objective is no longer convex, but a difference of convex functions, amenable to *difference convex programming* (or minimization-majorization, MM).

$$\frac{\text{Min}\{|\beta|, 1\}}{|\beta|} = \frac{1}{|\beta|} - \frac{1}{(|\beta|-1)_+}$$

Derivative analytics with Python
Y. Hilpisch (2015)

2. An option-pricing framework should account for different sources of risk: level, volatility, jump, and interest rate.

Perfect hedging is only possible with continuous rebalancing and in complete markets – in particular, without jumps.

3. For options, market stylized facts include:

- Returns have fat tails, prices present jumps;
- Volatility is stochastic, tends to cluster, mean-reverts, is negatively correlated with returns (leverage);
- Implied volatility has a smile, which is flatter for longer-term options (term structure);
- Interest rates are stochastic, mean-reverting, and often positive.

A market model should include stochastic volatility, jumps and stochastic short rates.

4. There is no arbitrage (in continuous time, “no free lunch with vanishing risk”) iff there is an equivalent martingale measure Q . It is unique iff the market is complete.

6a. If the risk-neutral density (RND) q is known, the price of a European option with payoff C_T can be computed as

$$C_0 = e^{-rT} \int_0^\infty C_T(s) q(s) ds.$$

The characteristic function (Fourier transform) $\hat{q}(u) = \mathbb{E}_{X \sim q}[e^{iuX}]$ is often known: the option price can be computed using Parseval’s identity (I ignore signs, normalization factors, discounting factor),

$$C_0 = \langle C_T, q \rangle = \langle \hat{C}_T, \hat{q} \rangle,$$

leading to the **Lewis formula**

$$C_0 = S_0 - \frac{\sqrt{S_0 K} e^{-rT/2}}{\pi} \int_0^\infty \text{Re}[e^{-izk} \phi(-z-i/2)] \frac{dz}{z^2 + \frac{1}{4}}.$$

6b. The **Carr-Madan formulas** compute \hat{C}_0 (where C_0 is a function of $k = \log K$) using Fubini’s theorem (simple closed-form formula); the option price can then be computed with the (inverse) fast-Fourier transform (FFT).

7. For American options, the option value V and its continuation value C can be computed as (primal ap-

proach)

$$\begin{aligned} V_t &= \sup_{\tau} E_0^Q [B_0(\tau) h_{\tau}(S_{\tau})] \\ C_t &= E_t^Q [e^{-r\Delta t} V_{t+\Delta t}(S_{t+\Delta t}) | S_t = s] \\ V_t(s) &= \text{Max}\{h_t(s), C_t(s)\}. \end{aligned}$$

This is a lower bound on the option value. The dual approach gives an upper bound.

$$\begin{aligned} V_0 &= \sum_{\tau} E_0^Q [B_0(\tau) h_{\tau}(S_{\tau})] \\ &= E_0^Q \text{Max}_t B_0(t) (h_t(S_t) - Q_t) \\ Q_t &= \sum_{u \leq t} (V_u(S_u) - E_{u-\Delta t}^0 V_u(S_u)). \end{aligned}$$

Both rely on least squares Monte Carlo (LSM, Longstaff-Schwartz).

8. The following models extend the Black-Scholes model (BSM73):

- Merton (M76): jumps;
- Heston (H93): stochastic volatility;
- Bates (B96): jumps and stochastic volatility;
- BCC97: jumps, stochastic volatility and stochastic rates.

$$\begin{aligned} \frac{dS}{S} &= (r - r_J)dt + v_t dZ_1 + JdN \\ dv &= \kappa(\theta - v)dt + \sigma\sqrt{v}dZ_2 \\ dr &= \kappa(\theta - r)dt + \sigma\sqrt{r}dZ_3 \quad (\text{CIR}) \end{aligned}$$

For a single CIR process, one can explicitly compute $B_0(T)$.

The characteristic function of the BCC97 model is the product of those of H93 and M76J (the stochastic rate only intervenes through $B_0(T)$).

Option valuation can be done by solving a PDE (the formula is similar to the Black-Scholes one, but involves an integral), Fourier transform (Lewis or Carr-Madan) or (for arbitrary options) Monte Carlo simulations (replace the drift with r , carefully discretize the SDE, simulate, and compute the average discounted payoff).

10. For Monte Carlo simulations, the price can be discretized with the Euler or log-Euler scheme. For the volatility, naive discretization is not exact: it can be discretized exactly, but this involves a non-central χ^2 distribution, which is slow; instead, one can truncate (or reflect – there are many variants) the naive discretization; this also easily accounts for the correlation between the volatility and price innovations.

Use all the Monte Carlo variance reduction tricks you can think of: antithetic variables, moment matching, control variates (European option prices, which can be computed exactly, when pricing Americal options).

11. The Black-Scholes model is complete; the Heston model (stochastic volatility) is not, but any option can be replicated with the underlying and one option.

The Bates model (with jumps) is not complete: one would need an infinite number of options to replicate any payoff. Consequently, the martingale measure Q is not unique: several prices are compatible with the absence of arbitrage. However, market prices correspond to one of those measures: *calibration* estimates it.

Calibrate the model parameters to liquid vanilla options (e.g., EURO STOXX 50, 3 maturities less than 1 year, 5 strikes, Eonia and Euribor up to 1 year), using, as loss function, the MSE of prices (for pricing), relative prices, or implied volatilities (for hedging), perhaps with some weights (e.g., vega-weighted implied volatility).

The CIR model can be calibrated from the forward rates; the forward rates can be computed from the yields

$$Y_T = -\frac{\log B_0(T)}{T} \quad f_T = Y_T + \frac{\partial Y_T}{\partial T} T.$$

Optimize in several steps: r , σ , J , and finally $\sigma + J$. There may be multiple local optimal: add an L^2 penalty to stay close to the previous-day solution.

13. Delta hedging is only exact if it is continuous, if the underlying is the only source of risk, if the price paths are continuous, and if volatility is constant.

Jump risk cannot be hedged away but, if there are options on many underlyers, it can be diversified away.

For a single option, delta hedging is insufficient: try to add options to the replicating portfolio.

Estimation of risk-neutral densities using positive convolution approximation **O. Bondarenko (2003)**

The risk-neutral density (RND) f satisfies

$$\text{Option price} = \int_0^{+\infty} \text{Payoff}(F) f(F) dF$$

and can be estimated from puts and calls

$$f(F) = \frac{\partial^2 P(k)}{\partial K^2} \Big|_{K=F} = \frac{\partial^2 C(k)}{\partial K^2} \Big|_{K=F}.$$

Intuitively, $f(x)dx$ is the price of an option paying \$1 if the spot S_T is in $[x, x + dx]$ and zero otherwise.

The *positive convolution approximation* (PCA) looks for a density of the form $f = \phi_h * u$, where ϕ_h is a fixed kernel (its shape is not that important, but its bandwidth is) and u an arbitrary density, to recover the put prices.

$$\begin{aligned} \text{Find} & \quad u \\ \text{To minimize} & \quad \sum [P_i - D^2 f(K_i)]^2 \\ \text{Such that} & \quad u \geq 0, \quad \int u = 1 \\ \text{Where} & \quad f = \phi_h * u \\ & \quad D^{-2} f(x) = \int_{-\infty}^x \int_{-\infty}^y f(z) dz dy \end{aligned}$$

After discretization, $f(x) = \sum a_j \phi(x - z_j)$, $\Delta z = 0.5h$, this becomes a quadratic optimization problem.

***A simple and reliable way to compute
option-based risk neutral distributions***
A.M. Malz (2014)

To estimate the risk-neutral density (RND) from the Breeden-Litzenberger formula

$$f(F) = \frac{\partial^2 P(k)}{\partial K^2} \Big|_{K=F} = \frac{\partial^2 C(k)}{\partial K^2} \Big|_{K=F}$$

fit the implied volatilities with a clamped cubic splines (set the first derivative to zero at the boundaries) and differentiate the Black-Scholes call prices. Check for no-arbitrage violations: the call price should be decreasing and convex.

***Exploring return dynamics
via corridor-implied volatility***
T.G. Andersen et al. (2015)

If there are no jumps, the realized variance is

$$E_0^Q[RV] = 2 \int_0^\infty \frac{M(K)}{K^2} dK$$

where $M(K) = \min\{P(K), C(K)\}$ and the realized variance is computed from the squared ratio- or log-returns (in the absence of jumps, they give the same result). With jumps, the result remains if we replace the squared returns with the difference

$$2(\text{ratio-returns} - \text{log-returns})$$

(which is approximately 2/3 of the squared ratio-returns and 1/3 of the log-returns).

The CBOE VIX estimates the *market-free implied volatility* (MFIV)

$$\text{MFIV} = \frac{2e^{rT}}{T} \left[\int_0^F \frac{P(K)}{K^2} dK + \int_F^\infty \frac{C(K)}{K^2} dK \right]$$

and is computed as

$$\begin{aligned} \sigma^2 &= \frac{2e^{rT}}{T} \sum \frac{\Delta K_i}{K_i^2} M(K_i) - \frac{1}{T} \left(\frac{F}{K_f} - 1 \right)^2 \\ \Delta K_i &= \frac{1}{2}(K_{i+1} - K_{i-1}) \\ \Delta K_1 &= K_2 - K_1 \\ \Delta K_N &= K_N - K_{N-1} \\ K_f &= \text{first strike below } F \end{aligned}$$

where only liquid strikes are used – but the corridor of strikes used, $[K_1, K_N]$, can change and create spurious jumps.

The *corridor implied volatility* uses the same formula for a more stable corridor, defined from the [3%, 97%] quantile range of the distribution defined by the cdf

$$R(K) = \frac{P(K)}{P(K) + C(K)}.$$

***Construction and interpretation
of model-free implied volatility***
T.G. Andersen and O. Bondarenko (2007)

Earlier paper on the corridor implied volatility (CIV), where the corridor is defined from the PCA (positive convolution approximation) risk-neutral density estimator.

There is a negative variance risk premium in the VIX.

***Model-free implied volatility
and its information content***
G.J. Jiang and Y.S. Tian (2003)

Derivation of the MFIV estimator from the Britten-Jones-Neuberger formula

$$E_0^Q \left[\int_{T_1}^{T_2} \left(\frac{dS_t}{S_t} \right)^2 \right] = 2 \int_0^\infty \frac{C(T_2, K) - C(T_1, K)}{K^2} dK$$

by adding a risk-free rate, setting $T_1 = 0$ so that the second term is a call payoff, either zero, or leading to a put price via the put-call parity.

***Option prices, implied price processes
and stochastic volatility***
M. Britten-Jones and A. Neuberger (2000)

(The formula is derived as the limit of a discrete model.)

Towards a theory of volatility trading
P. Carr and D. Madan (2002)

The model-free implied volatility (MFIV) can be computed as follows.

$$\begin{aligned} f(y) &= f(x) + f'(x)[(y-x)_+ + (x-y)_+] \\ &\quad + \int_0^x f''(t)(t-y)_+ dt + \int_x^\infty f''(t)(y-t)_+ dt \\ E_0^Q[f(F)] &= f(K)B_0 + f'(K)[C(K) - P(K)] \\ &\quad + \int_0^K f''(k)P(k)dk + \int_K^\infty f''(k)C(k)dk \end{aligned}$$

Letting $f(F) = \log(F_T/F_0)$ and $K = F_0$,

$$\begin{aligned} E_0^Q \left[\log \frac{F_T}{F_0} \right] &= - \int_0^{F_0} \frac{P(k)}{k^2} dk - \int_{F_0}^\infty \frac{C(k)}{k^2} dk \\ E_0^Q \left[\log \frac{F_T}{F_0} \right] &\stackrel{\text{It\^o}}{=} -\frac{1}{2} E_0^Q \int_0^T \sigma_t^2 dt. \end{aligned}$$

***Prices of state contingent claims
implicit in option prices***
D. Breeden and R. Litzenberger (1978)

Notice that

$$\frac{d}{dx} \int_x^\infty f(x, y) dy = \int_x^\infty \frac{\partial f(x, y)}{\partial x} dy - f(x, x)$$

and apply it to the price of a call option

$$C(K) = \int_0^\infty (S - K)_+ f(S) dS = \int_K^\infty (S - K) f(S) dS;$$

this gives

$$\frac{dC(K)}{dK} = \int_K^\infty -f(S) dS = 0$$

and finally

$$\frac{d^2 C(K)}{dK^2} = f(K).$$

***Is implied correlation worth calculating?
Evidence from foreign exchange options
and historical data***
C. Walter and J.A. Lopez (2000)

The correlation between (the log-returns of) two currency pairs A/C and B/C satisfies

$$\rho_{A,B/C} = \frac{\sigma_{A/C}^2 + \sigma_{B/C}^2 - \sigma_{A/B}^2}{2\sigma_{A/C}\sigma_{B/C}}.$$

Computing it from implied volatilities has sometimes (not always) some predictive power on future correlation.

***Implied correlation
for pricing multi-FX options***
P.V. Shechvhenko (2004)

For unrelated currency pairs, A/B and C/D,

$$\rho_{A/B,C/D} = \frac{\sigma_{C/B}^2 + \sigma_{A/D}^2 - \sigma_{D/B}^2 - \sigma_{C/A}^2}{2\sigma_{A/B}^2\sigma_{C/D}^2}.$$

***Implied correlation:
a new measure of diversification***
V.D. Skintzi and A.P.N. Refenes (2005)

The implied correlation is defined from the implied volatilities of an index and its components as

$$\rho = \frac{\sigma^2 - \sum_{i \neq j} w_i^2 \sigma_i^2}{\sum_{i \neq j} w_i w_j \sigma_i \sigma_j}.$$

***Measuring equity risk
with option implied correlations***
A. Buss and G. Vilkov (2012)

Adjust the historical correlations

$$\rho_{ij} = (1 - \lambda)\hat{\rho}_{ij} + \lambda$$

such that $\sigma^2 = \sum w_i w_j \sigma_i \sigma_j \hat{\rho}_{ij}$.

$$\lambda = \frac{\sigma^2 - \sum w_i w_j \sigma_i \sigma_j \hat{\rho}_{ij}}{\sum w_i w_j \sigma_i \sigma_j (1 - \hat{\rho}_{ij})}.$$

We can then define option implied betas

$$\beta_i = \frac{\sigma_i \sum w_j \sigma_j \rho_{ij}}{\sigma^2}.$$

***Estimating realistic implied
correlation matrix from option prices***
K.N. Numpacharoen (2013)

If $\sigma^2 > \hat{\sigma}^2$, replace $\rho_{ij} = (1 - \lambda)\hat{\rho}_{ij} + \lambda$ with

$$\rho_{ij} = (1 - \lambda)\hat{\rho}_{ij} - \frac{\lambda}{n - 1}.$$

Machine learning fund characterizations
D. Mehta et al. (2020)

Approaches to cluster funds (with k -means, hclust, fuzzy-C-means, SOM) often uses performance and risk measures as features (performance ratios, betas). Some use the bipartite graph of the top 10 holdings, projected, with spectral clustering.

Use aggregate data (proportion of assets in a given asset class, country, sector, capitalization bin, etc.) with a decision tree, random forest, or a neural net (FC, 3 layers, 512/256/128/ReLU, softmax) to reproduce the Morningstar classification (not clustering, but classification).

***Sequential deep learning for credit risk
monitoring with tabular financial data***
J.M. Clements et al. (2020)

Gradient boosted trees, commonly used to assess credit risk (from credit card data) do not leverage the time dimension of the data (without clever feature engineering): try temporal convolutions (TCN). Other baselines include MLP, TabNet (attention for tabular data) and LSTMs.

Winsorize using the boosted tree cutoffs.

***Covid-19 spreading in financial networks:
a semiparametric matrix regression model***
M. Billio et al. (2021)

Model the time-varying adjacency matrix of the financial network as

$$A_t = \sum_r B_r f_{rt} + E_t$$

$$E_t \sim \text{MN}(0, I, \Sigma)$$

$$\Sigma \text{ diagonal}$$

$$A_t, B_r, E_t \text{ matrices}$$

$$f_{it} \text{ scalars (risk factors)}$$

where the *matrix normal distribution* is

$$X \sim \text{MN}(M, U, V)$$

$$M: \text{ mean}$$

$$U: \text{ variance among rows}$$

$$V: \text{ variance among columns}$$

$$\text{vec } X \sim N(\text{vec } M, V \otimes U).$$

Use both stock returns and volatility, and separately model $A_{\text{ret,ret}}, A_{\text{ret,vol}}, A_{\text{vol,ret}}, A_{\text{vol,vol}}$.

Application: Bayesian inference, 500 European firms, pairwise Granger causality

Deep portfolio optimization via distributional prediction and residual factors
K. Imajo et al. (2020)

Do not forecast returns, but idiosyncratic returns – residuals, ε , of a factor model.

Forecast the return distribution using quantile regression: a neural network forecasting the quantiles of $\varepsilon_{i,t} | \varepsilon_{i,<t}$ (assume $\Sigma = \text{Var } \varepsilon$ is diagonal).

Account for inductive biases:

- Amplitude invariance (volatility clustering): $(x_t)_t$ and $(\lambda x_t)_t$ are equally likely, using homogeneous function $x \mapsto \|x\| \phi(x/\|x\|)$;
- Time-scale invariance: $(x_t)_t$ and $(x_{\lambda t})_t$ are equally likely, using shared weights at different scales.

Maximize the Sharpe ratio of the optimal portfolio $w = \lambda^{-1} \Sigma^{-1} \mu$.

Algorithms for learning graphs in financial markets
J.V.M. Cardoso et al. (2020)

The graphical lasso models financial returns as

$$\underset{\Sigma^{-1} \succcurlyeq 0}{\text{Minimize}} \text{tr}(\Sigma^{-1} S) - \log \det^*(\Sigma^{-1}) + \alpha \|\Sigma^{-1}\|_1.$$

Add a few constraints:

- The precision matrix Σ^{-1} is a graph Laplacian, $\Sigma^{-1} = \mathcal{L}W = \text{diag}(W\mathbf{1}) - W$;
- The graph has k connected components, i.e., $\text{rank } \Sigma^{-1} = p - k$;
- To avoid isolated nodes, each node has degree d , $\text{diag } W = d\mathbf{1}$.

The problem can be solved by alternatingly estimating Σ^{-1} and W (with ADMM).

$$\begin{array}{ll} \text{Find} & W \geq 0, \Theta \geq 0 \\ \text{To minimize} & \text{trace}(S\mathcal{L}W) - \log \det^* \Theta \\ \text{Such that} & \Theta = \mathcal{L}W \\ & \text{rank } \Theta = p - k \\ & \text{rank } \mathcal{L}W = p - k \\ & \text{diag } W = d\mathbf{1} \end{array}$$

The rank constraint can be enforced with $\sum_{i=1}^k \lambda_i = 0$, using

$$\sum_{i=1}^k \lambda_i(A) = \underset{\substack{V \in \mathbf{R}^{p \times k} \\ V'V = I}}{\text{Min}} \text{tr}(V'AV)$$

For robustness to outliers, replace the Gaussian distribution with a Student (the problem is no longer convex, but still amenable to MM).

ADMM solves

$$\begin{array}{ll} \text{Find} & x, z \\ \text{To minimize} & f(x) + g(z) \\ \text{Such that} & Ax + Bz = c \end{array}$$

by iterating

$$\begin{array}{l} x \leftarrow \text{Argmin } L(x, z, y) \\ z \leftarrow \text{Argmin } L(x, z, y) \\ y \leftarrow y + \lambda(Ax + Bz - c) \end{array}$$

where $L(x, z, y)$ is

$$f(x) + g(z) + y'(Ax + Bz - c) + \frac{1}{2} \|Ax + Bz - c\|^2.$$

R implementation in `fingraph`.

Learning high-dimensional Gaussian graphical models under total positivity without adjustment of tuning parameters
Y. Wang et al. (2020)

A Gaussian distribution is multivariate totally positive of order 2 (MTP₂, attractive Gaussian random field) if all partial correlations are positive.

A density f on \mathbf{R}^p is MTP₂ if

$$\forall x, y \in \mathbf{R}^p \quad f(x)f(y) \leq f(x \wedge y)f(x \vee y)$$

(where \wedge and \vee denote the elementwise min and max).

The CMIT algorithm estimates a sparse graphical model, starting with a complete graph, and removing edge $i-j$ if $|\rho_{ij|S}| \leq \lambda$ for some $S \subset [1, p]$, $|S| \leq \eta$ (max degree).

It can be modified for MTP₂ models: remove edge $i-j$ if $\hat{\rho}_{ij|S \cup \{k\}} < 0$ for some $S \subset \mathcal{N}(i) \setminus \{j\}$, $|S| \leq \ell$, and some $k \notin S \cup \{i, j\}$; progressively increase ℓ ; only estimate $\hat{\rho}$ on a minibatch.

cgam: an R package for the constrained generalized additive model
C. Liao and M.C. Meyer

Monotonicity and convexity constraints for GAMs; allows qualitative (ordered) variables.

Disparity of clustering coefficients in the Holme-Kim network model
R.I. Oliveira (2016)

The **Holme-Kim** random graph model extends the Barabasi-Albert one with a triad formation step (with some fixed probability) after each preferential attachment.

The *local clustering coefficient* of a node is the proportion of neighbours that are connected. The local clustering coefficient of a graph is the average of the local clustering coefficients of its nodes.

The *global clustering coefficient* of a graph is the proportion of paths of length 2  that can be completed in a triangle . Those coefficients are different: .

The local clustering coefficient of the Holme-Kim random graph remains bounded away from zero, but the global one slowly ($1/\log n$) tends to zero.

The atlas for the aspiring network scientist
M. Coscia (2020)

760-page illustrated book

fastnet: an R package for fast simulation and analysis of large scale social networks
X. Dong et al. (2020)

The H-index of a network and its relation to degree and coreness
L. Lü et al. (2015)

The core decomposition of a graph is obtained by removing all nodes of degree 1 (repeat until there are none left – new ones may be created), then all nodes of degree at most 2, and so on – the *coreness* of a node is the step at which it was removed. The H-index of a node is the largest h such that there are at least h neighbours with degree at least h . Iterating the H-index operator, starting with the degree, converges to the coreness; the updates can be asynchronous.

Characterization of complex networks: a survey of measurements
L.F. Costa et al. (2006)

List of graph metrics

Graph evolution: densification and shrinking diameters
J. Leskovec et al. (2007)

Real-world graphs grow with time and exhibit:

- densification: $(\#edges) \propto (\#nodes)^a$, $a > 1$;
- shrinking: the effective diameter (90% quantile of the distance distribution) decreases.

The *community-guided attachment model* builds a graph on the leaves of a complete b -ary tree of depth t (representing nested communities), by adding an edge i – j with probability proportional to $c^{d(i,j)}$, where the distance is measured on the tree; for a dynamic model, one can use all the nodes instead of just the leaves. It exhibits densification, but not shrinking.

The *forest fire model* adds nodes one by one, linking them to a random existing node, then to a random subset of its neighbours, then to a random subset of these neighbours' neighbours, and so on (citation networks arise like that). For a narrow range of parameters, it exhibits a heavy tail degree distribution, densification, shrinking, communities.

ANF: a fast and scalable tool for data mining in massive graphs
C.R. Palmer et al. (2002)

To approximately compute the size of neighbourhoods,

$$\mathcal{N}(x, h) = \{y \in V : d(x, y) \leq h\}$$

iterate (for all x , and increasing h)

$$\mathcal{N}(x, h) = \bigcup_{x-y} \mathcal{N}(y, h-1)$$

using HyperLogLog structure (to count distinct elements). Use approximate neighbours to speed computations further.

New methods for generating synthetic equivalents of real social networks
D. Xu et al. (2018)

Generate a random network with overlapping communities by assigning each node to a random number of random communities and connecting all the nodes in each community. Prune and/or rewire if desired.

Polychrome: creating and assessing qualitative palettes with many colours
K.R. Coombes et al. (2019)

If you need large palettes (up to 36 colours).

vsgoftest: and R package for goodness of fit testing based on KL divergence
J. Lequesne and P. Regnault (2020)

The Vasicek normality test relies on the Gaussian distribution maximizing entropy (for a fixed variance). The Vasicek-Song gof test generalizes it to arbitrary (continuous) distributions, by using the KL divergence between the sample and the null distributions.

Flexible regression models for count data based on renewal processes: the Countr package
T. Kharat et al. (2019)

Count data is often modeled as a Poisson distribution (or, sometimes, Geometric or Binomial), but this imposes $EY = \text{Var} Y$, has no memory, and constant hazard function. Instead, consider renewal processes with other inter-event distributions (Weibull, Gamma, Burr).

```
r <- renewalCount(y~1, d, "weibull")
```

Evaluating probabilistic forecasts with scoring rules
A. Jordan et al. (2019)

Scoring rules compare probabilistic forecasts: let F be the forecast (a probability distribution, parametric or given by samples), y the outcome, and $S(F, y)$ the score (lower is better).

A proper scoring rule satisfies

$$\forall F, G \quad \mathbb{E}_{Y \sim G} S(G, Y) \leq \mathbb{E}_{Y \sim G} S(F, Y),$$

with equality iff $F = G$. Examples include the logarithmic score and the *continuous ranked probability score* (CRPS)

$$\begin{aligned}\text{LogS}(F, y) &= -\log f(y) \\ \text{CRPS}(F, y) &= \int [F(z) - \mathbf{1}_{y \leq z}]^2 dz \\ &= \mathbb{E}_{X \sim F} |X - y| - \mathbb{E}_{X_1, X_2 \sim F} |X_1 - X_2|.\end{aligned}$$

If the forecast is provided as a sample, the CRPS can be efficiently computed from the order statistics.

Bayesian and non-Bayesian cause-specific competing risk analysis for parametric and non-parametric survival functions: the R package CFC
A.S. Mahani and M.T.A. Sharabiani

Cause-specific competing risk survival analysis is survival analysis with multiple, mutually-exclusive endpoints: $\hat{F}_k(t) = [1 - \sum F_\ell(t)] \lambda_k(t)$. By letting $E(t) = 1 - \sum F_k(t)$, we get $\dot{E}/E = -\sum \lambda_k$ and

$$\begin{aligned}E &= \prod S_k \\ S_k(t) &= \exp - \int_0^t \lambda_k(s) ds \\ F_k(t) &= \int_0^t \prod S_\ell(s) \lambda_k(s) ds.\end{aligned}$$

Randomized matrix decompositions using R
N.B. Erichson et al. (2019)

The `rsvd` package provides randomized (for big data) SVD, PCA, robust PCA, CUR, interpolative decomposition. Also check `irlba`, `RSpectra`, `svd::propack.svd`, `svd`.

ManifoldOptim: an R interface to the ROPTLIB library for Riemannian manifold optimization
S.R. Martin et al. (2020)

The *minimum average deviance estimation* (MADE) method for sufficient dimension reduction (SDR) looks for B such that the local regression (with weights from a kernel in the original space, and bandwidth from cross-validation) $y \sim B'X$ gives the best fit: it is an optimization on the Grassmanian.

In a linear model $Y = \mu + \beta X + \varepsilon$, $X \in \mathbf{R}^p$, $Y \in \mathbf{R}^r$, $\varepsilon \sim N(0, \Sigma)$, not all of Y contains relevant information: the Σ -envelope of $\text{Span } \beta$ is the smallest subspace $S \supset \text{Span } \beta$ such that $\Sigma = \Sigma_S + \Sigma_{S^\perp}$. Finding such a subspace can be formulated as an optimization problem on the Grassmanian.

Also check `Pymanopt` (Python), `GrassmanOptim` (R), `ROPTLIB` (C++, in Julia, or R: `ManifoldOptim`, `ldr` (likelihood based dimension reduction)).

An introduction to the augmented inverse propensity weighted estimator
A.N. Glynn and K.M. Quinn (2009)

The average treatment effect (ATE) is $\mathbb{E}[Y(1) - Y(0)]$. There are many more acronyms: ATT, ATC (average treatment effect on treated/control), SATC, PATE (sample/population ATE), CATE (conditional ATE – for a subgroup).

- *Propensity matching* is not data-efficient;
- The *regression estimator* fits a model $Y \sim T + Z$,

$$\widehat{\text{ATE}} = \text{Mean}_i [\hat{Y}(T = 1, Z = z_i) - \hat{Y}(T = 0, Z = z_i)]$$

- The *inverse propensity weighting* (IPW) estimator models the probability of treatment $\pi(z)$,

$$\widehat{\text{ATE}} = \text{Mean}_i \left[\frac{T_i}{\pi(Z_i)} Y_i - \frac{1 - T_i}{1 - \pi(Z_i)} Y_i \right]$$

It has poor small-sample properties (π can be close to zero) and can even be outside the possible range for $Y(1) - Y(0)$.

- IPW* normalizes the weights to ensure they sum to 1.

$$\begin{aligned}\widehat{\text{ATE}} &= \left(\sum \frac{T_i}{\pi(Z_i)} \right)^{-1} \sum \frac{T_i}{\pi(Z_i)} Y_i \\ &\quad - \left(\sum \frac{1 - T_i}{1 - \pi(Z_i)} \right)^{-1} \sum \frac{1 - T_i}{1 - \pi(Z_i)} Y_i\end{aligned}$$

- The covariate Z contains information, not only about T , but also about the outcome Y . The *augmented IPW* (AIPW) adjusts the ATE accordingly. It is *doubly robust*: it is consistent if either π or \hat{Y} is well specified. R implementation in `CausalGAM`.

Debiased inverse propensity score weighting for estimation of average treatment effects with high dimensional confounders
Y. Wang and R.D. Shah (2020)

The oracle estimator

$$\text{ATE} = \text{Mean}_i \frac{T_i}{\pi(Z_i)} Y_i - \text{Mean}_i \frac{1 - T_i}{1 - \pi(Z_i)} Y_i$$

is unbiased, but there is a bias of the propensity score is estimated from data.

If $\mu \perp\!\!\!\perp T|Z$,

$$\text{ATE} = \text{Mean}_i \frac{T_i}{\pi(Z_i)} (Y_i \mu_i) - \text{Mean}_i \frac{1 - T_i}{1 - \pi(Z_i)} (Y_i - \mu_i)$$

has the same properties, and we can choose μ to reduce the bias, e.g., with

$$\begin{aligned}\text{Find } & \mu \\ \text{To minimize } & \sum (\hat{Y}(Z = Z_i) - \mu_i)^2 \\ \text{Such that } & \left\| \frac{1}{n} Z'(\tilde{Y} - \tilde{f}(Z)) - \frac{1}{n} Z'(\mu - \tilde{f}(Z)) \right\|_\infty \leq \eta\end{aligned}$$

where

$$\tilde{Y} = \frac{T(1 - \hat{\pi})}{\hat{\pi}} Y + \frac{(1 - T)\hat{\pi}}{1 - \hat{\pi}} Y$$

(to ensure $\mu \perp T|Z$, split the data in 3: to estimate $\hat{\pi}$ and $\tilde{f} = \hat{Y}$, for the constraint, and for the rest).

Other methods include: IPW, AIPW, ARN (approximate residual rebalancing), TMLE (targeted MLE).

Zigzag expanded navigation plots in R: the R package zenplots

Zigzag plots are pairs plots where adjacent axes share the same variable.

Latent space approaches to social network analysis **P.D. Hoff et al. (2002)**

In a latent space network model, nodes have both features x_i and latent coordinates z_i , and the edge probabilities are

$$z_i \sim N(\mu, \Sigma)$$

$$\text{logit } y_{ij} = \beta x_i + \beta x_j + d(z_i, z_j)$$

GNAR: Generalized network autoregressive process in R **M. Knight et al. (2020)**

In GNARs, X_{it} is a linear combination of its past values (AR) and those of its neighbours (GCN), with weights depending on the lag and the distance (number of hops).

colorspace: a toolbox for manipulating and assessing colours and palettes **A. Zeilis et al. (2020)**

Tensor learning for regression **W. Guo and I. Patras (2012)**

A *tensor regression* is a linear regression with tensors, e.g., $Y_i = X_{ijk\ell} W_{jkl} + b$ where the weight tensor W has low weight (e.g., a CP decomposition – use alternating optimization)

TensorLy: tensor learning for Python **J. Kossaifi et al. (2019)**

ETAS: an R package for fitting the space time ETAS model of earthquake data

The ETAS (epidemic-type aftershock sequence) marked point process is a Hawkes-like model for earthquakes (time, position, magnitude).

Just interpolate: kernel ridge regression can generalize **T. Liang and A. Rakhlin (2018)**

In ridge regression

$$\underset{\beta}{\text{Minimize}} \|y - X\beta\|^2 + \lambda \|\beta\|^2$$

we can let $\beta \rightarrow 0$. If the model is overparametrized, the OLS solution is not unique and interpolates the data; the problem becomes

$$\begin{array}{ll} \text{Find} & \beta \\ \text{To minimize} & \|\beta\|^2 \\ \text{Such that} & y = X\beta. \end{array}$$

Surprises in high-dimensional ridgeless least squares interpolation **T. Hastie et al. (2020)**

Interpolation does not contradict generalization.

A continuous time view of early stopping for least squares **A. ALi et al. (2019)**

Early stopped gradient approximates ridge regression: with the gradient flow and $t = 1/\lambda$, the error is at most 1.7 times that of the ridge.

$$\begin{array}{ll} \beta \leftarrow \beta + \varepsilon \frac{X'}{n} (y - X\beta) & \text{Gradient descent} \\ \dot{\beta} = \frac{X'}{n} (y - X\beta) & \text{Gradient flow} \\ \beta(\lambda) = (X'X - n\lambda I)^{-1} X'y & \text{Ridge} \\ \beta(t) = (X'X)^\dagger (I - \exp -tX'X/n) X'y & \end{array}$$

Computing the Oja median in R: the package OjaNP **D. Fischer et al. (2020)**

There are several multivariate generalizations of the median:

- The *marginal median* is the coordinate-wise median; it is not affine equivariant;
- The *Tuckey median* is the intersection of the minimal halfplanes containing at least half the data;
- The *spatial median* μ minimizes $\sum_i \|x_i - \mu\|_2$; it is not affine-equivariant;
- The *Oja median* is

$$\underset{\mu}{\text{Argmin}} \sum_{i_1 < \dots < i_k} V(x_{i_1}, \dots, x_{i_k}, \mu)$$

where $V(x_1, \dots, x_{k+1})$ is the volume of the simplex (x_1, \dots, x_{k+1}) in \mathbf{R}^k .

They define *signs*

$$\begin{aligned}\text{msgn } x &= [\text{sign } x_1, \dots, \text{sign } x_k] \\ \text{msgn}_X x &= \text{msgn}(x - \text{mmed } X) \\ \text{ssgn } x &= \frac{x}{\|x\|} \text{ if } x \neq 0 \\ \text{ssgn}_X x &= \text{ssgn}(x - \text{smed } X) \\ \text{osgn}_X x &= \sum_{i_1 < \dots < i_{k-1}} \nabla_x \det[x_{i_1} - m, \dots, x_{i_{k-1}} - m, x - m]\end{aligned}$$

and ranks $\frac{1}{n} \sum \text{sign}(x_i - x)$, and rank (or sign) correlation matrices.

Covatest: an R package for selecting a class of space-time covariance functions
C. Cappello et al. (2020)

Classes of space-time covariance functions include:

- Sum-product: the increments of C , in the space and time directions, are constant

$$C(\mathbf{h}, u) = k_1 C_0(\mathbf{h}) C_1(u) + k_2 C_2(\mathbf{h}) + k_3 C_3(u);$$

- Integrated product: the increments of $1/C$ are constant;
- Gneiting: the increments of $\log C$ are constant.

BayesNetBP: an R package for probabilistic reasoning in Bayesian networks
H. Yu et al. (2020)

Exact inference in directed probabilistic graphical models (PGM), assuming the structure known (use `bnlearn`, `deal`, `catnet`, `pcalg` if needed) – `gRain` is limited to discrete Bayesian networks.

mlogit: random utility models in R
Y. Croissant (2020)

R package for generalizations of the multinomial logit/probit model (modeling discrete choices driven by n unobserved utility function): heteroskedasticity, correlated errors, individual heterogeneity (mixed models).

Pseudo-counts: how to compute them efficiently in R
M. Happ et al. (2020)

Comparing two or more samples with rank-based tests can lead to paradoxical results (e.g., $\mu_1 < \mu_2 < \mu_3 < \mu_1$): replace the ranks $\frac{1}{a} \sum \hat{F}(x)$ with the pseudo-ranks $\hat{F}(x)$ where

$$\begin{aligned}Y &\sim \text{Categorical}([1, a], p) \\ X &\sim F_Y \\ F &= \sum p_i F_i\end{aligned}$$

A data envelopment analysis toolbox for Matlab
I.C. Álvarez et al. (2020)

Data envelopment analysis (DEA) is a way of measuring the “distance” (of a firm, turning some input into some output) to the efficient frontier.

$$\begin{aligned}n: \# \text{ firms} & & X \in \mathbf{R}^{m \times n} \text{ inputs} \\ m: \# \text{ inputs} & & Y \in \mathbf{R}^{s \times n} \text{ outputs} \\ s: \# \text{ outputs}\end{aligned}$$

Let $P = \{(x, y) : \exists \lambda \in \mathbf{R}_+^n \ x \geq X\lambda, \ y \leq Y\lambda, \ \lambda' \mathbf{1} = 1\}$ be the set of attainable solutions (remove $\lambda' = 1$ is everything is scalable).

The *radial input-oriented model* measures the efficiency of firm i as $\theta_i = \text{Min}\{\theta : (\theta x_i, y_i) \in P\}$. If $\theta_i < 1$, we can improve (x_i, y_i) (produce the same with less). The *input excess* and *output shortfall* are $\theta x - X\lambda$ and $Y\lambda - y$. Similarly, the radial output oriented model is $\phi_i = \text{Max}\{\phi : (x_i, \phi y_i) \in P\}$. There are also directional variants.

The real numbers – a survey of construction
I. Weiss (2015)

Cauchy sequences and Dedekind cuts are not the only constructions of \mathbf{R} :

- Decimal expansions (but arithmetic is tricky); $\sum a_n/2^n$ with no restriction on a_n (up to equivalence);
- Nested families of intervals; Cauchy filters;
- $\sum_{s \in S} s$, where S is a multiset of elements of the form $1/n$; $\sum_{n \in A} 1/n$, $\sum_{n \in A} a_n$ for a fixed sequence a such that $a_n \rightarrow 0$, $\sum a_n = \infty$;
- Continued fractions; product $\prod (1 + 1/a_n)$; $a_0 + 1/a_1 + 1/a_2 + \dots$; $a_0 + 1/a_1 + 1/a_1 a_2 + 1/a_1 a_2 a_3 + \dots$;
- Approximate endomorphisms, *i.e.* $f : \mathbf{Z} \rightarrow \mathbf{Z}$ such that $\{f(x+y) - f(x) - f(y)\}$ be finite, up to equivalence $f \sim g$ if $\{f(x) - g(x)\}$ is finite;
- The universal property of the completion of \mathbf{Q} .

Fisher information distance: a geometric reading
S.I.R. Costa et al. (2014)

Formulas for computations on the Riemannian manifold of Gaussian distributions $N(\mu, \sigma^2)$.

Self-normalizing flows
T.A. Keller et al. (2020)

Normalizing flows require the Jacobian determinant, which is expensive to compute, unless it is triangular or easy to approximate – instead, have the network learn

both the flow at each layer and its inverse [cf. synthetic gradients].

***Explaining by removing:
a unified framework for model explanation***
I.C. Covert et al. (2020)

Most model explanation methods (SHAP, LIME, etc.) can be unified and presented as a 3-step process:

- Removal: remove part of the image (one or several circular regions, or regions from a segmentation algorithm) and replace it (with noise, a constant value, a generative model, blur, etc.);
- Behaviour: compute the effect of the removal (on the output, the loss, the average loss);
- Aggregation: aggregate those effects (smallest destroying subset, smallest sufficient subset, mean after inclusion/removal, Shapley value, linear model, etc.).

***Reservoir computing meets
recurrent kernels and structured transforms***
J. Dong et al. (2020)

A function $f : \mathbf{R} \rightarrow \mathbf{R}^k$ and random points w_i in \mathbf{R}^p (sampled from some distribution) define random features

$$\phi(u) = \frac{1}{\sqrt{N}} [f(\langle w_1, u \rangle), \dots, f(\langle w_N, u \rangle)]$$

and a kernel $k(u, v) = \langle \phi(u), \phi(v) \rangle$.

***C-space tunnel discovery
for puzzle path planning***
X. Zhang et al. (2020)

Rigid body disentanglement puzzles rely on narrow tunnels in configuration space. Find those tunnels by aligning the features (gap-gap or gap-notch) of the pieces:

- Euclidean-to-geodesic ratio pairs of points on a surface where the EGR is a *local* minimum are around gaps or notches;

$$\text{Minimize}_{u,v} \frac{d_E(u,v)}{d_G(u,v)} + \alpha d_E(u,v)$$

use the *heat kernel method* to compute the geodesics;

- Medial axis notch detection:
 - Compute the medial axis (a surface);
 - Use the *mean curvature flow* to reduce it to a curve, the skeleton;
 - For each point on the skeleton, find the closest point on the surface, and compute the distance to the opposite point;
 - Notches are local minima for this distance;
- Neural network, trained on data from simple puzzles (solved by a traditional planner), taking an image of the puzzle as input (5 channels: luminance, depth, normal) and predicting where the tunnels are.

This does not work on puzzles not relying on gap-gap or gap-notch alignment (e.g., Hanamaya Elk).

***Fast and flexible temporal point processes
with triangular maps***
O. Schur et al. (2020)

A *triangular map* is a map $f : \mathbf{R}^N \rightarrow \mathbf{R}^N$ such that $f_i(x_1, \dots, x_n)$ only depends on (x_1, \dots, x_i) and f_i is increasing in x_i . They are used in normalizing flows: if $x \sim p$, then $F(x) \sim \tilde{p}$, with

$$p(x) = |\det J_F(x)| \tilde{p}(F(x)) = \left(\prod \frac{\partial f_i}{\partial x_i} \right) \tilde{p}(F(x)).$$

This formula is strangely similar to the likelihood of a temporal point process (TPP)

$$\begin{aligned} p(t) &= \prod \lambda(t_i) \exp - \int_0^T \lambda(u) du \\ &= \left(\prod \frac{d\Lambda}{dt}(t_i) \right) \exp -\Lambda(T) \end{aligned}$$

where $\Lambda(T) = \int_0^T \lambda(u) du$.

To sample, draw z from a homogeneous Poisson process on $[0, \Lambda(T)]$ and compute $t = F^{-1}(z)$.

Examples include:

- Inhomogeneous Poisson processes: Λ is deterministic and $F = \Lambda$ (elementwise);
- Renewal processes: $\Lambda(t) = \Phi(t - t_1) + \sum_{j \leq t} \Phi(t_j - t_i)$, where t_i is the last event before t , and $\Lambda = C \circ \Phi \circ D$, where

$$D = \begin{pmatrix} 1 & & 0 \\ -1 & & \\ & \ddots & \\ 0 & -1 & 1 \end{pmatrix}$$

computes pairwise differences, $C = D^{-1}$ (cumulated sum) and Φ acts elementwise.

- Modulated renewal process:

$$\Lambda(t) = \Phi(\Lambda(r) - \Lambda(t_i)) + \sum_{j \leq t} \Phi(\Lambda(t_j) - \Lambda(t_{j-1}))$$

and $F = C\Phi D\Lambda$.

Use rational quadratic splines for Φ and Λ .

Generalize the model to $F = C\Phi_2 B_L \dots B_1 \Phi_1 D\Lambda$ where the B_ℓ are lower-triangular block-diagonal matrices.

Eigengame: PCA as a Nash equilibrium
I. Gemp et al. (2020)

To find the first eigenvector of a symmetric matrix $M = X'X$, one can solve the optimization problem

$$\begin{aligned} &\text{Find} && v \\ &\text{To maximize} && \frac{1}{2} v' M v \\ &\text{Such that} && \|v\| = 1 \end{aligned}$$

with Oja's rule (Krasulina's algorithm):

Mv	gradient
$(I + vv')Mv$	projection of Mv on TS^{n-1}
$v \leftarrow v + \eta(I + vv')Mv$	gradient step
$v \leftarrow v / \ v\ $	Projection on S^{n-1}

This can be generalized to the top k eigenvectors: replace \mathbf{S}^{n-1} with the Stiefel manifold and use Gram-Schmidt orthonormalization (matrix Krasulina).

We can recover the span of the top k eigenvectors by solving

$$\begin{array}{ll} \text{Find} & V \in \mathbf{R}^{n \times k} \quad (k < n) \\ \text{To maximize} & \text{tr}(V' M V) \\ \text{Such that} & V' V = I. \end{array}$$

For $k = n$, we want to maximize the trace, minimize the off-diagonal elements; to recover the order of the eigenvectors, each is only penalized by the previous ones.

$$\begin{aligned} v_1 &\leftarrow \underset{v_1' v_1 = 1}{\text{Argmax}} \langle v_1, M v_1 \rangle \\ v_2 &\leftarrow \underset{v_2' v_2 = 1}{\text{Argmax}} \langle v_2, M v_2 \rangle - \frac{\langle v_2, M v_1 \rangle^2}{\langle v_1, M v_1 \rangle} \\ v_i &\leftarrow \underset{v_i' v_i = 1}{\text{Argmax}} \langle v_i, M v_i \rangle - \sum_{j < i} \frac{\langle v_i, M v_j \rangle^2}{\langle v_j, M v_j \rangle} \end{aligned}$$

(the constraints $v_i' v_j = 0$ are redundant: $\langle v_i, M v_j \rangle = \lambda \langle v_i, v_j \rangle$ at the optimum.) The i th objective can also be written

$$\begin{aligned} u_i(v_i) &= \langle v_i, M v_i \rangle - \sum_{j < i} \frac{\langle v_i, M v_j \rangle^2}{\langle v_j, M v_j \rangle} \\ &= \|X v_i\|^2 - \sum_{j < i} \frac{\langle X v_i, X v_j \rangle^2}{\langle X v_j, X v_j \rangle}. \end{aligned}$$

PCA is the unique strict Nash equilibrium of this k -player differentiable game. Solve with Riemannian gradient ascent on the sphere, sequentially or (asynchronously) in parallel.

Learning undirected graphs in financial markets

J.V.M. Cardodo and D.P. Palomar (2020)

Do not learn a graph but its Laplacian $L = D - W$

$$\begin{array}{ll} \text{Find} & L \\ \text{To minimize} & \text{tr}(L S) - \log \text{gdet } L + h_\alpha(L) \\ \text{Such that} & L \mathbf{1} = 0 \\ & \forall i \neq j \quad L_{ij} = L_{ji} \leq 0 \end{array}$$

where S is the (detoned) correlation and gdet the pseudo-determinant (the product of the nonzero (positive) eigenvalues).

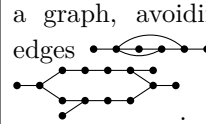

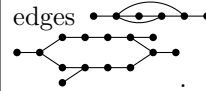

To constrain the number of connected components $k = \dim \ker L$, note that

$$\begin{aligned} \dim \ker L \geq k &\iff \sum_{i=1}^k \lambda_i(L) = 0 \\ \sum_{i=1}^k \lambda_i(L) &= \underset{\substack{V \in \mathbf{R}^{p \times k} \\ V' V = I}}{\text{Min}} \text{tr}(V' L V). \end{aligned}$$

The resulting problem can be solved in an alternating fashion.

$$\begin{array}{ll} \text{Find} & L \succcurlyeq 0 \\ & V \in \mathbf{R}^{p \times k} \\ \text{To minimize} & \text{tr}(L S) - \log \text{gdet } L + \eta \text{tr}(V' L V) \\ \text{Such that} & L \mathbf{1} = 0 \\ & \forall i \neq j \quad L_{ij} = L_{ji} \leq 0 \\ & \text{diag } L = \mathbf{1} \\ & V' V = I \end{array}$$

A step towards neural genome assembly **L. Vrček et al. (2020)**

De novo genome assembly looks for a path in a graph, avoiding short tips , transitive edges  and choosing a branch in bubbles .

Use a GNN for each of those three problems.

Sanity checks for saliency maps **J. Adebayo (2018)**

It is difficult to assess the quality of model explanations. Saliency maps (gradient, gradient \odot input, integrated gradient, guided backprop, guided GradGAM, smoothGrad) are misleading: they often give results similar to a simple (task-agnostic) edge detector – compare them with an untrained model, or a model with shuffled labels.

Coupling-based invertible neural networks are universal diffeomorphism approximators **T. Teshima et al. (2020)**

A set \mathcal{M} of functions $\mathbf{R}^m \rightarrow \mathbf{R}^n$ is a *distributionally universal approximator* if, for all absolutely continuous measure μ on \mathbf{R}^m , for all measure ν on \mathbf{R}^n , there exists a sequence $(g_i)_i$ in \mathcal{M} such that $g_{i*} \mu \xrightarrow{i \rightarrow \infty} \nu$.

Affine coupling flows are transformations of the form $\psi(x, y) = (x, e^{s(x)} \odot y + t(x))$ (the exponential is elementwise).

Combining affine flows (with y 1-dimensional) and invertible affine transformations gives an L^p universal approximator, and therefore a distributionally universal approximator.

Ignorance is bliss: adversarial robustness by design through analog computing and synaptic asymmetry **A. Cappelli et al. (2020)**

To fight adversarial attacks, insert a non-differentiable layer (an optical processing unit (OPU), $m = |R x|^2$, R random, input and output quantized to 8 bits) and use direct feedback alignment (DFA) instead of backpropagation to differentiate through it.

Hard negative mixing for contrastive learning
Y. Kalantidis et al. (2020)

Contrastive learning (learning an embedding in which different augmentations of the same image are closer than those of another image) benefits from better positive pairs (more data augmentation) or better negative pairs (SinCLR, MoCo): MoChi creates synthetic negatives by averaging two negative samples, or a negative and a positive sample.

SuperLoss:

a generic loss for robust curriculum learning

Early in training, downweight hard samples, identified by a large loss, (or a large loss with high confidence) by changing the loss function.

Deep transformation invariant clustering
T. Monnier et al.

Image clustering often relies on latent representations. Instead, work in pixel space, and jointly learn prototypes (for each cluster) and transformations (to align each image to its prototype – or the inverse). It is an image (parametric) analogue of dynamic time warp (DTW).

Clustering	$\underset{c_1 \dots c_K}{\text{Argmin}} \sum_i \ell(x_i, \{c_1, \dots, c_K\})$
TI clustering	$\underset{c_1 \dots c_K}{\text{Argmin}} \sum_i \underset{\beta_1 \dots \beta_K}{\text{Min}} \ell(x_i, \{T_{\beta_1} c_1, \dots, T_{\beta_K} c_K\})$
DTI clustering	$\underset{\substack{c_1 \dots c_K \\ f_1 \dots f_K}}{\text{Argmin}} \sum_i \ell(x_i, \{T_{f_1(x_i)} c_1, \dots, T_{f_K(x_i)} c_K\})$

The transformation parameters are computed by a neural network f . Each transformation is a sequence of parametric transformations $T_{\beta_1} \circ \dots \circ T_{\beta_M}$, including:

- Affine colour transformations;
- Spatial transformers networks;
- Morphological transformations, with the max and min of dilation and erosion replaced by softmax ($\alpha > 0$) and softmin ($\alpha < 0$).

$$T(x)_{uv} = \frac{\sum_{u'v'} x_{u+u',v+v'} \cdot a_{u+u',v+v'} \cdot \exp \alpha x_{u+u',v+v'}}{\sum_{u'v'} a_{u+u',v+v'} \cdot \exp \alpha x_{u+u',v+v'}}$$

The loss function can be from k -means of a Gaussian mixture (GMM). During training:

- Reassign tiny clusters to a noisy copy of the largest cluster;
- Progressively add more complex transformations (curriculum learning).

Image analysis using mathematical morphology
R.M. Haralich et al. (1987)

Spatial transformer network
M. Jaderberg et al. (2016)

Transform an image with a parametric transformation T_θ (affine, projective, peicewise affine, thin plate spline) with the parameters computed from the image itself:

$$x \mapsto T_{\theta(x)}(x).$$

Learning energy-based models by diffusion recovery likelihood
(ICLR 2021)

An energy-based model (EBM) $p_\theta(x) = f_\theta(x)/Z_\theta$ can describe a distribution on images x (use a CNN for f_θ): training is done with the gradient

$$\underset{x \sim \text{data}}{\text{E}} \frac{\partial f_\theta(x)}{\partial \theta} - \underset{x \sim p_\theta}{\text{E}} \frac{\partial f_\theta(x)}{\partial \theta}$$

and sampling with Langevin Monte Carlo

$$x_{t+1} \leftarrow x_t + \frac{\delta^2}{2} \nabla_x f_\theta(x_t) + \delta \varepsilon_t$$

but convergence is slow.

Recovery likelihood, from a noisy image $\tilde{x} = x + \sigma \varepsilon$ (or $\tilde{x} = ax + \sigma \varepsilon$, a, σ constants) is easier to sample from (less multimodal)

$$p(x|\tilde{x}) = \frac{\exp \left[f_\theta(x) - \frac{\|\tilde{x} - x\|^2}{2\sigma^2} \right]}{\tilde{Z}_\theta(\tilde{x})}$$

Use a sequence of EBMs, trained on increasingly noise versions of the dataset.

Score-based generative modeling through stochastic differential equations
(ICLR 2021)

Score-based generative models consider a sequence of noise scales $\sigma_1 < \dots < \sigma_N$, going from the data distribution p_{data} to near-Gaussian noise $p_{\text{data}} * N(0, \sigma_N I)$, and learn a score function s_θ minimizing

$$\sum_i \sigma_i^2 \underset{s \sim \text{Data}}{\text{E}} \underset{\tilde{x} \sim p_{\sigma_i}(\tilde{x}|x)}{\text{E}} \|s_\theta(\tilde{x}, \sigma_i) - \nabla_{\tilde{x}} \log p_{\sigma_i}(\tilde{x}|x)\|^2$$

Stochastic differential equations (SDE) provide a continuous generalization, progressively adding noise to an image with a diffusion

$$dx = f(x, t)dt + g(t)dW$$

and removing it with the *reverse-time SDE*

$$dx = [f(x, t) - g^2(t) \nabla_x \log p_t(x)]dt + g(t)dW.$$

**Reinforcement learning upside down:
don't predict rewards, just map them to actions**
J. Schmidhuber (2019)

UDRL learns a mapping

$$(\text{state}, \text{horizon}, \text{reward}) \mapsto \text{action}$$

using training data from the past

$$(s_1, t_2 - t_1, r_{[t_1, t_2]}, a_{[t_1, t_2]})$$

and extrapolate (use it to find actions leading to a higher reward in a shorter time frame).

**Extrapolation towards imaginary 0-nearest
neighbour and its improved convergence rate**
A. Okuno and H. Shimodaira (2020)

The k -nearest neighbour classifier is a weighted average, often with positive constant weights – but real weights can remove the bias and improve convergence.

Instead, the multiscale k -NN uses adaptive weights, by extrapolating the values as $k \rightarrow 0$, with a linear regression k -NN $\sim \text{distance}_k^2$.

**It is not what machines can learn,
it is what we cannot teach**
G. Yehuda et al. (2020)

Deep learning cannot solve NP-complete problems from data: that would require non-polynomial data generation.

**Movement pruning:
adaptive sparsity by fine-tuning**
V. Sanh et al. (2020)

For transfer learning, do not prune small weights, but weights that move towards zero when fine-tuning.

**On ranking via sorting
by estimated expected utility**
C. Calauzènes and N. Usunier (2020)

Learning-to-rank loss functions include

- The discounted cumulated gain

$$\text{DCG}_p = \sum_{i=1}^p \frac{\text{relevance}_i}{\log(1+i)}$$

- The expected reciprocal rank, the expectation of the inverse of the rank of the first relevant result, $E[1/\text{rank}]$, which encourages diversity.

A loss is compatible with expected utility iff the set of optimal ranking is connected (by transpositions of adjacent items).

**Tight nonparametric convergence rates
for stochastic gradient descent
under the noiseless linear model**
R. Berthier et al. (2020)

Kernel SGD performs interpolation as

$$f_k \leftarrow f_{k-1} - \gamma(f_{k-1}(x_k) - y_k)k(\cdot, x_k).$$

**Leverage the average:
an analysis of KL regularization in RL**
N. Vieillard et al. (2020)

Add the following penalties:

- Entropy, $\tau H(\pi)$, to penalize deterministic policies;
- Kullback-Leibler $-\lambda \text{KL}(\pi \parallel \pi_k)$, to remain close to the previous policy.

Munchausen reinforcement learning
N. Vieillard et al. (2020)

Augment the reward with the log-policy:

$$r(s, a) \rightsquigarrow r(s, a) + \alpha \log \hat{\pi}(s|a).$$

For the optimal policy:

$$\log \pi^*(a|s) = \begin{cases} 0 & \text{if } a \text{ is optimal} \\ -\infty & \text{otherwise.} \end{cases}$$

**Neumiss networks: differentiable programming
for supervised learning with missing values**
M. Le Morvan et al. (2020)

Under Gaussian assumptions, the linear model with missing values (MCAR, MAR – MNAR is more complex and requires more assumptions) is

$$f(x_{\text{obs}}) = \langle \beta_{\text{obs}}, x_{\text{obs}} \rangle + \langle \beta_{\text{mis}}, \mu_{\text{mis}} + \Sigma_{\text{mis, obs}} \Sigma_{\text{obs}}^{-1} (x_{\text{obs}} - \mu_{\text{obs}}) \rangle.$$

The model can be estimated with a neural network:

- β, μ, Σ are parameters to estimate;
- At each step, multiply elementwise the vectors with the missingness pattern m or $1 - m$, and matrices by mm' ;
- For Σ^{-1} , use a Neumann series, *i.e.*, $\Sigma^{-1} = \sum_{k \geq 0} (I - \Sigma)^k$, but learn the weights W (instead of using $W - I - \Sigma$).

$$\begin{aligned} S_0 &= W_0 \\ S_1 &= (W_1 \odot mm')S_0 + I \\ S_2 &= (W_2 \odot mm')S_1 + I \\ S_2 \odot mm' &\approx \Sigma_{\text{obs}}^{-1} \end{aligned}$$

**Statistical and topological properties
of sliced probability divergences**
K. Nadjahi et al. (2020)

The sliced Wasserstein distance (average of the Wasserstein distances after projection on random 1-dimensional subspaces) has good theoretical properties (similar to, and sometimes even better than the original Wasserstein distance).

The *generalized sliced Wasserstein distance* uses a non-linear projection, e.g., a neural network with a 1-dimensional output.

**The dynamics of learning
with feedback alignment**
M. Refinetti et al. (2020)

Backpropagation propagates the error ε of a neural net from the output to the input: each layer receives this error, transformed by a product of matrices $A_{\ell+1}A_{\ell+2} \cdots A_n\varepsilon$.

Instead, **direct feedback alignment** (DFA) uses fixed random matrices.

Evidence from shallow networks shows two phases:

- First, the weights change until the DFA direction becomes aligned with the actual gradient;
- Only then does learning actually start.

**Direct feedback alignment scales to modern
deep learning tasks and architectures**
J. Launay et al. (2020)

Extensive survey of DFA on complex architectures: they fail with CNNs, struggle with graph neural nets, but work surprisingly well with everything else (fully-connected networks, attention, etc.).

**Low-dimensional hyperbolic
knowledge graph embedding**
I. Chami et al. (2020)

A knowledge graph encodes different types of relations: hierarchical (e.g., “is a”), symmetric (e.g., “married to”), asymmetric, etc.

Embed both entities and relations in hyperbolic space, with a *learned* curvature c , different for each type of relation.

For the relations r , do not only learn an embedding, but also a rotation Rot_r , and a reflection Ref_r ; apply them to the head h of the triplet (h, r, t) ; combine them with an attention mechanism, and translate (Möbius addition) with the relation embedding

$$\text{Att}(\text{Rot}_r \cdot h, \text{Ref}_r \cdot h) \oplus^c r.$$

Data from WorldNet, Freebase, Yago3.

The (non-commutative, non-associative) Möbius addition is defined from the parallel transport:

$$x \oplus y = \exp_x P_{0 \rightarrow x} \log_0 y.$$

Learning clique forests
G.P. Massara and T. Aste (2019)

A *clique* is a maximal complete subgraph. A *separator* is an intersection of two cliques. A *clique graph* has cliques as nodes and separators as edges. It is a **clique forest** if it has no cycles (forest) and satisfies the “clique intersection property”: if C_1 and C_2 are cliques, then $C_1 \cap C_2$ is in all the cliques on the path from C_1 to C_2 .

A *perfect elimination order* is an ordering $\sigma = (v_1, \dots, v_n)$ of the vertices such that each $\text{Adj}(v_i) \cap G_{i:n}$ is a clique in $G_{i:n}$, where $\text{Adj}(v)$ is the set of vertices adjacent to v .

A graph is *chordal* iff it has a clique forest iff it has a perfect elimination order. The junction tree algorithm provides efficient exact inference on chordal undirected probabilistic graphical models (chordal Markov random fields).

The **maximally filtered clique forest** (MFCF) is an alternative to the graphical lasso (or other PGM structure inference algorithms: PC, etc.) which progressively builds a clique forest by adding vertices one by one with *clique expansion* to maximize the gain (increase in the “score”, e.g., the sum of the edge weights (correlations), or the log-likelihood).

Complex networks on hyperbolic surfaces
T. Aste et al. (2004)

Filter a graph by progressively adding edges as long as it remains embeddable in an orientable surface of genus g .

The genus of a graph (minimum genus of an orientable surface on which the graph can be embedded without edge intersections) is a measure of complexity; it is higher for small-world networks (which have “worm-holes”).

**A tool for filtering information
in complex systems**
M. Tuminello et al. (2005)

Idem.

**Network filtering for big data:
triangulated maximally filtered graph**
G.P. Massara et al. (2015)

The planar maximally filtered graph (PMFG) can be constructed greedily, but with p planarity tests at $O(p^2)$, it is still $O(p^3)$.

The **deltahedron heuristic** starts with a tetrahedron $K_4 = \triangle$ and progressively adds vertices \triangleright .

Choose the triangle to maximize the sum of the edge weights; add the vertices in some predetermined order, e.g., using the sum or maximum of the incident edges. The result is a tree of 4-cliques separated by 3-cliques.

The *triangulated maximally filtered graph* (TMFG) chooses the optimal vertex and triangle at each step; it is still $O(p^2)$. It can be extended with more local moves

Topological regularization with information filtering networks T. Aste

The maximally filtered clique forest (MFCF), from the squared Kendall correlation, with different maximum clique sizes, can be used to infer the sparsity structure of the concentration matrix of a multivariate Gaussian or Student distribution, as an approximate penalty. Use training/validation sets to separately estimate the model and choose the hyperparameter (maximum clique size).

Topological regularization via persistence sensitive optimization A. Nigmatov et al. (2020)

Persistence holomogy can help control the complexity of the solution of an optimization problem, e.g., the decision boundary of a classifier, or the latent representation of an auto-encoder, by removing low-persistence 0-dimensional features (noise).

$$\text{Loss} = \sum_{d_i - b_i \leq \varepsilon} (d_i - b_i)^2$$

The 0-dimensional persistence diagram of a function $f : X \rightarrow \mathbf{R}$ is

$$\text{Dgm}(f) = \{(f(v_{\text{birth}}), f(v_{\text{death}}))\}.$$

An ε -simplification of f is a function g such that $\|f - g\|_\infty \leq \varepsilon$ and

$$\text{Dgm}(g) = \{(b, d) \in \text{Dgm } f : |d - b| > \varepsilon\}.$$

Persistence-sensitive optimization (PSO) alternates between two gradient descents (each with its own momentum):

- Gradient step to reduce $\text{Loss}(\theta)$;
- ε -simplification g of f_θ ;
- Gradient step to reduce $\|f_\theta - g\|^2$ (g fixed).

Second-order optimization made practical R. Anil et al. (2020)

Updates for gradient-based optimization are of the form $w \leftarrow w - \eta g$. Preconditioning methods are $w \leftarrow w - Pg$, where P is an $n \times n$ matrix computed from the Hessian (Newton) or gradient-gradient correlations. AdaGrad assumes P is diagonal, while *Shampoo* uses

$$\begin{aligned} W &\in \mathbf{R}^{m \times n} \\ L_t &= \sum_{s=1}^t G_s G_s' \in \mathbf{R}^{m \times m} \\ R_t &= \sum G_s' G_s \in \mathbf{R}^{n \times n} \\ w &\leftarrow w - \eta L^{-1/4} G R^{-1/4}. \end{aligned}$$

The condition number for L is bad ($\geq 10^7$): double precision computations are required.

Also check: K-FAC, GGT.

The non-convex Burer-Monteiro approach works on smooth semi-definite programs N. Boumal et al. (2018)

The semi-definite program

$$\begin{aligned} \text{Find} \quad & X \in \mathbf{R}^{n \times n} \\ \text{To minimize} \quad & \langle C, X \rangle \\ \text{Such that} \quad & AX = b \\ & X \succeq 0 \end{aligned}$$

can be reformulated, if X has rank p , as

$$\begin{aligned} \text{Find} \quad & Y \in \mathbf{R}^{n \times p} \\ \text{To minimize} \quad & \langle CY, Y \rangle \\ \text{Such that} \quad & AYY' = b. \end{aligned}$$

It is not convex but, under reasonable assumptions, first- and second-order optimality conditions are also sufficient.

Fairwashing explanations with off-manifold detergent C.J. Anders et al. (2020)

Most explanations of black-box methods (gradient, $x \odot \text{grad}$ (contribution), integrated gradient, layerwise relevance propagation) ignore the data manifold and can be manipulated: keep the model as is on the data manifold and alter it orthogonally – in practice, add the desired explanation to the loss function (it is Goohart's law).

Projecting the explanations tangentially to the manifold makes them more robust (use the k -nearest neighbours, or an autoencoder, to estimate the tangent space).

***NCVis: noise contrastive approach
for scalable visualization***
A. Artemenkov and M. Panov (2020)

Noise contrastive estimation (NCE) maximizes

$$\mathbb{E}_{x \sim \text{data}} \log \frac{p_{\theta}(x)}{p_{\theta}(x) + \nu p_{\text{noise}}(x)} + \nu \mathbb{E}_{x \sim \text{noise}} \log \frac{\nu p_{\text{noise}}(x)}{p_{\theta}(x) + \nu p_{\text{noise}}(x)}$$

Simplify t-SNE by:

- Replacing the Gaussian distributions in the input space with uniform distributions on the k nearest neighbours;
- Treating the normalization constant in the low-dimensional space as a parameter;
- Using NCE with, as noise distribution, the data distribution on edges with one end replaced at random.

Python code available. Also check UMAP (slower), FIt-SNE.

***Efficient algorithms for t-distributed stochastic
neighbourhood embedding***
G.C. Linderman et al. (2017)

FIt-SNE is a faster implementation of t-SNE (`fast_tsne` in R or Python).

It is also useful in dimension 1: plot it several times, with dodging, and colours from DBscan or features of interest.

***Arbitrary style transfer in real-time
with adaptive instance normalization***
X. Huang and S. Belongie (2017)

Instead of *training* a style transfer network so that the statistics of the latent representation match those of the target image (a time-consuming optimization), **AdaIN** (adaptive instance normalization) just *rescales* them.

***RealMix: towards realistic
semisupervised deep learning algorithms***
V. Nair et al. (2019)

Semi-supervised learning relies on a few ideas:

- Consistency training: outputs on unlabeled data should be invariant to small perturbations;
- Entropy minimization: decision boundaries should avoid dense regions (the model should be more confident);
- MixUp: linear interpolation of (labeled) data points;
- Data augmentation;
- Out-of-distribution masking: mask unlabeled samples with low confidence (to account for different distributions in the labeled and unlabeled sets);
- Training signal annealing: limit training on labeled samples (there are too few of them) to avoid overfitting.

***Inclusive GAN: improving data
and minority coverage in generative models***
N. Yu et al. (2020)

Implicit maximum likelihood estimation (IMLE) alleviates the mode collapse problem of GANs by matching each real sample with a generated one (instead of the opposite).

$$\text{Minimize}_{\theta} \mathbb{E}_{z_1, \dots, z_n \sim N(0, I)} \mathbb{E}_{x \sim \text{data}} \min_i \|G_{\theta}(z_i) - x\|^2$$

(use a fast nearest neighbour algorithm, e.g., prioritized DCI). One can combine adversarial and reconstructive (IMLE) losses.

***Fast k-nearest neighbour search
via prioritized DCI***
K. Li and J. Malik (2017)

Fast (approximate) nearest neighbour search can be done with k-d-trees (only in low dimension) or locality-sensitive hashing (LSH – but performance degrades if there are large density variations).

Dynamic continuous indexing (DCI) does not partition the points, but uses indices, each ordering the points in a random direction. *Prioritized DCI* does not visit one point from each index at each iteration, but prioritizes them (with the distance, along the projection direction, between the query and the next point).

***Finding nearest neighbours
in growth-restricted metrics***
D.R. Karger and I.M. Ruhl (2002)

To perform nearest neighbour search in an arbitrary metric space, store, for each observation, a random list of neighbours at distance $\leq r$, for several values of r , and use them, progressively reducing r , to move closer to the target point.

A discrete metric space has (ρ, c) -expansion if

$$\forall p \in X \quad |B_p(r)| \leq \rho \implies |B_p(2r)| \leq c |B_p(r)|.$$

For instance, (\mathbf{Z}^d, L^1) has $(1, 2^d)$ -expansion.

Applications if the KR dimension include internet routing and machine learning (the manifold hypothesis).

***JASS: Japanese-specific sequence to sequence
pretraining for neural machine translation***
Z. Mao et al. (2020)

Pretrain the model on units larger than words (文節 \approx noun or verb phrase) on a masked prediction or re-ordering task.

***Tapas: weakly supervised table parsing
via pre-training***
J. Herzig et al. (2020)

Train a BERT model for question answering on table data (free-form questions, asking which cells to select and which aggregation function (sum, avg, count, nop) to use) on data from Wikipedia (Infobox, Wikitable).

***Synthesizer: rethinking self-attention
for transformer models***
Y. Tay et al. (2020)

In the transformer $X \mapsto \text{Softmax}(QK')V$, replace the dot product QK' with:

- a shallow net $F : \mathbf{R}^d \rightarrow \mathbf{R}^\ell$, operating identically on each of the ℓ tokens $\mathbf{R}^{d \times \ell} \rightarrow \mathbf{R}^{\ell \times \ell}$
- or a random matrix.

SIGN: scalable inception graph neural network
F. Frasca et al. (2020)

Graph neural nets do not scale well to large graphs: one often uses seed nodes (picked at random, or using PageRank), adds their neighbourhoods, and only computes the loss on the seed nodes.

Instead, use a shallow net of the form

$$X \mapsto A_0 X \Theta_0, \dots, A_r X \Theta_r \xrightarrow{\sigma} Z \mapsto Z \Omega \xrightarrow{\sigma} \sigma(Z \Omega)$$

where Θ_k and Ω are parameters and the A'_k s are fixed operators (so that $A_k X$ can be precomputed), e.g., B^k , where B is the adjacency, the personalized pagerank adjacency, or triangle-based adjacency.

***Erdős goes neural:
an unsupervised learning framework
for combinatorial optimization on graphs***
N. Karalias and A. Loukas (2020)

To solve combinatorial optimization problems with deep learning, do not directly look for a solution, but for a *probability distribution* on candidate solutions: if $\mathbb{E}[f(S)] = a$, we know there is a solution S with $f(S) \leq a$.

For instance, given a graph G , to find a set of vertices $S \subset V(G)$ minimizing $f(S)$, for some nonnegative function f , use independent Bernoulli distributions on the vertices and $\text{Loss} = \mathbb{E}[f(S)]/(1-t)$: by the Markov inequality, it guarantees

$$P[f(S) \leq \text{loss}] \geq t.$$

To account for constraints $S \in \Omega$, add $\mathbf{1}_{S \in \Omega} \cdot \beta$ to f and find a computable differentiable upper bound for $P[S \in \Omega]$.

For box constraints

$$\sum_{v_i \in S} a_i \in [b_\ell, b_h],$$

rescale the probabilities to satisfy the constraint in expectation

$$p_i \leftarrow \text{clamp}(cp_i, 0, 1)$$

$$\sum_{v_i \in V} a_i p_i = \frac{1}{2}(b_\ell + b_h).$$

To retrieve integral solutions, use (sampling or) conditional expectations: sort the vertices by decreasing

probabilities and decide to add them to S one by one, by comparing

$$\mathbb{E}[f(S) \mid v_{i+1} \in S]$$

and $\mathbb{E}[f(S) \mid v_{i+1} \notin S, S_i \subset S]$.

Applications include max-clique and constrained min-cut.

***An alternative to backpropagation
in deep reinforcement learning***
S. Chung (2020)

If the mapping from state S to action A is given by a multi-layer network of *stochastic units*

$$H_\ell \sim P(H_\ell | H_{\ell-1}, W_\ell),$$

the REINFORCE gradient estimator

$$\nabla_W \mathbb{E} G = \mathbb{E}[G \nabla_W \log P(A|S)]$$

can be written

$$\nabla_{W_\ell} \mathbb{E} G = \mathbb{E}[G \nabla_{W_\ell} \log P(H_\ell | H_{\ell-1})]$$

which suggests the update rule

$$W_\ell \leftarrow W_\ell + \alpha G \nabla_{W_\ell} \log P(H_\ell | H_{\ell-1}).$$

The following has lower variance

$$W_\ell \leftarrow W_\ell + \alpha G \mathbb{E}[\nabla_{W_\ell} \log P(H_\ell | H_{\ell-1}) | S, A]$$

and the expectation can be approximated at the mode \hat{H}_ℓ of $P(H_\ell | S, A)$

$$W_\ell \leftarrow W_\ell + \alpha G \nabla_{W_\ell} \log(\hat{H}_\ell | \hat{H}_{\ell-1});$$

the modes can be estimated by gradient ascent.

***Realm: retrieval-augmented
language model pre-training***
K. Guu et al. (2020)

Augment a masked language model (BERT) with a retrieval system (maximum inner product search) and train them together.

Sampled softmax with random Fourier features
A.S. Rawat et al. (2020)

Since sampling from the full softmax distribution p is expensive

$$h : \text{input embedding}$$

$$c_i : \text{embedding of class } i$$

$$o_i = \tau h' c_i \text{ raw score (logit)}$$

$$p_i = e^{o_i} / Z \text{ probability}$$

$$t : \text{true label}$$

$$\mathcal{L}(x, t) : \text{loss}$$

$$\nabla_{\theta} \mathcal{L} = -\nabla_{\theta} o_t + \mathbb{E}_{s \sim p} [\nabla_{\theta} o_s]$$

it is often replaced by an easier distribution, e.g., uniform, or some prior – but the softmax distribution is

the only one which gives an unbiased estimator. To have a low bias, we need the p_i/q_i to be close to 1.

Kernel-based sampling uses $q_i \propto k(h, c_i)$, where $k : \mathbf{R}^d \times \mathbf{R}^d \rightarrow \mathbf{R}$ is some kernel. If the kernel can be linearized, $k(h, c) = \phi(h)' \phi(c)$, for $\phi : \mathbf{R}^d \rightarrow \mathbf{R}^D$, sampling can be done in $O(D \log n)$ by a divide-and-conquer algorithm (put the classes in a binary tree: we only need $\sum_{c \in S} \phi(c)$ for the subtrees S).

The softmax is obtained for $k(h, c) = \exp(\tau h'c)$. The quadratic kernel

$$k(h, c) = \alpha(h'c)^2 + 1$$

$$\phi(x) = [\sqrt{\alpha}(z \otimes z), 1]$$

is not a good approximation of the exponential kernel, and does not scale well with the embedding dimension d .

Use *random Fourier features* (and a normalized embedding)

$$\phi(u) = \frac{1}{\sqrt{D}} [\cos w'_1 u, \dots, \cos w'_D u, \sin w'_1 u, \dots, \sin w'_D u]$$

$$w_i \sim N(1, 1/\tau)$$

$$\exp -\frac{\tau}{2} \|x - y\|^2 \approx \phi(x)' \phi(y).$$

Transformers are RNNs: fast autoregressive transformers with linear attention
A. Katharopoulos et al. (2020)

The softmax in the attention mechanism can be linearized, e.g., with a quadratic kernel, random Fourier features, or $\phi(x) = \text{elu}(x) + 1$.

Language ID in the wild: unexpected challenges on the path to a thousand-language web text corpus
I. Caswell et al. (2020)

Language identification on real (dirty, web-crawled) data for low-resource languages is tricky: avoid overly cleaned data, deduplicate, balance the data, use curated wordlists (500/language), train a transformer and check the types or errors (mojibake, create use of Unicode, obfuscation boilerplate, high-resource nearly language, n -gram overlap, antspeak, repetitions, etc.)

A convenient generalization of Schlick's bias and gain functions
J.T. Barron (2020)

Increasing functions $[0, 1] \rightarrow [0, 1]$ with at most one

inflection point $(a, t \in (0, 1), s \geq 0)$.

$$B(x, a) = \frac{x}{(1/a - 2)(1 - x) + 1}$$

$$G(x, a) = \begin{cases} \frac{B(2x, a)}{2} & \text{if } x < 1/2 \\ \frac{B(2x - 1, 1 - a) + 1}{2} & \text{if } x \geq 1/2 \end{cases}$$

$$C(x, s, t) = \begin{cases} \frac{tx}{x + s(t - x) + \varepsilon} & \text{if } x < t \\ \frac{(1 - t)(x - 1)}{1 - x - s(t - x) + \varepsilon} + 1 & \text{if } x \geq t \end{cases}$$

***q*-neurons: neuron activations based on stochastic Jackson's derivative operators**
F. Nielsen and K. Sun (2018)

Replace the activation function f with

$$g_q(x) = \frac{f(x) - f(qx)}{1 - q},$$

with $q \sim N(1, \sigma^2)$ (but remove a small interval around 1 for stability). The gradient of g contains second-order information:

$$\lim_{\text{Var } q \rightarrow 0} g'_q(x) = f'(x) + f''(x)x.$$

The q - and (p, q) -derivatives (from quantum calculus) are

$$D_q f(x) = \frac{f(x) - f(qx)}{(1 - q)x}$$

$$D_{p,q} f(x) = \frac{f(px) - f(qx)}{(p - q)x}.$$

Learning with differentiable perturbed optimizers
Q. Berthet et al. (2020)

To differentiate through an Argmax

$$C = \text{Conv}\{y_1, \dots, y_n\}$$

$$F(\theta) = \text{Max}_{y \in \{y_1, \dots, y_n\}} \langle y, \theta \rangle = \text{Max}_{y \in C} \langle y, \theta \rangle$$

$$y^*(\theta) = \text{Argmax}_{y \in C} \langle y, \theta \rangle = \nabla_{\theta} \text{Max}_{y \in C} \langle y, \theta \rangle$$

add noise $z \sim \exp -U(z)$ (this generalizes the Gumbel softmax trick, for which $C = \Delta$ is the standard simplex).

$$F_{\varepsilon}(\theta) = \mathbb{E}_z [F(\theta) + \varepsilon Z]$$

$$y_{\varepsilon}^*(\theta) = \mathbb{E}_z [\text{Argmax}_y \langle y, \theta + \varepsilon Z \rangle] = \nabla_{\theta} F_{\varepsilon}(\theta)$$

The Jacobian can be computed with Monte Carlo simulations.

$$y_\varepsilon^*(\theta) = \mathbb{E}[F(\theta + \varepsilon Z) \nabla_Z \nu(Z) / \varepsilon]$$

$$J_\theta y_\varepsilon^*(\theta) = \mathbb{E}[F(\theta + \varepsilon Z) \nabla_X \nu(Z) \nabla_Z \nu(Z)' - \nabla_Z \nu(Z)^2 / \varepsilon^2]$$

Applications include rank correlation, shortest path.

Geometric distances via optimal transport
D. Alvarez-Melis and N. Fusi (2020)

Optimal transport on $(\mathcal{X}, \mathcal{Y})$ can be used to compare datasets (e.g., to choose the closest one for transfer learning). If the labels are not the same, replace them with the corresponding distribution in feature space (input), and use the optimal transport distance between those distributions as “distance” (transportation cost) between the labels.

Lambda networks: modeling long-range interactions without attention
(2020)

Lambda layers are a variant of / an alternative to attention layers, which map a context to a linear function, which is then applied to the input (keys).

Fourier neural operator for parametric partial differential equations
Z. Li et al. (2020)

An infinite-dimensional generalization of neural nets approximates a function

$$G : A = \mathcal{F}(D, \mathbf{R}^{d_a}) \longrightarrow U = \mathcal{F}(D, \mathbf{R}^{d_u})$$

by minimizing $\mathbb{E}_{a \sim \mu} \text{Cost}(G_\theta(a), G(a))$. First, lift the input to a higher-dimensional representation, with a shallow neural net

$$\begin{aligned} v_0 : D &\longrightarrow \mathbf{R}^{d_a} \\ v_1 : D &\xrightarrow{v_0} \mathbf{R}^{d_a} \xrightarrow{P} \mathbf{R}^{d_v}, \end{aligned}$$

then apply iterative updates

$$v_{t+1}(x) = \sigma \left(W v_t(x) + \int_D k_\phi(x-y) v_t(y) dy \right);$$

parametrize $k_\phi : \mathbf{R}^{d_a} \longrightarrow \mathbf{R}^{d_v \times d_v}$ in Fourier space and use the FFT to compute the convolution.

Algebraic statistics in practice
M. Casanellas et al. (2019)

Exponential random graph models (ERGM) are of the form

$$p_\theta(G) \propto \exp\langle T(G), \theta \rangle.$$

The *fiber* of G is the set of graphs with the same sufficient statistic $\{G' : T(G') = T(G)\}$. For log-linear models, *i.e.*, $T(G) = BA_G$, where A_G is the adjacency matrix, *toric ideals* can help describe the fiber and sample from it (Metropolis-Hastings), to perform goodness-of-fit tests.

The number of Markov equivalence classes (MEC) of directed graphical models on n nodes, and the number of MECs with only one GDAG, are open problems in combinatorics.

To infer the structure of a directed graphical model with conditional independence tests, it has to be *faithful*, *ie*, causal effects should not cancel out: (for Gaussian linear structural equation models (SEM)), that condition defines a real algebraic surface, and the volume of tubes around it tells us how many samples are needed.

Instead of testing all conditional independence relations, choose an order on the vertices and only test for $X_i \perp\!\!\!\perp X_j \mid X_{\leq j, \neq i, j}$, $i < j$. Prefer the order leading to the sparsest DAG (sparsest permutation search – a vertex on the permutahedron, polytope whose vertices are orderings of $\llbracket 1, n \rrbracket$ and with edges when two permutations differ by a transposition of adjacent elements). (Things get even more complicated with unobserved variables.)

Phylogenetics models consider a probability distribution on $\{A, C, T, G\}^n$ at the root of the tree (e.g., uniform), a transition matrix for each edge (e.g., with a single parameter, $P(x|y)$ for $x \neq y$), and we observe the probabilities on the leaves. Some relations between the probabilities on the leaves (the fact that some matrix has low rank) depend on the structure of the tree and the model: they can help identify the tree, select the model, or prove model identifiability.

Factor investing with Black-Litterman-Bayes: incorporating factor views and priors in portfolio construction
P.N. Kolm and G. Ritter (2020)

1. The simplified Black-Litterman framework models stock returns as

$$\begin{aligned} r &\sim N(\mu, \Sigma) && \text{stock returns} \\ Z &\sim N(0,) && \text{views uncertainty} \\ Q &= Pr + Z && \text{views} \end{aligned}$$

and then computes the conditional distribution of returns given the views, $r \mid Q = q$.

2. The textbook Black-Litterman model is more complicated: the views are not on the returns but on the expected returns.

$$\begin{aligned} \mu &\sim N(\pi, C) && \text{expected stock returns} \\ r &\sim N(\mu, \Sigma) && \text{stock returns} \\ Z &\sim N(0, \Omega) && \text{uncertainty of the views} \\ Q &= P\mu + Z && \text{views on expected returns} \end{aligned}$$

We can then compute the conditional distributions $\mu \mid Q = q$ and $r \mid Q = q$, and the optimal (unconstrained) portfolio

$$w^* = \underset{w}{\text{Argmax}} w' \mu - \frac{1}{2} \lambda w' \Sigma w = \lambda^{-1} \Sigma^{-1} \mu.$$

3. The *factor Black-Litterman* replaces the stock return model, $r \sim N(\mu, \Sigma)$, with a factor model, $r = Xf + \varepsilon$; the views are on the expected factor returns μ (not the factor returns).

$$\begin{aligned}\mu &\sim N(\xi, V) && \text{expected factor returns} \\ f &\sim N(\mu, F) && \text{factor returns} \\ r &= Xf + \varepsilon && \text{factor model} \\ \varepsilon &\sim N(0, D) \\ Z &\sim N(0, \Omega) && \text{uncertainty of the views} \\ Q &= \mu + Z && \text{views on expected factor returns}\end{aligned}$$

From this model, we can compute the conditional distributions of the expected factor returns $\mu | Q = q$, then of the factor returns $f | Q = q$, then of the stock returns $r | Q = q$.

***Portfolio optimization
with drawdown constraints***
A. Chekhlov et al. (2003)

The *conditional drawdown* (or conditional drawdown at risk, or conditional expected drawdown) is the average of the worst $\alpha\%$ drawdowns. Average and maximum drawdowns are special cases ($\alpha = 1$ or 0). For portfolio optimization, assume the portfolio weights are constant and consider “uncompounded” returns (*i.e.*, assume that log- and ratio-returns are the same).

***Drawdown:
from practice to theory and back again***
L.R. Goldberg and O.Mahmoud (2014)

Deep fundamental factor models
M.F. Dixon and N.G. Polson (2019)

Use a neural network to forecast 1-period ahead stock returns (Russell 1000) from stock-level investment factors,

$$y_{t+1} = f(x_t) + \text{noise}.$$

The gradient (and the Hessian, for interactions) makes the model interpretable. [Data and code available]

***A study on the use of artificial intelligence
for learning characteristics of fund's behavior***
T. Tajiri (2020)

Dimension reduction (VAE) from holdings data.

A basket half-full: sparse portfolios
E. Seregina (2020)

Nodewise regression estimates the precision matrix (inverse of the variance) of x_1, \dots, x_n with a regression for each column, $\beta_{ij} = \text{coef}(x_i \sim s_{-i})$, as

$$C = \begin{pmatrix} 1 & -\beta_{12} & \dots & \dots \\ -\beta_{21} & \ddots & \ddots & \ddots \\ \vdots & \ddots & \ddots & \ddots \\ \vdots & \vdots & \vdots & 1 \end{pmatrix}$$

with a lasso penalty to encourage sparsity, rescaled with the variance of the residuals $\Theta = \Sigma^{-2}C$, $\Sigma = \text{diag}(\sigma_1^2, \dots, \sigma_n^2)$; symmetrize (with $\text{Min}(C, C')$) and discard negative eigenvalues. If there are many variables, first use a low-rank factorization $X = BF + E$, then sparse nodewise regression on the residuals, and finally Woodbury's formula to recover the precision of X .

***When bots take over the stock market:
evasion attacks against algorithmic traders***
E. Nehemya et al. (2020)

To build an adversarial attack on an automatic trading algorithm f , find a perturbation v such that $f(x+v) = y$ with high probability, where x is the input and y the desired output (we do not know $f(x)$ in advance: it could already be y). It is a white-box attack, but it may transfer.

Quant bust 2020
Z. Kakushadze (2020)

Quant strategies such as stat-arb and, more generally, medium-term strategies (1 day to 1 month) rely on long-term investors keeping their positions and ignoring potentially profitable medium-term fluctuations. During the Covid-19 crisis, they sold their positions: that assumption was broken.

***Deep reinforcement learning
for asset allocation in US equities***
M. Alonso and S. Srivastava (2020)

CNN, RNN, LSTM, from 50 years of HLC prices for 25 stocks to maximize the average log-returns; the generated weights are combined with the previous 20 ones with a 1×1 convolution to reduce turnover (this drastically reduces performance as well).

***Explainable machine learning
in credit risk management***
N. Bussmann et al. (2020)

Use the correlation between the Shapley contributions to group the predictors.

An operational measure of riskiness
D.P. Foster and S. Hart (2009)

Given a discrete random variable X modeling the outcome of a gamble, *i.e.*, such that $EX > 0$ and $P[X < 0] > 0$, its Foster-Hart risk r is the positive solution of

$$E \log \left(1 + \frac{X}{r} \right) = 0;$$

it is greater than the maximum loss and guarantees no-bankruptcy. For continuous distributions, it need not be defined: use the maximum loss instead.

Parametric UMAP: learning embeddings with deep neural networks for representation and semi-supervised learning
T. Sainburg et al. (2020)

UMAP learns an embedding of the data points that preserves the graph structure of the data; parametric UMAP uses a neural network to compute that embedding (instead of looking for the coordinates of each point in the dataset), which allows adding new points. Contrary to t-SNE, the loss function uses negative sampling and does not require normalization.

$$\begin{aligned}
 p_{j|i}^{\text{t-SNE}} &\propto \exp - \frac{d(x_i, x_j)}{2\sigma_i^2} \\
 p_{j|i}^{\text{UMAP}} &= \exp - \frac{d(x_i, x_j) - \rho_i}{\sigma_i} \\
 q_{ij}^{\text{t-SNE}} &\propto (1 + \|z_i - z_j\|^2)^{-1} \\
 q_{ij}^{\text{UMAP}} &= (1 + a \|z_i - z_j\|^{2b})^{-1} \\
 \text{Loss}^{\text{t-SNE}} &= \text{KL}(p, q) = \sum_{i \neq j} p_{ij} \log \frac{p_{ij}}{q_{ij}} \\
 \text{Loss}^{\text{UMAP}} &= \text{CE}(p, q) \\
 &= \sum_{i \neq j} p_{ij} \log \frac{p_{ij}}{q_{ij}} + (1 - p_{ij}) \log \frac{1 - p_{ij}}{1 - q_{ij}}
 \end{aligned}$$

The UMAP loss can be used as a regularization to learn a latent representation preserving the structure of the data, in autoencoders or for semi-supervised learning.

From trees to continuous embeddings and back: hyperbolic hierarchical clustering
I. Chami et al. (2020)

Hierarchical clustering algorithms are often heuristics. More rigorously, one can minimize the DasGupta cost

$$\begin{aligned}
 \text{Cost}(T) &= \sum_{ij} w_{ij} |\text{leaves } T(i \vee j)| \\
 &= \sum_{ijk} (w_{ij} + w_{ik} + w_{jk} - w_{ijk}) + 2 \sum_{ij} w_{ij}
 \end{aligned}$$

where

$$\begin{aligned}
 i, j: & \text{leaves} \\
 i \vee j: & \text{lowest common ancestor (LCA)} \\
 T(i \vee j): & \text{tree below } i \vee j \\
 w_{ij}: & \text{similarity of } i \text{ and } j \\
 w_{ijk} &= \begin{pmatrix} w_{ij} \\ w_{ik} \\ w_{jk} \end{pmatrix} \cdot \begin{pmatrix} \mathbf{1}_{\{i,j|k\}} \\ \mathbf{1}_{\{i,k|j\}} \\ \mathbf{1}_{\{j,k|i\}} \end{pmatrix} \\
 \{i, j|k\}: & i \vee j \text{ is a descendant of } i \vee j \vee k.
 \end{aligned}$$

This combinatorial optimization problem can be relaxed by looking for a hyperbolic embedding, replacing $i \vee j$ with the point on the geodesic between i and j closest to the origin, and

$$\begin{pmatrix} \mathbf{1}_{\{i,j|k\}} \\ \mathbf{1}_{\{i,k|j\}} \\ \mathbf{1}_{\{j,k|i\}} \end{pmatrix} \quad \text{with} \quad \text{softmax}_{\tau} \begin{pmatrix} d(i \vee j, 0) \\ d(i \vee k, 0) \\ d(j \vee k, 0) \end{pmatrix}.$$

To reconstruct the tree, use $d(i \vee j, 0)$. (To speed up the $O(n^3)$ sum, use all (i, j) pairs, but sample a single k at random.)

This can be used as a (differentiable) step in a longer ML pipeline (end-to-end training).

AlgebraNets
J. Hoffmann et al. (2020)

Try using algebras other than \mathbf{R} for weights and activations (\mathbf{C} , \mathbf{H} , $\mathbf{C}^{2 \times 2}$, $\mathbf{R}^{2 \times 2}$, $\mathbf{R}^{3 \times 3}$, $\mathbf{R}^{4 \times 4}$, dual numbers $\mathbf{R}[\varepsilon]/\langle \varepsilon^2 \rangle$, cross-product \mathbf{R}^3): often, fewer parameters suffice.

Fast and simple PCA via convex optimization
D. Garber and E. Hazan (2015)

To find the largest eigenvalue of a positive definite matrix, use the power method on $M^{-1} = (\lambda I - X)^{-1}$ for $\lambda > \lambda_1(X)$: it has the same eigenvectors, but its condition number $\lambda_1/(\lambda_1 - \lambda_2)$ can be lower. The product $M^{-1}w$ required by the power method can be efficiently computed by solving a convex problem, $M^{-1}w = \text{Argmin}_z \frac{1}{2} z' M z - w' z$.

Use variance-reduced stochastic gradient (SVRG) and progressively reduce λ to bring it closer to $\lambda_1(X)$.

Sharpness minimization for efficiently improving generalization
P. Foret et al. (2020)

Simultaneously minimize loss and loss sharpness by replacing $\text{Loss}(w) + \lambda \|w\|_2^2$ with

$$\text{Max}_{\|\varepsilon\|_p \leq \rho} \text{Loss}(w + \varepsilon) + \lambda \|w\|_2^2.$$

Use the first-order expansion of the loss to approximate the solution of the inner maximization problem and compute the gradient). Only compute the sharpness, $\text{Max}_{\varepsilon} \text{Loss}(w + \varepsilon) - \text{Loss}(w)$, on minibatches.

Fact or fiction: verifying scientific claims
D. Wadden et al. (2020)

Given a statement, use BERT (SciBERT, BioMet ROBERTa) to label sentences from paper abstracts as supports/refutes/no_info.

Automatic generation of reviews of scientific papers
A. Nikiforovskaya et al. (2020)

Combine bibliometric analysis (PageRank and Louvain community detection on the citation, co-citation, or text similarity graphs) with extractive summarization (BERTSUM computes the relevance of each sentence for a summary) to generate a review “paper” for a domain, i.e., identify and summarize the (many) relevant papers in a domain (the output is a table with columns

“paper”, “summary”, “relevance”). The *citation context* (the sentence citing a paper) provides additional context.

***Descending through a crowded valley:
benchmarking deep learning optimizers***
R.M. Schmidt et al. (2020)

The best optimizer is problem-dependent, but:

- Adam, RAdam, NAdam, AMSBound, AdaBound have robust default parameters;
- A non-constant learning rate schedule may help: cosine λ , cosine with restarts $\lambda \lambda \lambda$, or trapezoidal λ .

***Beyond vector spaces:
compact data representation
as differentiable weighted graphs***
D. Mazur et al. (2019)

To account for arbitrary geometries, embed your data in a graph rather than a vector space [PyTorch implementation available].

$p_\theta(i, j)$ edge probability

$w_\theta(i, j)$ edge weight

$$d(i, j) = \min_{\pi: i \rightarrow j} \sum_{e \in \pi} w_\theta(e)$$

$$\text{Loss} = \mathbb{E}_{G \sim p_\theta} L(G) + \frac{1}{|E|} \sum_{ij} p_\theta(i, j)$$

(use the “log-derivative trick” (REINFORCE) for the gradient). After optimization, the edge probabilities are close to 0 or 1: discard all those below 0.5 to have a sparser graph. Examples include generalization of MDS (or Poincaré MDS) and collaborative filtering.

$$L(G) = (\|x_i - x_j\| - d(i, j))^2$$

$$L(G) = \left[1 + \frac{e^{-d(u_i, x^+)}}{e^{-d(u_i, x^-)}} \right]^{-1}$$

***Embedding words in non-vector spaces
with unsupervised graph learning***
M. Ryabinin et al. (2020)

Embedding words (GloVe) in Euclidean or hyperbolic space (constant curvature) assumes the geometry of the space is the same everywhere: instead, use a graph embedding.

Poincaré GloVe: hyperbolic word embedding
A. Tifrea et al. (2019)

The *Gromov δ -hyperbolicity* measures how tree-like (hyperbolic) a metric space is: it is half (the average of) the difference between the biggest two of $d(x, y) + d(z, t)$, $d(x, z) + d(y, t)$, $d(x, t) + d(y, z)$ (normalize it by dividing by the average distance; hyperbolic spaces have lower values).

Words can be embedded as Gaussian distributions – but the space of Gaussian distributions is hyperbolic –

the space of diagonal Gaussians is isometric to a product of Poincaré half planes $(\mathbb{H}^2)^n$.

***Gradient estimation
with stochastic softmax tricks***
M.B. Paulus et al. (2020)

Sampling from a discrete distribution

$$U \sim U(0, 1)$$

$$i = \text{Max}\{i : p_1 + \dots + p_{i-1} \leq U\}$$

$$Z = \text{onehot}(i)$$

can be parametrized with a Gumbel distribution

$$G_i \sim \text{Gumbel}(0, 1)$$

$$i = \text{Argmax}(G_i + \log p_i)$$

$$Z = \text{onehot}(i)$$

and relaxed (*Gumbel softmax*)

$$G_i \sim \text{Gumbel}(0, 1)$$

$$X_i = G_i + \log p_i$$

$$Z = \text{softmax}(X).$$

The “reparametrization trick” is used to differentiate wrt the parameters of a discrete distribution (in the backward pass – in the forward pass, you may still use discrete distributions). It can also be written

$$Z = \text{Argmax}_{x \in \text{conv } \mathcal{X}} U'x - tf(x)$$

$$U \sim \text{Gumbel}$$

$$\mathcal{X} = \Delta_n$$

$$f(x) = \sum x_i \log x_i$$

t : temperature

Deep Bayes 2019

1. Frequentist and Bayesian approaches do not disagree: maximum likelihood only provides asymptotic guarantees, and is asymptotically equivalent to the Bayesian approach.

Frequentist and Bayesian approaches use probabilities to encode different types of randomness. The frequentist approach assumes randomness in the data generation process – even though there is rarely any actual physical (e.g., quantum) randomness, just complex, chaotic phenomena that look random. The Bayesian approach uses probability theory to model uncertainty.

Likelihood	Parameters	Conjugate prior
Gaussian	μ	Gaussian
	σ^{-2}	Gamma
	(μ, σ^{-2})	Gaussian-Gamma
	Σ^{-1}	Wishart
Bernoulli	p	Beta
Multinomial	(p_1, \dots, p_m)	Dirichlet
Poisson	λ	Gamma
Uniform	θ	Pareto

2. The posterior distribution $p(\theta|x)$ is often intractable: **variational inference** replaces it with a simpler distribution $q(\theta)$, as close as possible for the (mode-seeking) Kullback-Leibler divergence.

$$q = \underset{q}{\operatorname{Argmax}} \operatorname{KL}(q(\theta) \parallel p(\theta|x))$$

$$\operatorname{KL}(q \parallel p) = \int \log \frac{q(\theta)}{p(\theta)} q(\theta) d\theta$$

Since the posterior is intractable, so seems the KL divergence.

However, the *evidence* $p(x)$ can be decomposed as

$$\begin{aligned} \log p(x) &= \int \log p(x) q(\theta) d\theta \\ &= \int \log \frac{p(x, \theta)}{p(\theta|x)} q(\theta) d\theta \\ &= \int \log \left(\frac{p(x, \theta)}{p(\theta|x)} \frac{q(\theta)}{q(\theta)} \right) q(\theta) d\theta \\ &= \int \log \frac{p(x, \theta)}{q(\theta)} q(\theta) d\theta + \int \log \frac{q(\theta)}{p(\theta|x)} q(\theta) d\theta \\ &= \mathcal{L}(q(\theta)) + \operatorname{KL}(q(\theta) \parallel p(\theta|x)). \end{aligned}$$

Since the lhs does not depend on q , to minimize the KL divergence, it suffices to maximize the **evidence lower bound** (ELBO) $\mathcal{L}(q(\theta))$.

Note that, since $\operatorname{KL} \geq 0$, it is indeed a lower bound: $\log p(x) \geq \mathcal{L}(q(\theta))$.

The ELBO can be decomposed as

$$\begin{aligned} \mathcal{L}(q(\theta)) &= \int \log \frac{p(x, \theta)}{q(\theta)} q(\theta) d\theta \\ &= \underset{\theta \sim q}{\operatorname{E}} [\log p(x|\theta)] - \operatorname{KL}(q(\theta) \parallel p(\theta)). \end{aligned}$$

The first term, the expected log-likelihood, is maximum if $q = \delta_{\hat{\theta}_{\text{MLE}}}$; the second term, the KL divergence with the prior $p(\theta)$, is minimum if $q = p$, and acts as a regularizer. This decomposition is similar to the Bayes formula:

$$\begin{aligned} \text{Posterior} &\propto \text{likelihood} \times \text{prior} \\ \text{ELBO} &= \text{data term} + \text{regularizer}. \end{aligned}$$

The *mean-field approximation* constrains q to be of the form $q(\theta) = \prod_i q_i(\theta_i)$. *Block coordinate descent* updates the estimate of q_j while keeping the other q_i 's

fixed.

$$\begin{aligned} \mathcal{L}(q(\theta)) &= \int \log \frac{p(x, \theta)}{q(\theta)} q(\theta) d\theta \\ &= \underset{\theta \sim q}{\operatorname{E}} \log p(x, \theta) - \underset{\theta \sim q}{\operatorname{E}} \log q(\theta) \\ \underset{\theta \sim q}{\operatorname{E}} \log p(x, \theta) &= \underset{\theta_j \sim q_j}{\operatorname{E}} \underset{\substack{\theta_i \sim q_i \\ i \neq j}}{\operatorname{E}} \log p(x, \theta) \\ \underset{\theta \sim q}{\operatorname{E}} \log q(\theta) &= \sum_i \underset{\theta_i \sim q_i}{\operatorname{E}} \log q_i(\theta_i) \\ &= \underset{\theta_j \sim q_j}{\operatorname{E}} \log q_j(\theta_j) + \text{const} \\ \mathcal{L}(q(\theta)) &= \underset{\theta_j \sim q_j}{\operatorname{E}} \left[\underset{\substack{\theta_i \sim q_i \\ i \neq j}}{\operatorname{E}} \log p(x, \theta) - \log q_j(\theta_j) \right] + \text{const} \\ &= \underset{\theta_j \sim q_j}{\operatorname{E}} [\log r_j(\theta_j) - \log q_j(\theta_j)] + \text{const} \\ &= -\operatorname{KL}(q_j(\theta_j) \parallel r_j(\theta_j)) + \text{const} \end{aligned}$$

This is maximum for $q_j = r_j$; it can be computed if prior and likelihood are conditionally conjugate, *i.e.*, when $p(\theta_j|\theta_{i \neq j})$ and $p(\theta_j|x, \theta_{i \neq j})$ are in the same family.

3. To estimate a mixture of Gaussians

$$\begin{aligned} Z_i &\sim \text{Categorical}(\pi_1, \dots, \pi_k) \\ X_i &\sim N(\mu_{z_i}, \sigma_{z_i}^2) \\ \theta_j &= (\mu_j, \sigma_j^2), \end{aligned}$$

use the evidence decomposition

$$\begin{aligned} \log p(X|\theta) &= \int \log \frac{p(X, Z|\theta)}{q(Z)} q(Z) dZ + \\ &\quad \int \log \frac{q(Z)}{p(Z, X, \theta)} q(Z) dZ \\ &= \mathcal{L}(q, \theta) + \operatorname{KL}(q(Z) \parallel p(Z|X, \theta)) \\ &\geq \mathcal{L}(q, \theta) \end{aligned}$$

Insead of maximizing $p(X|\theta)$, maximize $\mathcal{L}(q, \theta)$, wrt q and θ . The *EM algorithm* is the block-coordinate ascent algorithm to maximize \mathcal{L} .

$$\begin{aligned} \text{E step} \quad q &= \underset{q}{\operatorname{Argmax}} \mathcal{L}(q, \theta) \\ &= \underset{q}{\operatorname{Argmin}} \operatorname{KL}(q(Z) \parallel p(Z|X, \theta)) \\ &= p(Z|X, \theta) \\ \text{M step} \quad \theta &= \underset{\theta}{\operatorname{Argmax}} \mathcal{L}(q, \theta) \\ &= \underset{\theta}{\operatorname{Argmax}} \underset{Z \sim q}{\operatorname{E}} \log p(X, Z|\theta) \end{aligned}$$

If Z is discrete, this is tractable.

$$\begin{aligned} q(Z_i = k) &= \frac{p(x_i|Z_i = k, \theta)p(Z_i = k|\theta)}{\sum_{\ell} p(x_i|Z_i = \ell, \theta)p(Z_i = \ell|\theta)} \\ \theta &= \underset{\theta}{\operatorname{Argmax}} \sum_i \sum_k q(Z = k) \log p(x_i, Z = k|\theta) \end{aligned}$$

Variational EM uses variational inference in the E step.

A variational lower bound of f satisfies

$$\begin{aligned}\forall x \forall \xi \quad f(x) &\geq g(\xi, x) \\ \forall x \exists \xi \quad f(x) &= g(\xi, x)\end{aligned}$$

The MM algorithm iterates

$$\begin{aligned}x &\leftarrow \underset{x}{\operatorname{Argmax}} g(\xi, x) \\ \xi &\leftarrow \underset{\xi}{\operatorname{Argmax}} g(\xi, x)\end{aligned}$$

The *Ada-gram* (adaptive skipgram) algorithm extends the word2vec model by considering several embeddings for each word, corresponding to different meanings. Add a latent variable to select the meaning; use a Dirichlet process to have an unbounded number of meanings per word.

4. PCA is a latent variable model

$$\begin{aligned}p(X, Z|\theta) &= \prod_i p(x_i|z_i, \theta) p(z_i|\theta) \\ &= \prod_i N(x_i|Vz_i + \mu, \sigma^2 I) N(z_i|0, I);\end{aligned}$$

it can be estimated with the EM algorithm, generalized to *mixture PCA*

$$p(X, Z, Y|\theta) = \prod_i N(x_i|V_{t_i}z_i + \mu_{t_i}, \sigma_{t_i}^2 I) N(z_i|0, I) \pi_{t_i}$$

or non-linear PCA

$$\begin{aligned}p(X, Z|\theta) &= \prod_i p(x_i|z_i, \theta) p(z_i|\theta) \\ &= \prod_i \left[\prod_j N(x_{ij}|\mu_j(z_j), \sigma_j^2(x_j)) \right] N(z_i|0, I)\end{aligned}$$

(mean and variance of the factorized (diagonal) Gaussian are nonlinear functions of the latent variables instead of linear or constant).

For the E step, we need $q(z) = \prod_i p(z_i|x_i, \theta)$, which is intractable: use a variational approximation

$$\begin{aligned}q(z_i|x_i, \phi) &\approx p(z_i|x_i, \theta) \\ q(z_i x_i, \phi) &= \prod_j N(z_{ij}|\mu_j(x_i), \sigma_j^2(x_i))\end{aligned}$$

where μ_j and σ_j are other neural nets. The ELBO

$$\mathcal{L}(\phi, \theta) = \int q(Z|X, \phi) \log \frac{p(X|Z, \theta)p(Z)}{q(Z|X, \phi)} dZ$$

is intractable:

- Instead of doing a full optimization at each step, alternatively for ϕ and θ , optimize jointly for (ϕ, θ) using gradient descent;
- Use mini-batches;
- Express $\nabla_{\theta} \mathcal{L}$ and $\nabla_{\phi} \mathcal{L}$ as expectations, and approximate them with Monte Carlo;
- Somehow reduce the variance of those gradient estimators.

$$\nabla_{\theta} \mathbb{E}_{z \sim q_{\phi}} [f(z, \theta)] = \mathbb{E}_{z \sim q} [\nabla_{\theta} f(z, \theta)]$$

$$\nabla_{\phi} \mathbb{E}_{z \sim q_{\phi}} [f(z, \phi)] = \mathbb{E}_{z \sim q_{\phi}} [\nabla_{\phi} f(z, \phi)] + \mathbb{E}_{z \sim q_{\phi}} [f(z, \phi) \nabla_{\phi} \log q_{\phi}(z)]$$

Monte Carlo estimators of the second term (REINFORCE estimator) are unstable: the score function, $\nabla_{\phi} \log q_{\phi}(z)$, whose expectation is zero, oscillates. To reduce the variance, use a baseline,

$$\mathbb{E}_{z \sim q_{\phi}} [(f(z, \phi) - B(\phi)) \nabla_{\phi} \log q_{\phi}(z)]$$

with $B(\phi) \approx E[f]$, or use the *reparametrization trick* (only for continuous variables), replacing $z \sim q_{\phi}$ with $\varepsilon \sim r, z = g_{\phi}(\varepsilon)$.

$$\begin{aligned}\nabla_{\phi} \mathbb{E}_{z \sim q_{\phi}} [f(z, \phi)] &= \nabla_{\phi} \mathbb{E}_{\varepsilon \sim r} [f(g_{\phi}(\varepsilon), \phi)] \\ &= \mathbb{E}_{\varepsilon \sim r} [\nabla_{\phi} f(g_{\phi}(\varepsilon), \phi)]\end{aligned}$$

q	r	$y = g_{\phi}(\varepsilon)$
$N(\mu, \sigma^2)$	$N(0, 1)$	$y = \mu + \sigma \varepsilon$
$\text{Gamma}(1, \beta)$	$\text{Gamma}(0, 1)$	$y = \beta \varepsilon$
$\text{Exp}(\lambda)$	$U(0, 1)$	$y = -\lambda^{-1} \log \varepsilon$
$N(\mu, AA')$	$N(0, I)$	$y = \mu + A \varepsilon$

A meta-transfer objective for learning to disentangle causal mechanisms Y. Bengio et al. (2019)

Latent representations that best encode causal relations are better at transfer learning: optimize for fast transfer learning and robustness to distributional changes.

For instance the following two models, for discrete variables, are equivalent,

$$\begin{aligned}P(A, B) &= P(A)P(B|A) \\ P(A, B) &= P(B)P(A|B)\end{aligned}$$

but if one undergoes a sparse change (e.g., an unknown intervention in a correct causal model), it will adapt faster.

Instead of considering separate models, one can consider a mixture.

$$\begin{aligned}R &= \log [\sigma(\gamma) \cdot \text{Lik}_{A \rightarrow B} + (1 - \sigma(\gamma)) \cdot \text{Lik}_{B \rightarrow A}] \\ \frac{\partial R}{\partial \gamma} &= \sigma(\gamma) - \sigma(\gamma + \Delta) \\ \Delta &= \log \frac{\text{Lik}_{A \rightarrow B}(\text{new data})}{\text{Lik}_{B \rightarrow A}(\text{new data})}\end{aligned}$$

The variables A and B need not be observed: they can be a latent representation.

1. A causal model contains more information than a probabilistic model.

2. A joint probability on (X, Y) is consistent with both $X \rightarrow Y$ and $X \leftarrow Y$:

$$p(x, y) = p(x)p(y|x) = p(y)p(x|y).$$

To infer the direction of causality, we can rely on:

- Interventions: change x and check if y changes;
- The “independence” of cause p_X and mechanism $p_{Y|X}$ – for a notion of independence to be defined;
- The independence of the noises in the **structural causal model** (SCM):

$$\begin{aligned} X &= N_X \\ Y &= f(X, N_Y) \\ N_X &\perp\!\!\!\perp N_Y. \end{aligned}$$

(The influence of time is not always clear: in psychology, cause and effect tend to be simultaneous; at the microscopic scale, the laws of physics are invertible.)

3. To model an *intervention* with a SCM, just change the corresponding assignment.

To study *counterfactuals* with an SCM

$$\begin{aligned} X &= N_X \\ Y &= f(X, N_Y), \end{aligned}$$

observe (x, y) , compute N_X and N_Y , then change the value of X (equivalently, N_X) and see how it affects Y . Counterfactual statements are not transitive ($X = 2 \Rightarrow Y = 5$, $Z = 2 \Rightarrow Y = 10$, $X = 2 \not\Rightarrow Z = 10$).

Do not confuse conditional probabilities, interventions (do-calculus) and counterfactuals: even if the interventional probabilities are the same, the counterfactual statements can differ.

4. Causal inference is possible with just two variables, but requires additional assumptions.

$$\begin{array}{ccc} C & \longrightarrow & E \\ \text{cause} & & \text{effect} \end{array}$$

Indeed, every joint distribution (X, Y) can be written $Y = f(X, N_Y)$, $X \perp\!\!\!\perp N_Y$: just set $f(x, n_Y) = F_{Y|X}^{-1}(n_Y)$, $N_Y \sim U(0, 1)$.

One can restrict the class of models, so that they can only be written in one direction (and hope that this direction is the “causal” one).

- Linear models with non-Gaussian additive noise (LiNGAM), $E = \alpha C + N_E$, $N_E \perp\!\!\!\perp C$;
- Non-linear additive noise model (ANM), $Y = f(X) + N_Y$, $N_Y \perp\!\!\!\perp X$;
- Discrete additive noise;
- Post-nonlinear model, $Y = g(f(X) + N_Y)$, $N_Y \perp\!\!\!\perp X$.

One can choose the direction in which P_C and $P_{E|C}$ are “independent”, in some sense.

- For a deterministic relation,

$$Y = f(X), \quad f: [0, 1] \rightarrow [0, 1], \quad f(0) = 0, \quad f(1) = 1,$$

IGCI (information geometric causal inference) independence is defined as $\text{Cor}[\log f', p_X] = 0$ (where $\log f'$ and p_X are seen as probability densities). We then have $\text{Cor}[\log(f^{-1})', p_Y] \geq 0$, with equality if $f = \text{id}$ (the peaks of p_Y are regions where f has small slope and f^{-1} large slope: p_Y contains information on f^{-1}).

- In high dimension, the model $Y = AX + N_X$, $N_X \perp\!\!\!\perp X$, $A \in \mathbf{R}^{e \times d}$ satisfies the *trace condition* if $\tau_e(A \Sigma_{XX} A') = \tau_d(\Sigma_{XX}) \tau_e(AA')$, where $\tau_k(B) = \text{trace}(B)/k$ (it measures the “independence” of A and P_X). If A is invertible and $N_X = 0$, then $\tau(A^{-1} \Sigma_{YY} A^{-1'}) \leq \tau(\Sigma_{YY}) \tau(A^{-1} A^{-1'})$, with equality if all the singular values of A have the same absolute value.
- P_C and $P_{E|C}$ are *algorithmically independent* if the algorithmic mutual information

$$I(P_C : P_{E|C}) := K(P_C) + K(P_{E|C}) - K(P_{C,E})$$

is zero, where K is the Kolmogorov complexity. This implies $K(P_C) + K(P_{E|C}) \leq K(P_E) + K(P_{E|C})$ (it is easier to describe $C \rightarrow E$ than $E \rightarrow C$).

Implementation:

- Regression with subsequent independence tests (RESIT), for additive noise models, estimates $y \sim x$ and $x \sim y$, and tests $x \perp\!\!\!\perp y - \hat{y}$ and $y \perp\!\!\!\perp x - \hat{x}$, with an independence test looking beyond correlation, e.g., HSIC (in R, use `mgcv::gam(y~x)` and `dHsic::dhsic.test`). Alternatively, compute the log-likelihoods

$$L_{X \rightarrow Y} = -\log \text{Var } X - \log \text{Var}(y - \hat{y}).$$

- For IGCI, estimate $C_{X \rightarrow Y} = \int_0^1 \log f'(x) p(x) dx$ as

$$\hat{C}_{X \rightarrow Y} = \frac{1}{N-1} \sum_{j=1}^{N-1} \log \left| \frac{y_{j+1} - y_j}{x_{j+1} - x_j} \right|,$$

where $x_1 < x_2 < \dots < x_N$; it should be smaller in the causal direction; one could also use $H(X)$ instead of $C_{X \rightarrow Y}$

- For the trace method, compute

$$r_{X \rightarrow Y} = \frac{\tau(A_Y \Sigma_{XX} A_Y')}{\tau(A_Y A_Y') \tau(\Sigma_{XX})}$$

it is closer to 1 in the causal direction.

One could train a machine learning model, using datasets (or *dataset features*) as inputs.

5. *Semi-supervised learning* does not work well if $X \rightarrow Y$ (but even in this case, knowing P_X can help build a classifier with lower loss: the loss involves \hat{p}_X).

Covariate shifts can help, if a change in $P_{X,Y}$ is better explained by a change in P_X (with $P_{Y|X}$ unchanged) than by a change in P_Y .

6. SCMs satisfy the *Markov property*, equivalently:

- d -separation implies conditional independence;
- Any X is independent of its non-descendants given its parents;
- $P(X) = \prod P(X_i | \text{Pa}(X_i))$.

Two graphs are in the same Markov equivalence class if they have the same skeleton and the same v -structures (or “immoralities”: two non-directly-linked parents).

The *completed partially directed acyclic graph* (CPDAG) of a Markov equivalence class contains a directed edge $i \rightarrow j$ iff one of the DAGs in the equivalence class has it.

The *Markov blanket* of a node contains its parents, its children, and its children’s parents.

A probability distribution is *faithful* wrt a graph if conditional independence implied d -separation.

A causal effect is *confounded* if

$$P^{\text{do } X=x}(y) \neq P(y | X = x).$$

In the kidney stone example (Z is the size of the stone, large or small, T the treatment, invasive or not, and R , the outcome),

the average causal effect (**ACE**) is

$$P^{\text{do } T=A}(R=1) - P^{\text{do } T=B}(R=1) \\ \neq P(R=1 | T=A) - P(R=1 | T=B)$$

(the signs can even be different: Simpson’s paradox), but we can adjust for Z :

$$P^{\text{do } T=A}(R=1) = \sum_z P(R=1 | T=A, Z=z) P(Z=z).$$

When those equalities hold, Z a *valid adjustment set* of $T \rightarrow R$.

The parents of X form a valid adjustment set for Y (if $Y \notin \text{Pa}(X)$) More generally, Z is a valid adjustment set if it blocks all non-directed paths from X to Y and contains no descendant of any node on a directed path from X to Y .

In a linear Gaussian model, the effect of X on Y can be summarized by a single number,

$$\frac{\partial}{\partial x} E^{\text{do } X=x}[Y].$$

The *propensity score* compresses the influence of several confounders Z into a lower-dimensional variable L .

Pearl’s *do-calculus* is a list of (three) rules saying when we can add or remove a condition, or a “do” action, or replace an action by a condition.

To check *interventional equivalence*, it suffices to consider interventions on single variables, replacing them with noise.

The *unit-level causal effect* is $B_u(t=1) - B_u(t=0)$. The *average causal effect* is

$$CE = \text{Mean}_u B_u(t=1) - B_u(t=0).$$

For a randomized experiment, it can be estimated as

$$\widehat{CE} = \frac{1}{\#U_1} \sum_{u \in U_1} B_u(t=1) - \frac{1}{\#U_0} \sum_{u \in U_0} B_u(t=0).$$

SCMs can be generalized to non-statistical information measures, non-probabilist notions of independence. Let $R : 2^V \rightarrow \mathbf{R}_+$ be a non-decreasing function, measuring the information in a subset $x \subset V$. The conditional information is $R(x, y) - R(y) \geq 0$. The conditional mutual information is

$$I(x : y | z) = R(x, z) + R(y, z) - R(x, y, z) - R(z);$$

it is non-negative if R is modular. We can write $x \perp\!\!\!\perp_R y | z$ when it is zero. For a graph such that $R(x_j, \text{Pa}_j, n_j) = R(\text{Pa}_j, n_j)$ (a node x_j does not contain more information than its parents and its unobserved node n_j) and $R(n_1, \dots, n_d) = \sum R(n_j)$ (the unobserved nodes are independent), d -separation implies conditional independence (wrt R). Examples of such an R include the number of words in a text, or the multi-information,

$$I(x_1, \dots, x_d) = K(x_1, \dots, x_d) - \sum_j K(x_j),$$

where K is the Kolmogorov complexity. The algorithmic independence of conditionals,

$$I(P_{X_1 | \text{Pa}_1}, \dots, P_{X_d | \text{Pa}_d}) = 0$$

is equivalent to

$$K(P_{X_1, \dots, X_d}) = \sum K(P_{X_j | \text{Pa}_j}).$$

7. The DAG is identifiable in the following cases:

- Linear Gaussian with equal error variances;
- Linear non-Gaussian acyclic model (LiNGAM),

$$X_i = \sum_{k \in \text{Pa}_i} \beta_{ik} X_k + N_i;$$

- Nonlinear Gaussian additive noise model

$$X_i = f_i(\text{Pa}_i) + N_i,$$

and its special case, the causal additive model (CAM),

$$X_i = \sum_{k \in \text{Pa}_i} f_{ik}(X_k) + N_i.$$

Known interventions can also help identify the graph.

There are two types of algorithms to infer the structure of an SCM.

- Some (IC (inductive causation), PC, SGS) test for conditional independence, *i.e.*, d -separation: we can detect v-structures; the CPDAG is identifiable. The conditional independence tests can be based on partial correlation, or be nonlinear: $X \perp\!\!\!\perp Y|Z$ if $X - E[X|Z] \perp\!\!\!\perp Y$ or $Y - E[Y|Z] \perp\!\!\!\perp X$.
- Score-based methods assume that the correct graph gives a better fit to the data and maximize the BIC, or the Bayesian Dirichlet (BD) score (for discrete variables, following a multinomial distribution, with a Dirichlet prior), or the BDe (BD equivalent, accounting for Markov-equivalence). (Greedy equivalence search (GES) uses the BIC, starts with an empty graph, greedily adds edges until a local maximum, then tries to remove some of them, and stops there.)

It is possible to combine score- and independence-based approaches (MaxMin hill climbing). The following can also help infer the structure of the graph:

- Intervention with known targets;
- Intervention with unknown targets (models with a smaller number of intervened variables are more likely);
- Environment changes (we sometimes observe the same SCM, with different parameters).

R software to estimate SCMs include `pcalg`, `bnlearn`, `CompareCausalNetworks`, `InvariantCausalPrediction`, `daggity`.

8. Half-sibling regression was used for exoplanet search.

9. Simpson's paradox shows that ignoring hidden variables can lead to incorrect causal conclusions – causal reasoning is very sensitive to model mis-specification.

A set of random variables is *causally sufficient* if there are no hidden causes influencing more than one variable.

An *instrumental variable* Z allows us to find the ACE

(average causal effect) α in $Y = \alpha X + \delta H + N_Y$.

If you ignore the hidden variables (and apply the PC algorithm), you can get incorrect causal conclusions.

DAGs are not closed under marginalization; there are many extensions:

- MAG (maximal ancestral graphs);
- PAG (partially ancestral graphs);
- IPG (induced path graph);
- POIPG (completed partially oriented induced path graph);
- ADMG (acyclic directed mixed graph);
- Chain graphs.

The FCI (fast causal inference) algorithm is a generalization of the PC algorithm to PAGs.

Conditional independences are not the only constraints that can help identify a model:

- Verma constraints,

$$\sum_b P(b|a)P(d|a, b, c) = f(c, d)$$

which can detect the presence of a directed edge $A \rightarrow D$;

- Bell's inequality (which ruled out hidden variables in quantum mechanics);
- Elementary inequalities, in information theory, and their generalizations;
- Covariance-based constraints, such as

$$\rho_{AC}\rho_{BD} = \rho_{AD}\rho_{BC} = \rho_{AB}\rho_{CD}$$

- An additive model

$$\begin{aligned} H &= N_H \\ X &= f(H) + N_X \\ Y &= g(H) + N_Y \end{aligned}$$

can be estimated by (nonlinear) dimension reduction;

- One can detect if a path is blocked by a hidden variable with few values.

10. With time series, the DAG is often identifiable, even in presence of instantaneous effects.

Granger causality relies on

$$X_t^k \perp\!\!\!\perp X_{<t}^j | X_{<t}^{-j} \implies X^j \rightarrow X^k$$

(if there are no instantaneous effects). There are non-linear variants of Granger causality. The transfer entropy $TE(X \rightarrow Y) = I(Y_t : X_{<t} | Y_{<t})$ looks tempting, but it fails to measure the strength of an influence.

VAR models can be generalized

$$X_t^i = f_i((Pa_q^i)_{t-q}, \dots, (Pa_0^i)_t) + N_t^j.$$

The **spectral independence criterion** (SIC) is another way of formalizing the independence between cause and mechanism.

$$\begin{aligned} Y_t &= \sum_{k \geq 1} h(k) X_{t-k} \\ C_{XX}(\tau) &= E[X_t X_{t-\tau}] \\ S_{XX} &= \hat{C}_{XX} \text{ (Fourier transform)} \\ S_{YY}(\nu) &= \left| \tilde{h}(\nu) \right|^2 S_{XX}(\nu) \end{aligned}$$

The SIC is

$$\langle S_{XX} \cdot |\tilde{h}(\nu)|^2 \rangle = \langle S_{XX} \rangle \langle |\tilde{h}(\nu)|^2 \rangle,$$

where $\langle f \rangle = \int_{-1/2}^{1/2} f(\nu) d\nu$; one then has

$$\langle S_{YY} \cdot |\tilde{h}(\nu)|^2 \rangle \leq \langle S_{YY} \rangle \langle |\tilde{h}(\nu)|^2 \rangle,$$

with equality if $|\tilde{h}(\nu)|$ is constant.

Machine learning in finance **M.F. Dixon et al. (2020)**

The inconsistent notations make the book needlessly difficult to read.

1. Statistics assumes the data generation process is known, while machine learning does not, but the models are very similar:

- ARIMA and RNN (*i.e.*, NARX) model stationary time series;
- GARCH and GRNN model stationary, heteroskedastic time series;
- CNN generalizes exponential smoothing;
- Auto-encoders generalize PCA.

In supervised learning, a “teacher” provides the right answer; in reinforcement learning (RL), the teacher only provides a “reward”.

The optimal investment problem can be written

$$\begin{aligned} S_{t+1} &= S_t \cdot (1 + \phi_t) && \text{asset price} \\ W_{t+1} &= (1 - u_t)W_t + u_t W_t (1 + \phi_t) && \text{wealth} \\ r_t &= \frac{W_{t+1} - W_t}{W_t} = u_t \phi_t && \text{portfolio returns} \\ R_t &= r_t - \lambda \text{Var}[r_t] && \text{reward.} \end{aligned}$$

The policy u_t maximizing $E \sum R_t$ is

$$u_t^* = \frac{E[\phi_t]}{2\lambda \text{Var}[\phi_t]}$$

Other examples include:

- Algorithmic trading, where the state is the 5-day returns (momentum of all 500 stocks in the S&P 500) and the action whether to buy the S&P500 for 5 days or not;
- Execution: the input is the limit order book (LOB), the output, the next mid-price;
- Mortgage: the output is the mortgage state, the input the previous state and explanatory variables.

2. Neural networks are well-suited to point-wise estimation – we also want to estimate uncertainty.

For frequentists, the source of uncertainty is that we only have a sample, not the whole population (θ is fixed, and $\hat{\theta}$ is a random variable, which depends on the sample).

$$\begin{aligned} \text{MSE}(\hat{\theta}) &:= E \left\| \hat{\theta} - \theta \right\|_2^2 \\ \text{bias}(\hat{\theta}, \theta) &:= E[\hat{\theta} - \theta] = E[\hat{\theta}] - \theta \\ \text{MSE}(\hat{\theta}, \theta) &= \text{tr Var}[\hat{\theta}] + \left\| \text{bias}(\hat{\theta}, \theta) \right\|_2^2 \end{aligned}$$

- If n is large and p small, the frequentist and **Bayesian approaches** are (asymptotically) equivalent.
- If p is large or the likelihood intractable, the Bayesian approach is easier.
- If n is small, prefer the Bayesian approach: frequentist results are often only asymptotic.

For model selection, frequentist tests and AIC assume the models are nested.

If the priors are equal, the Bayes factor is equal to the posterior odds.

$$\begin{aligned} B &= \frac{P(\text{data}|\text{model}_1)}{P(\text{data}|\text{model}_2)} \\ P(\text{data}|\text{model}) &= \int_{\theta} p(x|M, \theta) p(\theta|M) d\theta \\ \frac{P(\text{model}_1|\text{data})}{P(\text{model}_2|\text{data})} &= \frac{P(\text{model}_1) P(\text{data}|\text{model}_1)}{P(\text{model}_2) P(\text{data}|\text{model}_2)} \end{aligned}$$

The Bayesian approach prevents overfitting: if the model is too complex, $P(\text{data}|\text{model})$ is low.

Bayesian model averaging uses $P(\text{model}|\text{data})$ as weights.

Logistic regression is a *discriminative model* estimating $P(y|x)$. The naive Bayes model is the corresponding *generative model*:

$$P(x, y) = p(y) \prod p(x_i | y).$$

3. Bayesian linear regression is a **Gaussian process**:

$$\begin{aligned} \theta_0, \theta_1 &\sim N(0, 1) \\ y &= \theta_0 + \theta_1 x \\ E[y_i y_j | x_i, x_j] &= 1 + x_i x_j \end{aligned}$$

An $\text{AR}(p)$ model is a discrete equivalent of GP regression with a Matern kernel.

Gaussian process regression is available in `sklearn`, `GpyTorch` or `Stan`.

In finance, GP regression can be used for option pricing (train on a grid):

parameters \mapsto price, greeks, precision.

For large amounts of data, use **structured kernel interpolation** (SKI):

- Choose a subset of points U ;
- Use local cubic interpolation: $K_{X,U} \approx W_X K_{U,U}$, with W_X sparse;
- Note that $K_{X,Z} \approx W_X K_{U,U} W_Z'$.

If the inducing points U form a grid and K is an RBF kernel, $K_{U,U}$ is a Kronecker product of Toeplitz matrices: $K_{U,U} = T_1 \otimes \dots \otimes T_p$. Use conjugate gradient (CG) to solve $K^{-1}y$, and compute $\log \det K$ with an approximate diagonalization (Toeplitz matrices are almost circulant, and circulant matrices are diagonalizable with a Fourier transform); rescale to $[0, 1]^n$ for numeric stability. For extrapolation, combine squared exponential (SE) and linear kernels.

The GP also provides analytic derivatives (Greeks): $\partial_{x^*} \mathbb{E}[f|x, y, x^*] = \partial_{x^*} \mu_{x^*} + \partial_{x^*} K_{x^*,x} (K_{x,x} + \sigma^2 I)^{-1} y$

Gaussian processes can have a multi-dimensional response:

$$f \sim \text{MGP}(m\mu, K, \Omega)$$

$$\text{vec}[f(x_1), \dots, f(x_n)] \sim N(\text{vec } M, \Sigma \otimes \Omega)$$

4. The VC dimension of a **feed-forward network** is

$$\text{VC dim} \geq W \times L \times \log \frac{W}{L}$$

where L is the number of layers and W their width.

If the payoff of an option, the option price is a convex function of the spot price: to ensure convexity in a neural net, have the weights of all the layers but the first be positive.

Neural networks can be used in option pricing, e.g., to compute the option price V from the spot price S (with constraints: $V \geq 0$, convex, $0 \leq \Delta \leq 1$) or to predict the implied volatility σ from the moneyness $M = S/K$ (with constraints: $\sigma > 0$, convexity) – more constraints may be needed to avoid arbitrage (e.g., option price increasing wrt T , convex wrt K).

Bayesian neural nets add noise to the weights.

5. To interpret a neural net, compute its **sensitivities**, $\partial y / \partial x$, and $\partial^2 y / \partial x_i \partial x_j$ for the interactions

For instance, the linear risk model $r = Bf + \varepsilon$ can be generalized into a nonlinear risk model $r_t = F_t(B_t) + \varepsilon_t$; the sensitivities can be interpreted as (non-linear) factor returns.

7. The *stochastic volatility model with leverage and jumps* (SVLJ) is

$$y_t = \varepsilon_t \cdot e^{x_t/2} + J_t \pi_t$$

$$x_{t+1} = \mu(1 - \phi) + \phi x_t + \sigma \eta_t$$

$$\begin{pmatrix} \eta_t \\ \varepsilon_t \end{pmatrix} \sim N(0, \Sigma)$$

$$\Sigma = \begin{pmatrix} 1 & \rho \\ \rho & 1 \end{pmatrix}$$

$$\rho < 0 \text{ (leverage)}$$

$$\pi_t \sim N(0, \sigma^2)$$

$$J_t : \text{ jump, with parameter } p$$

8. The generalized RNN (GRNN) accounts for heteroskedasticity by using the Mahalanobis distance in the loss.

Use stationarity and autocorrelation tests to decide which lag to use in a RNN; for stationary time series, a plain RNN is good enough, for non-stationary ones, GRU or LSTM are preferable.

CNNs generalize weighted moving averages; one can also use non-uniform lags, e.g., 2^k (non-sequential model).

Auto-encoders generalize PCA, for instance to model the yield curve (from the changes in yields).

With ReLU activations, the nonlinear factors learned by an auto-encoder to explain the variability of a portfolio can be built from puts and calls – they are investible.

9. The exploration-exploitation dilemma only appears in online RL – *batch-mode RL*, more common in finance, cannot explore.

SARSA (on-policy) or Q-learning (off-policy) can solve the optimal stock execution problem (linear impact model), after discretizing everything (prices, shares left to sell, time, action):

$$S_{t+1} = S_t(1 - \mu a_t) + \sigma Z_t$$

$$a_t : \text{ shares sold}$$

$$\sum a_t = V$$

$$s_t \geq 0$$

$$r_t = a_t S_t = \lambda \text{Var}[S_{t+1} x_{t+1}] \text{ reward}$$

$$a_t S_t : \text{ value of the shares sold}$$

$$X_{t+1} : \text{ shares left to sell}$$

Portfolio trading (multi-period portfolio management) is another example: the state, $s_t = (p_t, b_t, X_t)$, contains the portfolio composition (stock), the bond investment, and the market state (Markov or, if the lag is too large, HMM). The reward is

$\text{reward}_t = \text{portfolio return} - \lambda \cdot \text{Var}[\text{portfolio return}]$.

The max can be replaced with the *mellow max*

$$\text{mm}(\mathbf{x}) = \frac{1}{\omega} \log \left(\frac{1}{n} \sum e^{\omega x_i} \right).$$

10. Reinforcement learning is trickier in finance, because of the higher dimension and the lower signal/noise ratio.

In option pricing, RL can provide replicating portfolios, minimizing the risk-adjusted cost of hedging:

$$\begin{aligned} H_T(S_T) & \quad \text{payoff} \\ \Pi_t = u_t S_t + B_t & \quad \text{hedge portfolio} \\ u_T = 0 \\ \Pi_T = B_T = H_T(S_T) \\ u_t S_{t+1} + e^{r\Delta t} B_t = u_{t+1} S_{t+1} + B_{t+1} \\ B_t = e^{-r\Delta t} [B_{t+1} + (u_{t+1} - u_t) S_{t+1}] \end{aligned}$$

$$u_t^*(S_t) = \underset{u}{\text{Argmin}} \text{Var}[\Pi_t | \mathcal{F}_t] = \frac{\text{Cov}(\Pi_{t+1}, \Delta S_t | \mathcal{F}_t)}{\text{Var}(\Delta S_t | \mathcal{F}_t)}$$

In higher dimensions, prefer probabilistic methods to Q-learning.

$$\begin{aligned} x_t & \quad \text{portfolio values} \\ b_t & \quad \text{cash} \\ v_t = \mathbf{1}' x_t + b_t & \quad \text{portfolio value} \\ x_t^+ = x_t + u_t & \quad \text{investment decision} \\ \mathbf{1}' u_t + b_t^+ - b_t = 0 & \quad \text{self-financing, } v_t = v_t^+ \\ p_{it} & \quad \text{asset prices} \\ r_t & \quad \text{asset returns} \\ x_{t+1} = (\mathbf{1} + r_t) \odot x_t^+ & \\ r_t - r_f \mathbf{1} = W z_t + M' u_t + \varepsilon_t & \quad \text{asset return model} \\ z_t & \quad \text{predictors} \\ M' u_t & \quad \text{market impact} \\ z_{t+1} = (I - \Phi) \odot z_t + \varepsilon_t^z & \quad \text{OU process} \\ y = \begin{pmatrix} x \\ z \end{pmatrix} & \quad \text{state} \\ R^0 = (r_t - r_f \mathbf{1})'(x_t + u_t) & \quad \text{wealth gain} \\ R = R^0 - \lambda \text{Var}[R^0] - \text{impact} - \text{fee} & \quad \text{reward} \end{aligned}$$

The Bellman equation can be written

$$\begin{aligned} V^*(y) &= \underset{a}{\text{Max}} R(y, a) + \gamma \text{E}[V^*(y')] \\ &= \underset{\pi}{\text{Max}} \underset{a \sim \pi}{\text{E}} [R(y, a) + \gamma \text{E}[V^*(y')]]. \end{aligned}$$

One can then add a penalty

$$\frac{1}{\beta} \log \frac{\pi(a|y)}{\pi_0(a|y)}$$

for each time step

$$\frac{1}{\beta} \sum_{t' \geq t} \gamma^{t'-t} \log \frac{\pi(a_{t'}|y_{t'})}{\pi_0(a_{t'}|y_{t'})}.$$

G-learning is Q-learning with a stochastic policy and an entropy penalty, for noisy environments (the G-function is the Q-function with an entropy penalty).

F-learning is the analogue for the the state value function V . *Soft-Q-learning* is G-learning with a uniform prior π_0 .

RL also applies to wealth management,

$$W_{t+1} = (W_t - c_t)[(1 - \alpha_t)R + \alpha_t R_f]$$

where the policy is $(c_t, \alpha_t)_{0 \leq t < T}$ and the reward CRRA utility.

For instance, for a defined-contribution retirement plan,

$$\begin{aligned} x_t &: \text{asset values (including cash)} \\ u_t &: \text{changes} \\ r_t &: \text{returns} \\ \bar{r}_t &: \text{average returns} \\ \Sigma_t & \\ c_t &: \text{cash inflow} \\ -c_t &: \text{consumption} \end{aligned}$$

the reward is

$$-c_t - \lambda \text{E}[(\text{target} - (1 + r_t)(x_t + u_t))_+] - u_t' \Omega u_t,$$

where the second term is a penalty for missing a target portfolio value (replace it with a quadratic penalty for tractability), and the last term is a regularizer.

11. *Behavioural cloning* does not generalize well: the model does not understand the dynamics of the system. Instead, learn the reward function.

In **inverse reinforcement learning** (IRL), the data is (s, a, s') , not (s, a, r, s') , and the goal is to find both a reward function r and a policy π . The reward function is not well-specified: the optimal policy is unchanged if the reward is transformed as

$$\tilde{r}(a, a, s') = r(s, a, s') + \gamma \Phi(s') - \Phi(s).$$

GAIL (generative adversarial imitation learning) calibrates the reward function so that the solution of the RL problem looks like the demonstration.

We can also learn from failed trajectories (labeled as such) – they are actions to avoid. IRLF (IRL from failure) looks for a policy leading to trajectories close to the successful ones and far from the failed ones.

T-REX (Trajectory-ranked Reward EXtrapolation) learns preferences: not the absolute values $r(s, a)$, but just whether $r(s, a) > r(s', a')$.

Financial applications Infer the reward function of a single agent: - high-frequency trading strategy identification (e.g., for fraud detection by regulators): cluster the strategies using the learned reward functions, rather than arbitrary features, which could be uninformative - reward function of a risk-averse option trader: assuming the trader uses the QLBS model, there is only one parameter to find, the risk aversion - reward function of a portfolio investor (...) Infer the reward function of the "average" investor: - Investor

sentiment State: market data Actions: sentiment (discretized into 3 levels), from news Reward: to estimate – it will yield “useful” features; dimension reduction of market data - Inflow/outflow for a single stock Idem, but the actions are the inflow/outflow for a single stock

Machine learning for factor investing **G. Coqueret and T. Guida (2020)**

The authors provide data: 100 characteristics, uniformized, for 1000 stocks (in the US), monthly, over 20 years.

4. Fama-MacBeth regressions proceed in two steps:

- For each stock, regress the returns against the factor returns, yielding the exposure β_{ik} of stock i to factor k ;
- For each date, regress the stock returns against the exposures, yielding the premium γ_{tk} of factor k at time t .

Note the difference between *characteristics* (e.g., E/P) and *exposures* (e.g., β to the “high E/P minus low E/P ” portfolio).

The factor portfolios are often cryptically called SMB (size), HML (value), WML (momentum), RMW (profitability), CMS (investment), BAB (low risk).

5. The features are autocorrelated but the label (the variable to predict) is not: try to remove the autocorrelation.

Removing noisy observations (not only outliers, but also 60% of the values in the center of the distribution) may help.

10. The **BART** package provides Bayesian additive regression trees (regression trees with a prior which, after Monte Carlo sampling, can be used as ensemble).

12. Combine several models with ensembles, forecast combinations (find weights w , nonnegative and summing to 1, to combine forecasts from several models – the nonnegative constraint has a sparsifying effect) and stacked ensembles.

Use decision trees to forecast the absolute error of a model from macro-economic variables; then, use it as a regime indicator.

13. In portfolio optimization, try to add a diversifying constraint $w'w \leq \delta$ (or a penalty) on the Herfindahl index.

Try to forecast returns scaled by volatility, r/e^σ , instead of returns.

14. To interpret models, check the **iml**, **lime**, **breakDown** packages.

15. To infer a causal graph from data, check the **pcalg**, **CAM** or **baycn** package.

The **CausalImpact** and **bsts** packages fit structural time series models, to detect or test for the presence of regime changes.

The **ReinforcementLearning** package provides Q -

learning on SARS data (state, action, reward, next state), for discrete state and action spaces.

Towards a definition of disentangled representations **I. Higgins et al. (2018)**

A latent representation is disentangled wrt a symmetry group of the set of world states, decomposed as a direct product $G = G_1 \times \dots \times G_n$, if:

- The action of G on the world states extends to an action on the latent representations, making the map

$$\text{World states} \mapsto \text{Latent representations}$$

equivariant;

- The space of latent representations decomposes as $V = V_1 \times \dots \times V_n$, such that each G_i acts on V_i and leaves the other V_j ’s invariant.

Note that:

- The decomposition of G is not unique (e.g., for translations in the plane, any basis gives a decomposition $\mathbf{R}^2 \approx \mathbf{R} \times \mathbf{R}$);
- There may be no non-trivial decompositions of G (e.g., rotations, $\text{SO}(3)$).

If V is a vector space and the action linear, we can further decompose the latent space into irreducible representations.

Disentangling by subspace diffusion **D. Pfau et al. (2020)**

Let M be an orientable Riemannian manifold. The parallel transport along a loop $\gamma : [0, 1] \rightarrow M$, $\gamma(0) = \gamma(1) = x$ at a point $x \in m$, defines a linear map $H_\gamma : T_x M \rightarrow T_x M$ – the *holonomy* of γ . The **holonomy group** at x , $\text{Hol}_x(M)$, is the set of all such maps. If $M = M_1 \times \dots \times M_n$, then $T_x M = \bigoplus T_x M_i$ (orthogonal decomposition) and the action of each $\text{Hol}_x(M)$ leaves each $T_x M_i$ invariant. If M is simply connected and geodesically complete, the converse is true (*deRham decomposition theorem*): if a proper subspace $U \subsetneq T_x M$ is invariant under $\text{Hol}_x M$ for some x , then $M = M_1 \times M_2$, $U = T_x M_1$, $U^\perp = T_x M_2$.

The holonomy group requires all loops: instead, we can get the same information from random walks, and the corresponding diffusion

$$\frac{\partial p(x, t)}{\partial t} = \Delta^0 p(x, t),$$

where Δ^0 is the Laplace-Beltrami operator on functions on M . The Laplacian can be generalized to a Laplacian Δ^1 on TM , and a “second-order connection Laplacian” Δ^2 on $T^*M \otimes TM$. If $M = M_1 \times \dots \times M_n$, then the projections $T_x M \rightarrow T_x M_i$ are in the kernel of Δ^2 (eigenfunctions for $\lambda = 0$).

The Geomancer (genmetric manifold component estimator) algorithm estimates Δ^2 from points in M :

- Build the symmetric nearest neighbour graph;

- For each i , perform PCA on the $x_j - x_i$, $j \in N(i)$, to get local coordinates U_i and local tangent vectors v_j : $x_j - x_i \approx U_i v_j$;
- Compute the graph Laplacian

$$\Delta^0 f = \left(\sum_{j \in N(i)} f_i - f_j \right)_i$$

$$\Delta^1 v = \left(\sum_{j \in N(i)} v_i - Q'_{ij} v_j \right)_i$$

$$\Delta^2 \Sigma = \left(\sum_{j \in N(i)} \Sigma_i - Q'_{ij} \Sigma_j Q_{ij} \right)_i;$$

- The parallel transport Q_{ij} induced by the ambient (Euclidean) space can be estimated from the local coordinates $Q_{ij} = U_{ij} V'_{ij}$, where $U'_j U_i = U_{ij} \Sigma_{ij} V'_{ij}$ is the SVD decomposition;
- To avoid spurious eigenfunctions (skew symmetric matrices, and small eigenvalues from Δ^0), consider the action of Δ^2 on symmetric, zero-trace matrices
 - the eigenfunctions are linear combinations of the desired projections.

***Robustly disentangled causal mechanisms:
validating deep representations
for interventional robustness***

R. Suter et al.

The VAE penalty can be modified to impose more structure on the latent space: β -VAE (stronger penalty); FactorVAE, β -TCVAE (ICA); DIP-VAE.

If the “generative factors” G_i are known (orientation, position, shape, colour, etc.), one can try to minimise $MI(G_i, Z_i)$ and minimize $MI(G_i, Z_j)$, $i \neq j$.

We can allow for confounding in the latent factors Z_i by asking that $Z_{\setminus i}$ be a *valid adjustment set* for $Z_i \rightarrow X$.

Towards conceptual compression
K. Gregor et al. (2016)

VAEs output blurry images: *recurrent VAEs* progressively improve the result.

***Reinforcement learning
under moral uncertainty***

E. Ecoffet and J. Lehman (2020)

To ensure robots behave “ethically”, we need a moral theory, but there is no single “correct” one – utilitarianism, deontology and virtue ethics all have their proponents. This *moral uncertainty* can be addressed with multi-agent reinforcement learning and some voting system.

An ethical theory should have an influence over outcomes “proportional” to its credence, regardless of the scale of its rewards (*proportional say*).

In *Nash voting*, each agent (moral theory) has a voting budget and uses part of it, at each step, to vote on the possible actions; the winning theory sees its budget decrease accordingly. Nash voting is unlikely to find compromises.

***Assessing game balance with AlphaZero:
exploring alternative rule sets in chess***

N. Tomašev et al. (2020)

[To plot and compare the entropy of several distributions, show the histogram of the negative log-likelihoods $-\log p$: the average gives the entropy.]

Path signature on Lie groups

D. Lee and R. Ghrist (2020)

The path signature can be generalized to Lie-group-valued time series.

Let G be a Lie group, \mathfrak{g} its Lie algebra, PG the set of paths in G . A path in G , $\gamma : [0, 1] \rightarrow G$, defines a path in \mathfrak{g} , $\gamma' : [0, 1] \rightarrow \mathfrak{g}$; conversely, a path in \mathfrak{g} , $f : [0, 1] \rightarrow \mathfrak{g}$, defines a path in G via the ODE

$$\gamma'_t = f_t(\gamma_t)$$

$$\gamma_0 = g$$

A time series $s(\hat{\gamma}_i)_i$ in G defines a path in G , via the discrete derivative and linear interpolation

$$\hat{\gamma}'_i = \log(\hat{\gamma}_i^{-1} \hat{\gamma}_{i+1}) \in \mathfrak{g}$$

$$\gamma_y = \hat{\gamma}_i \exp[(t - \tau) \hat{\gamma}'_i], \quad t \in [i, i + 1).$$

Note that:

- The logarithm is not always defined: the points should be sufficiently close;
- The exponential is not always surjective (for compact Lie groups, it is);
- The Lie and Riemann exponentials differ (but they coincide for biinvariant metrics; compact Lie groups have such a metric).

The *path signature* of a path $\gamma \in PG$ is a formal power series in \mathfrak{g} , $S(\gamma) \in T((\mathfrak{g}))$ (it can also be defined with

iterated integrals).

$I = (i_1, \dots, i_m)$ multi-index

$N = \dim G$

$1 \leq i_k \leq N$

Δ_m simplex

$\omega_1, \dots, \omega_N$ basis of \mathfrak{g}^*

$$S(\gamma) = \int_{\Delta_m} \omega_{i_1}(\gamma'_{t_1}) \cdots \omega_{i_m}(\gamma'_{t_m}) dt_1 \cdots dt_m \in \mathbf{R}$$

As in Euclidean spaces, the signature characterizes paths up-to tree-like equivalence.

To detect a lead-lag relation between two paths, γ_1 and γ_2 , check the sign of $S^{1,2}(\gamma)$ and $S^{2,1}(\gamma)$, where $\gamma = (\gamma_1, \gamma_2)$.

You may want to transform the time series, e.g.:

- Replacing γ_t with (t, γ_t) , which removes the reparametrization invariance;
- Prepending a path from 0 to γ_0 , which removes translation invariance;
- Replacing γ_t with $(\gamma_t, \gamma_{t-\tau}, \dots, \gamma_{t-m\tau})$.

The signature does not use the Lie algebra structure of \mathfrak{g} . There is a signature-preserving bijection between paths in G and paths in \mathbf{R}^N : we can apply Euclidean data analysis techniques to Lie-group-valued time series.

The (normalized) signature transform is a *universal* and *characteristic* feature map (those properties are equivalent).

- (i) Any continuous bounded function $f : OG \rightarrow \mathbf{R}$ can be approximated by a linear function;

$$f(\cdot) \approx \langle \ell, S(\cdot) \rangle$$

- (ii) The map

$$\begin{cases} \mathcal{M}(PG) & \longrightarrow T(\mathfrak{g}) \\ \mu & \longmapsto E_\mu[S], \end{cases}$$

where $\mathcal{M}(PG)$ is the set of finite Borel measures on PG , is injective.

Fast differentiable sorting and ranking
M. Blondel et al. (2020)

Let $\sigma(\theta)$, $s(\theta)$, $r(\theta)$ denote the arg sort, sort and rank of a vector $\theta \in \mathbf{R}^n$. Arg-sort and rank can be defined as

$$\sigma(\theta) = \underset{\sigma}{\operatorname{Argmax}} \langle \theta_\sigma, \rho \rangle$$

$$r(\theta) = \underset{\pi}{\operatorname{Argmax}} \langle \theta, \rho_\pi \rangle$$

where $\rho = (n, n-1, \dots, 1)$ and θ_σ is θ permuted by σ . The *permutahedron* of a vector $x \in \mathbf{R}^n$ is the convex hull of its permutations.

$$P(w) = \operatorname{Conv}\{w_\sigma, \sigma \in \mathfrak{S}_n\} \subset \mathbf{R}^n$$

Sorting and ranking are solutions of linear programs,

$$s(\theta) = \underset{y \in P(\theta)}{\operatorname{Argmax}} \langle y, \rho \rangle$$

$$t(\theta) = \underset{y \in P(\rho)}{\operatorname{Argmax}} \langle y, -\theta \rangle$$

The optimization problem

$$\underset{\mu \in P(w)}{\operatorname{Argmax}} \langle \mu, z \rangle$$

can be regularized with $Q(\mu) = \frac{1}{2} \|\mu\|^2$, which gives

$$\underset{\mu \in P(w)}{\operatorname{Argmin}} \frac{1}{2} \|\mu - z\|^2$$

(projection onto the permutahedron) or the entropic regularization $E(\mu) = \langle \mu, \log \mu - 1 \rangle$, which gives

$$\log \underset{\mu \in P(e^w)}{\operatorname{Argmax}} \langle z, \mu \rangle - E(\mu) = \log \underset{\mu \in P(e^w)}{\operatorname{Argmin}} \operatorname{KL}(\mu, e^z).$$

To control the regularization strength, multiply Q or E by ε or, equivalently, divide z by ε . Fine-tuning ε is important for some applications (top- k classification), but irrelevant for others. The solution can be computed as $z - v(z_\sigma(z), w)_{\sigma^{-1}(z)}$, where

$$v_Q(s, w) = \underset{v_1 \geq \dots \geq v_n}{\operatorname{Argmin}} \frac{1}{2} \|v - (s - w)\|^2$$

$$e_E(s, w) = \underset{v_1 \geq \dots \geq v_n}{\operatorname{Argmin}} \langle e^{s-v}, 1 \rangle + \langle e^w, v \rangle.$$

These isotonic regressions can be computed efficiently with the “pool adjacent violator” (PAV) algorithm. The Jacobian is easy to compute. The whole algorithm is $O(n \log n)$. Code available (Numpy, Jax, PyTorch, TensorFlow): **fast-soft-sort**.

Applications include rank correlation and trimmed least squares.

***Predicting what you already know helps:
provable self-supervised learning***
J.D. Lee et al. (2020)

Self-supervised pretraining works well if

$$\text{input} \perp\!\!\!\perp \text{pretext task} \mid \text{downstream task}$$

Approximate conditional independence can be quantified with partial correlation.

***PDE-constrained optimization
and the adjoint method***
A.M. Bradley (2010)

The adjoint method computes the gradient, $df(x(p))/dp$, of an implicit function $x(p)$ defined by $g(x, p) = 0$, using the Lagrangian $L(x, p, \lambda) =$

$$f(x) + \lambda' g(x, p).$$

$$\begin{aligned} \frac{df}{dp} &= \frac{d}{dp} L(x(p), p, \lambda) \\ &= \frac{d}{dp} [f(x) + \lambda' g(x(p), p)] \\ &= \frac{df}{dx} \frac{dx}{dp} + \lambda' \left(\frac{\partial g}{\partial x} \frac{dx}{dp} + \frac{\partial g}{\partial p} \right) \\ &= \left(\frac{df}{dx} + \lambda' \frac{\partial g}{\partial x} \right) \frac{dx}{dp} + \lambda' \frac{\partial g}{\partial p} \end{aligned}$$

If dx/dp is difficult to compute, we can choose λ to make the first term disappear.

$$= - \left(\frac{\partial g}{\partial x} \right)^{-1} \frac{df}{dx} \frac{\partial g}{\partial p}$$

We can get the same result directly by differentiating $g(x, p) = 0$, but this is useful for PDE-constrained optimization,

$$\begin{array}{ll} \text{Find} & p, x \\ \text{To minimize} & F(x, p) = \int_0^T f(x(t), p, t) dt \\ \text{Such that} & h(x, \dot{x}, p, t) = 0 \\ & g(x(0), p) = 0 \end{array}$$

where directly computing

$$\frac{dF}{dp} = \int_0^T \left(\frac{\partial f}{\partial x} \frac{dx}{dp} + \frac{\partial f}{\partial p} \right) dt$$

is difficult because of dx/dp . The Lagrangian is

$$L = \int_0^T (f + \lambda h) + \mu' g,$$

and we can choose λ (a function) and μ (a vector) to make the terms in dx/dp disappear: we are left with a differential equation for λ .

Applications of PDE-constrained optimization include:

- Finding the parameters of a PDE given observations;
- Design optimization (e.g., airplane wing).

**Neural CDEs for long time series
via the log-ODE method
J. Morill et al. (2020)**

Neural ODEs are a continuous analogue of ResNets. Neural controlled differential equations are continuous analogues of RNNs.

A *controlled ODE* (CDE) is an equation of the form

$$Z_t = Z_a + \int_a^t f(Z_s) dX_s$$

where $X : [a, b] \rightarrow \mathbf{R}^n$ and f is unknown.

In a neural CDE, X is known (linear interpolation of an irregularly sampled time series), $X + Z$ is a latent (*i.e.*, hidden) variable, and $Y_t = \ell(Z_t)$ is observed; given X and Y , we want to estimate f and ℓ . As for RNNs,

estimation for long time series is challenging. The *log-ODE* method uses

$$Z_t = Z_a + \int_a^t \hat{f}(Z_s) \text{LogSig}_{a,b}^N(X) ds,$$

where $\text{LogSig}_{a,b}^N$ is the depth- N log-signature and \hat{f} extends f to the Lie algebra where $\text{LogSig}_{a,b}^N$ lives (but the implementation directly estimated f and ignores the Lie algebra structure).

**Efficient transformers: a survey
Y. Tay et al (2020)**

Transformers combine vector embedding, positional encoding, self- (and cross-)attention, layer normalization, and residual connections.

The attention matrix is too large for the model to efficiently deal with large sequences, but it can be approximated with fixed patterns (blocks, strides, connected blocks), learnable patterns (e.g., k -means clustering of the tokens), side memory, low-rank factorizations, kernels.

**Tensor programs I:
wide feedforward or recurrent networks
of any architecture are Gaussian processes
G. Yang (2019)**

Random, shallow, infinitely wide neural nets are Gaussian processes. This generalizes to “tensor programs”, involving three types,

- G : vector, asymptotically Gaussian,
- H : vector,
- A : matrix, asymptotically Gaussian,

and three operations,

$$\begin{aligned} \text{MatMul} : & \begin{cases} A \times G & \longrightarrow G \\ (A, x) & \longmapsto Ax \end{cases} \\ \text{LinComb} : & \begin{cases} G^k & \longrightarrow G \\ (x_1, \dots, x_n) & \longmapsto \sum a_i x_i \end{cases} \\ \text{NonLin} : & \begin{cases} G^k & \longrightarrow H \\ (x_1, \dots, x_n) & \longmapsto \phi(x_1, \dots, x_n) \end{cases} \end{aligned}$$

**Tensor programs II:
neural tangent kernel for any architecture
G. Yang (2020)**

“Neural tangent kernel” refers to two results, corresponding to the initialization and the training of a neural net.

- (i) For a shallow network f with random weights, $\Theta(x, y) = \langle \nabla_{\theta} f_{\theta}(x), \nabla_{\theta} f_{\theta}(y) \rangle$ converges to a deterministic kernel as the width of f tends to infinity.
- (ii) During gradient descent, the kernel remains constant and describes the evolution of the neural net:

$$f_t - f_{\text{data}} = e^{-\eta t \Theta} (f_0 - f_{\text{data}}).$$

**Neural tangent kernel:
convergence and generalization in neural nets**
A. Jacot (2018)

Original NTK paper.

**Generative language modeling
for automated theorem proving**
S. Polu and I. Sutskever (2020)

A transformer model (GPT-like, 36 layers) can generate proof for MetaMath:

- Predict a proof step from a goal;
- Pretrain on text (arxiv, Math StackExchange, Github);
- Train on synthetic data (n -digit arithmetic, ring algebra) and real data (set.mm: 38k theorems, 3m steps);
- Also learn a value function

MetaMath is a proof assistant based on string substitution – it is simpler than human-friendly alternatives (Coq, HOL Light, Lean), but its *de Bruijn factor*, the ratio of the length of a formal proof to that of a textbook, is $10 \sim 20$, instead of $1 \sim 3$.

**KarateClub: an API-oriented
open-source Python framework
for unsupervised learning on graphs**
B. Rozemberczki et al. (2020)

Sclearn-like API for community detection, wholegraph embedding, node and graph classification; built on Numpy (dense matrices), Scipy (sparse matrices), gensim (matrix factorization), PyGSP (signal processing on graphs), NetworkX. GraphTool (community detection) and SNAP are more limited.

**Efficiently sampling functions
from Gaussian process posteriors**
J.T. Wilson et al. (2020)

One can sample from a Gaussian process

$$y|X \sim N(0, K_{XX})$$

as follows

$$\begin{aligned}\mu_* &= K_*(K_{XX} + \sigma^2 I)^{-1} y \\ \Sigma_* &= K_{**} - K_{*X}(K_{XX} + \sigma^2 I)^{-1} K_{X*}.\end{aligned}$$

The *Nystrom approximation* approximates K_{XX} using a subset $Z \subset X$ of the data,

$$K \approx K_Z K_{ZZ}^{-1} K'_Z.$$

The *fully independent training conditional* (FITC) method uses an arbitrary set of points (not necessarily among the observations),

$$K \approx K_Z K_{ZZ}^{-1} K'_Z + \text{diag}(K_{XX} - K_{XZ} K_{ZZ}^{-1} K_{ZX}) + \sigma^2 I$$

(it is obtained by integrating those points out

$$p(y|x) = \int_u p(y, u|x, z) = \int_u p(y|u, x, z) p(u|z)$$

and assuming that the variance of the first factor is diagonal). The computations can be simplified using Woodbury's formula.

Besides those *function space approximations*, the *weight space approximation* expresses f as a linear combination of random Fourier features.

$$\begin{aligned}\phi_i(x) &= \cos(\theta_i x + \tau_i) \\ f &= \sum w_i \phi_i \\ w|x, y &\sim N(\mu, \Sigma) \\ \mu &= (\Phi' \Phi + \sigma^2 I)^{-1} \Phi' y \\ \Sigma &= (\Phi' \Phi + \sigma^2 I)^{-1} \sigma^2\end{aligned}$$

If (a, b) is Gaussian, then (*Matheron's rule* – equality in distribution)

$$(a|b = \beta) \stackrel{d}{=} a + \text{Cov}(a, b) \text{Cov}(b, b)^{-1} (\beta - b)$$

can be used to incrementally update a sample from a Gaussian process.

Towards an API for the real numbers
H.J. Boehm (2020)

Recursive real arithmetic replaces real numbers $x \in \mathbf{R}$ with (computable) functions $f_x : \mathbf{R}_+^\times \rightarrow \mathbf{Q}$ where $f_x(e)$ is a rational approximation of x with error bounded by e : $|x - f_x(e)| \leq e$. Equality of recursive reals is undecidable (halting problem), except in some special cases (often, when the computations only involve integers, the 4 operations, log, exp, trigonometric functions and their inverses).

Applications include calculators (Google's Android calculator, for users who do not understand IEEE floating point arithmetic) and testing the accuracy claims of floating point implementations.

Also check F. Johansson's Calcium.

**Traditional and heavy-tailed regularization
in neural network models**
C.H. Martin and M.W. Mahoney (2019)

As the optimization progresses, the spectral density of the weight matrices (distribution of the singular values) changes: Marchenko-Pastur (MP), corresponding to Gaussian weights; MP with outliers, corresponding to Gaussian weights plus a low-rank matrix; power law distribution. Code available.

**A neural network based framework
for financial model calibration**
S. Liv et al. (2020)

Train a neural network to model the mapping from SDE parameters to option price; then, train another one to learn the inverse mapping.

Learning to see through observations

Y.L. Liv et al (2020)

Remove window reflections or fence obstructions from short videos using the motion difference between the obstruction and the background.

Modeling 3D shapes by reinforcement learning

C. Lin et al.

Generate 3D shapes, as humans do in 3D software, in two steps:

- First, approximate the shape with 3D primitives;
- Then, edit the mesh (edge loops rather than vertices) for the details.

Use imitation learning of a heuristic policy as pretraining before actual reinforcement learning.

Stanza: a Python NLP toolkit for many human languages

P. Qi et al. (2020)

If CoreNLP, Flair, Spacy, UDpipe do not cover enough languages (includes Japanese, Chinese, Arabic, but also ancient Greek, old French, etc. – much fewer for NER).

Deep rank-based transposition invariant distances on musical sequences

G. Hadjeres and F. Nielsen

To compute a distance between musical sequences, train a seq2seq autoencoder (or a seq2seq network to transpose motifs) and use a permutation-based distance (rank correlation or Kendall's τ) on the high-level features (only use the ℓ largest features).

QuantGAN:

deep generation of financial time series

M. Wiese et al. (2019)

GAN, with a TCN in the generator, to model volatility, drift and innovations separately and reproduce the stylized facts of time series (fat tails, clustered volatility, leverage $\text{Cor}(r, \sigma) < 0$).

$$(\eta_t)_t \mapsto (\sigma_t, \mu_t, \varepsilon_t)_t \mapsto (\mu_t + \sigma_t \cdot \varepsilon_t)_t$$

Generative adversarial networks for financial trading strategies fine-tuning and combination

A. Koshiyama et al. (2019)

QuantNet: transferring learning across systematic trading strategies

A. Koshiyama et al. (2020)

Build a stock-level but market-specific (technical analysis) trading strategy using market-specific weights for the first and last layers (linear or LSTM, “encoder” and “decoder”) and shared weights in the middle, with the Sharpe ratio as loss.

Compact representation of uncertainty in hierarchical clustering

C.S. Greenberg et al. (2020)

Hierarchical clusterings are often built with greedy algorithms, beam search, or sequential Monte Carlo. Consider a (posterior) probability distribution on hierarchies H ,

$$\text{linkage function} \quad E : \mathcal{P}(X) \times \mathcal{P}(X) \longrightarrow \mathbf{R}_+$$

$$\text{energy of a tree} \quad E(H) = \prod_{\substack{X_i, X_j \in H \\ X_i \cup X_j = X}} E(X_i, X_j).$$

The partition function can be computed, exactly, with *dynamic programming*, using

$$Z(X) = \sum_H E(H) = \sum_{\substack{Y \subset X \text{ s.t.} \\ x \in X \\ |X| > 1}} E(X_i, X \setminus X_i) \cdot Z(X_i) \cdot Z(X \setminus X_i).$$

The MAP hierarchical clustering can be computed similarly, using Max instead of \sum (the complexity is “only” $O(2^{2m})$, much less than the number of hierarchies, $(2n - 3)!!$).

Scalable nearest neighbour search for optimal transport

A. Backurs et al. (2020)

The Wasserstein-1 distance on a finite set $X \subset \mathbf{R}^n$ can be used, for instance, to compare documents, seen as distributions on words, after word2vec or glove embedding, but it is expensive to compute. Approximations include:

- Mapping each point in the support of μ to the nearest point in the support of ν ;
- Building a random quad-tree (k-d tree) on X and using

$$W_1(\mu, \nu) \approx \sum_{x \in X} 2^{\ell(x)} |\mu(x) - \nu(x)|$$

where $\ell(x)$ is the level of x in the tree.

Instead, actually compute the optimal transport on the tree,

$$f = \underset{\substack{f \text{ s.t.} \\ \text{pr}_1 f = \mu \\ \text{pr}_2 f = \nu}}{\text{Argmin}} \sum_{x, y \in X} f(x, y) t(x, y)$$

where t is the distance on the tree, and use it with the actual Euclidean distance instead

$$W_1(\mu, \nu) \approx \sum_{x, y \in X} f(x, y) \|x - y\|.$$

***On the limitations
of representing functions on sets***
E. Wagstaff et al. (2019)

Representing arbitrary permutation-invariant functions with a neural net (deep set) requires a latent representation layer at least the input dimension – dimension reduction would require discontinuous functions.

Evolving normalization-activation layers
H. Liu et al. (2020)

Layer search (as oppsed to architecture search) for a replacement for the BatchNorm-ReLU (or BatchNorm-Swish) combination commonly used as a computation graph made of elementary operations (+, ×, /, max, neg, σ , tanh, exp, log, abs, \cdot^2 , $\sqrt{\cdot}$) and aggregations on some dimensions of the input tensor (batch/channel/instance/group mean/sd) leads to a combination of batch and instance normalization.

***Enhance social recommendation
with adversarial graph convolutional networks***
J. Yu et al. (2020)

Social recommendation systems do not work that well because the relations between users are noisy, heterogeneous and too few. Use an autoencoder to generate *alternate neighbourhoods* (intuitively, informative neighbourhoods, and/or users with similar taste) by applying a GCN (with skip-layer connections) to motif-induced adjacency matrices

to get a user embedding, and then decoding it.

The user embedding and the reconstructed graph can then be used in a discriminator (GCN with attention) to ensure that the alternate neighbourhoods contain the users contributing the most.

***Increasing generality in machine learning
through procedural content generation***
S. Riss et al. (2020)

The interplay between machine learning (ML) and procedural content generation (PCG) goes both ways:

- ML can generate new contents;
- PCG can help train ML systems: data augmentation, domain randomization, curriculum learning, generating new environments (metalearning: POET).

Constructive PCG runs in fixed time, with no search (Perlin noise, L-systems, cellular automata, etc.).

Search-based PCG can use CMA-ES, differential evolution, constraint satisfaction, to search for good contents, sometimes with multiple objective functions (for diversity), which require the computer to play the game for which the contents is being generated.

GANs do not work well: they generate contents that looks right, but does not work (is not playable); they can be combined with search (in the latent space). Reinforcement learning can also be used, to progressively modify random contents into playable contents.

***bayestestR: describing effects and their
uncertainty, existence and significance
within the Bayesian framework***
S. Makowski et al. (2019)

The *probability of direction* (PD) is a Bayesian analogue of a p -value: it is the proportion of the posterior density (of a coefficient in a regression) with the same sign as the median; it varies between 50% (corresponding to $p = 1$) and 100% ($p = 0$). Like the p -value, it does not account for effect size.

In a Bayesian context, the point null hypothesis $H_0 : \beta = 0$ has probability zero and should be replaced by a *region of practical equivalence* (ROPE), e.g., $H_0 : \beta \in [-0.1\sigma, +0.1\sigma]$. The null hypothesis can be rejected if $P_{\text{posterior}}(H_0) \leq \alpha$ (do not use it if the parameters are highly correlated).

The package relies on `rstanarm` and also computes (and plots) MAP estimates, credible intervals and Bayes factors.

***AutoML-Zero: evolving machine learning
algorithms from scratch***
E. Real et al. (2020)

AutoML often limits the search to one aspect of the model, e.g., architecture search using hand-designed block, optimization algorithms, LSTM-like gating mechanisms, data augmentation. A more flexible search space considers three functions, `setup`, `predict`, `learn`; `predict` and `learn` are called in a loop; they are made up of assembler-like operations on scalars (s), vectors (v) and matrices (m), of the same size as the input, with no control structures, e.g.,

$$\begin{aligned} m_1 &= s_2 \times m_2 \\ s_0 &= \text{mean}(v_1) \\ s_3 &= \sin(s_4) \\ s_1 &= \text{runif}(). \end{aligned}$$

The search space is too large for random search, but evolutionary strategies fare better. To speed up the search, use small datasets, and detect equivalent algorithms by hashing their outputs on 10 inputs.

The search rediscovers gradient descent, multiplicative interactions, normalized gradient, weight averaging, dropout, learning rate decay.

This approach can also be used to improve existing algorithms to adapt them to different situations (e.g., little data, fast training, more classes, etc.)

Scaling laws for neural language models
J. Kaplan et al. (2020)

The loss of a transformer model depends on compute time, dataset size, model size.

$$\text{Loss} \propto \text{Compute}^{-0.05} \times \text{Data}^{-0.10} \times \text{Size}^{-0.10}$$

Fawkes: protecting personal privacy against unauthorized deep learning models
S. Shan et al. (2020)

Modify your pictures before distributing them (imperceptibly, in feature space) to prevent their use to train face recognition systems.

FixMatch: simplifying semisupervised learning with consistency and confidence
K. Sohn et al. (2020)

FixMatch performs semi-supervised learning using *pseudolabels* (forecasts of the model, when the model is sufficiently confident) and consistency regularization (similar inputs should give similar outputs).

Stable neural flows
S. Massaroli et al. (2020)

To learn a mapping $u \mapsto v$, *neural ODEs* find a vector field f whose integration gives the desired function.

$$\begin{aligned}\dot{x} &= f(x) \\ x(0) &= u \\ x(1) &= v\end{aligned}$$

More generally, one can add affine maps

$$u \xrightarrow{g} x(0) \mapsto x(1) \xrightarrow{h} v$$

if the dimensions do not match.

$$\begin{aligned}\dot{x} &= f(u, x) \\ x(0) &= g(u) \\ h(x(1)) &= v\end{aligned}$$

The resulting ODE may have stiff dynamics and chaotic behaviour (sensitivity to small perturbations in the input lead to adversarial attacks). Replace $\dot{x} = f(u, x)$ with $\dot{x} = -\partial_x \varepsilon(u, x)$ (or, more generally, a Hamiltonian model).

Dissecting neural ODEs
S. Massaroli et al. (2020)

Vanilla neural ODEs (continuous-depth neural nets) are not universal approximators.

$$\begin{aligned}\frac{dh}{ds} &= f_\theta(s, h) \\ h(0) &= x \\ h(1) &= y\end{aligned}$$

They can be augmented,

$$\begin{aligned}\frac{d}{ds} \begin{pmatrix} h \\ a \end{pmatrix} &= f_\theta(s, h, a) & \frac{d}{ds} \begin{pmatrix} h \\ a \end{pmatrix} &= f_\theta(s, h, a) \\ h(0) &= x & \text{or} & \begin{pmatrix} h(0) \\ a(0) \end{pmatrix} = g(x) \\ a(0) &= 0 & & \\ h(1) &= y & & h(1) = y.\end{aligned}$$

(Higher-order ODEs can also be formulated as augmented neural ODEs.)

Data-controlled neural ODEs incorporate the input x in the vector field,

$$\frac{dh}{ds} = f_\theta(s, h, x).$$

adaptive depth neural ODEs use a data-dependent integration interval

$$\begin{aligned}\frac{dh}{ds} &= f_\theta(s, h) \\ h(0) &= 0 \\ h(s(x)) &= y.\end{aligned}$$

[The implementation uses `torchdiffeq`.]

Representation learning through latent canonicalizations
O. Litany et al. (2020)

Approaches to learn from simulated data include:

- Pretraining on simulated data and fine-tuning on real data;
- Domain adaptation, if there is a lot of unlabeled real data;
- Domain randomization.

To learn a “disentangled” representation (this often just means “isotropic”), train an autoencoder and linear transformations of the latent space which reset one or two parameters of the (generated) input (e.g., colour, background colour, size, rotation, font) to a default value.

$$\begin{aligned}p(x, z) &= p(x|z)p(z) & (\text{generative model}) \\ p(x, z) &= p(x|z) \underbrace{p(z_1) \cdots p(z_n)}_{\text{disentangled}}\end{aligned}$$

Meta-pseudo labels
H. Pham et al. (2020)

A classifier can be trained with the true labels (e.g., binary), smoothed labels, with the labels from a teacher network trained independently (log-probabilities, also available for non-labeled data), or “meta-labels”, still from a teacher network, not trained to produce good forecasts, to help train the student.

Random projections for manifold learning
C. Hegde et al. (2007)

The *Grassberger-Proccaccia algorithm* computes the *intrinsic dimension* of a cloud of points from pairwise distances using the “scale-dependent correlation dimension”

$$C(r) = \text{Mean}_{i \neq j} \mathbf{1}_{\|x_i - x_j\| \leq r}$$

$$\hat{k} = D(r_1, r_2) = \frac{\log C(r_1) - \log C(r_2)}{\log r_1 - \log r_2}$$

where r_1, r_2 are chosen so that C be linear on $[r_1, r_2]$ and $[r_1, r_2]$ be large. It can be computed from a random projection $\mathbf{R}^N \rightarrow \mathbf{R}^M$, with $M \propto K \log N$.

Rethinking batch normalization in transformers
S. Shen et al. (2020)

Since batch statistics, in natural language processing, have much higher variance than in computer vision, layer-norm is often preferred. BatchNorm can be used, but with running statistics instead of batch statistics (“powernorm”).

NeRF: representing scenes as neural radiance fields for view synthesis
M. Mildenhall et al. (2020)

A scene can be represented as a non-convolutional, fully-connected neural net

$$\begin{cases} \mathbf{R}^5 & \rightarrow \mathbf{R}^4 \\ (x, y, z, \theta, \phi) & \mapsto (R, G, B, A) \end{cases}$$

computing the radiance emitted at a point (x, y, z) in direction (θ, ϕ) and turned into an image using volumetric rendering, which is differentiable. It can be learnt from several (100) views of the same scene (processed with COLMAP (SfM)). The density (alpha) only depends on the position, but the colour also depends on the direction, to account for specular effects.

To capture high-frequency details (neural nets are biased towards low-frequency functions, map each coordinate to a high-dimensional space

$$\begin{cases} [-1, 1] & \rightarrow [-1, 1]^{2L} \\ x & \mapsto (\sin 2^0 \pi x, \cos 2^0 \pi x, \dots, \sin 2^{L-1} \pi x, \cos 2^{L-1} \pi x) \end{cases}$$

(this is the Transformer’s positional embedding).

Do not use columetric rendering with fixed points (deterministic quadrature), but with N points sampled at random in evenly-spaced bind (stratified sampling).

Use two networks, a coarse one, with stratified sampling, to estimate the density (alpha channel), as a piecewise constant pdf, and a finer one, for density and colour, using points sampled from this pdf instead of stratified sampling (hierarchical sampling strategy).

On the spectral bias of neural networks
N. Rahaman et al. (2019)

The Fourier transform of ReLU networks can be computed explicitly: lower frequencies are learned first, and they are more robust to random perturbations of the parameters.

Structure from motion
J.L. Schönberger et al. (CVPR 2016)

Structure-from-motion (SfM) reconstructs a 3D scene from an unordered image collection, in several steps:

- Feature extraction: SIFT or learned features;
- Matching: identification of potentially overlapping images;
- Geometric verification and triangulation;
- Adjustments, to avoid error accumulation and down-play outliers.

COLMAP is an open-source implementation, with a series of improvements to increase robustness.

Volatility is rough
T. Gatheral et al. (2014)

Log-volatility looks like a fractional Brownian motion

$$m(q, \Delta) = \langle |\log \sigma_{t+\Delta} - \log \sigma_t|^q \rangle \propto \Delta^{qH}, \quad H \approx 0.1$$

(data from <http://realized.oxford-man.ox.ac.uk>). This explains the power law seen in the skew,

$$\left. \frac{\partial \sigma}{\partial K} \right|_{K=0} \sim \tau^{-(\frac{1}{2}-H)}.$$

Buy rough, sell smooth
P. Glasserman and P. He (2018)

Buy stocks whose implied volatility roughness is high.

The market generator
A. Kondratyev and C. Schwarz

A *restricted Boltzman machine* (RBM) has two layers of binary variables, visible v and hidden h .

$$E(v, h) = -a'v - b'h - v'wh$$

$$p(v, h) \propto \exp -E(v, h)$$

$$\begin{aligned} w &\leftarrow w + \eta[\langle v'h \rangle_{\text{data}} - \langle v'h \rangle_{\text{model}}] \\ a &\leftarrow a + \eta[\langle v \rangle_{\text{data}} - \langle v \rangle_{\text{model}}] \\ b &\leftarrow b + \eta[\langle h \rangle_{\text{data}} - \langle h \rangle_{\text{model}}] \end{aligned}$$

To get an unbiased estimate of $\langle v'h \rangle_{\text{model}}$, one could iteratively sample from $h|v$ and $v|h$, for long enough (10^3 times).

$$p(h_j = 1|v) = \sigma(b_j + w'_{\cdot j}v)$$

$$p(h_i = 1|h) = \sigma(a_i + w'_i h)$$

Instead, k -step *contrastive divergence* (CD) iterates for k steps only:

$$\Delta w_{ij} = \eta[p(h_j = 1|v^{(0)})v_i^{(0)} - p(h_j = 1|v^{(k)})v_i^{(k)}]$$

$$\Delta a_i = \eta[v_i^{(0)} - v_i^{(k)}]$$

$$\Delta b_j = \eta[p(h_j = 1|v^{(0)}) - p(h_j = 1|v^{(k)})]$$

To deal with real (non-binary) data, round number in $[x_{\text{Min}}, x_{\text{Max}}]$ to 16-bit binary numbers.

Experiments on 4 time series of FX returns and 30 hidden units can reproduce the marginal distributions and the correlation structure.

To generate autocorrelated samples, initialize the RBM with the previous values S_{t-1} and sample h and v a small number of times ($\ll 10^3$). To account for non-stationarity (volatility clustering), add a binary indicator for each input time series, indicating if the volatility is high or low (3-month vs long-term), and keep them fixed.

Handling risk-on/risk-off dynamics with correlation regimes and correlation networks
J. Papenbrock and P. Schwendner (2015)

Cluster correlation matrices (estimated at different points in time) to identify regimes: 25 assets (equities, bonds, commodities, FX), daily returns, 1-month window, filtered with average linkage clustering (why not a minimum spanning tree?), k -means, $k = 5$.

Deep generative models
A. Soleimany (2020)

VAEs can help increase diversity: do not use $N(0, 1)$ to sample in the latent space but something more dispersed (larger variance or fatter tails).

CycleGANs have two generators and two discriminators; they can be applied, not only to images, but also to sounds (to change the voice from one person to another, via spectrograms).

BANANAS: Bayesian optimization with neural architectures for NAS
C. White et al. (2019)

Cell-based search spaces for network architecture search (e.g., from NASBench) assume the network architecture is fixed, with “cells” to be filled in, from a few building blocks; each cell can be encoded by listing the paths in it (there is an exponential number of possible paths, but if the length is limited, it remains reasonable).

For Bayesian optimization, use a neural net (of an ensemble of neural nets) instead of a Gaussian process, to predict (the mean and variance of) the accuracy of an architecture, and Thompson sampling.

Multiplicative interactions and where to find them
S.M. Jayakumar et al. (ICLR 2020)

Try replacing concatenation with multiplication – gating, hypernetworks, dynamic convolutions, attention, etc. Replace linear maps $(x, z) \mapsto W[x; z] + b$ with bilinear ones $(x, z) \mapsto z'Wx + z'U + Vx + b$ (W is then a 3-dimensional tensor).

Big Bird: transformers for longer sequences
M. Zaheer et al. (2020)

The quadratic size of the attention matrix does not allow BERT to scale to large texts. Instead of a dense matrix, use a sparse one, combining:

- Random links: with several layers, random sparse matrices can approximate dense ones;
- A window, *i.e.*, non-zero elements close to the diagonal;
- Bidirectional links between important tokens (e.g., CLS) and all other tokens.

Bootstrap your own latent: a new approach to self-supervised learning
J.B. Grill et al. (2020)

SimCLR performs self-supervised learning by combining augmentations and negative samples. Negative samples are not really needed: use two neural networks, the trained one (“online”) and an exponentially weighted moving average (“target”), the online network predicting the latent representation of the target one under a different augmentation.

Direct feedback alignment scales to modern deep learning tasks and architectures
J. Launay et al. (2020)

Given a neural network

$$\cdots \rightarrow h_{i-1} \xrightarrow{W_i} a_i \xrightarrow{f_i} h_i \xrightarrow{W_{i+1}} a_{i+1} \rightarrow \cdots,$$

back-propagation computes

$$\begin{aligned}\frac{\partial \mathcal{L}}{\partial W_i} &= \frac{\partial \mathcal{L}}{\partial a_{i+1}} \frac{\partial a_{i+1}}{\partial h_i} \frac{\partial h_i}{\partial a_i} \frac{\partial a_i}{\partial W_i} \\ &= \frac{\partial \mathcal{L}}{\partial a_{i+1}} W_{i+1} f'_i(a_i) W_i.\end{aligned}$$

Direct feedback alignment (DFA) replaces the first two factors (since they come from the next layer, they are not biologically plausible, and they prevent parallelization) with

$$\frac{\partial \mathcal{L}}{\partial a_N} B_i$$

where B_i is a fixed random matrix, randomly projecting the global error.

DFA works well for fully-connected architectures (not convolutional ones).

Deep unsupervised learning P. Abbeel et al. (2020)

1. Deep unsupervised learning includes *generative models* which sample from the data manifold, and *self-supervised learning* (e.g., guessing the angle of a rotated image). Those models provide one or more of:

- Probability density;
- Sampling;
- Latent representation.

Applications include (conditional) data generation, anomaly detection, compression (WaveOne is better than JPEG2000), pretraining for text (GPT2, BERT) and vision (CPC, MoCo).

2. *Likelihood-based models* allow us to sample $x \sim p$ and to compute probabilities $p(x)$. For discrete distributions, we could use a *histogram*, but this does not scale (a 28×28 binary image would require $2^{28 \times 28}$ bins) and generalizes poorly. Instead, look for a parametric distribution, estimated using maximum likelihood or, equivalently,

$$\text{KL}(\text{data} \| p_\theta) = \mathbb{E}_{x \sim \text{data}} [-\log p_\theta(x)] - H(\text{data}).$$

If the probability p_θ is modeled by a neural net, we need to ensure that

$$\begin{aligned}\forall x \quad p_\theta(x) &\in [0, 1] \\ \sum_x p_\theta(x) &= 1\end{aligned}$$

This can be done with a *Bayesian net*,

$$\log p_\theta(x) = \sum_i \log p_\theta(x_i | \text{parents}(x_i)),$$

e.g., an **autoregressive model**

$$\log p_\theta(x) = \sum_i \log p_\theta(x_i | x_{1:i-1})$$

where $p(x_1)$ is given by a histogram and $p(x_i | x_{1:i-1})$ by a neural network with a softmax. *Recurrent networks* allow some parameter sharing – they even work

for MNIST, but try to add skip connections $(i-1, j) \rightarrow (i, j)$ and/or use positional encoding

$$(i, j, \text{previous state}) \mapsto (\text{output}, \text{next state}).$$

Masking-based models, such as MADE (masked autoencoder for distribution estimation) take a neural net and remove connections (apply a mask) such that output i only depends on inputs $1 : i-1$.

There are two types of layers, A and B, containing only connections from i to j where $i < j$ (A) or $i \leq j$ (B); use at least one layer of type A, anywhere. The mask depends on the ordering; you can use several orderings (masks) on the same underlying network (but not too many).

Causal convolutions naturally provide the autoregressive structure, with shared parameters, but they have a limited receptive field.

WaveNet uses dilated convolutions, gated residual blocks and skip connections.

A 2-dimensional generalization of WaveNet would have a blind spot.

PixelCNN uses filters of the form  but only above the pixel of interest (“vertical stack”),

combined with a 1-dimensional network to address the blindspot on the left (“horizontal stack”); the vertical stack is fed to the horizontal stack.

Using a multinomial distribution (softmax) for pixel values is suboptimal: similar pixel values have similar probabilities. PixelCNN++ uses a mixture of logistic distributions (the cdf is a sigmoid), with downsampling and (UNet) skip connections.

Convolutions have a limited receptive field: PixelSNAIL uses CNNs and self-attention,

$$A(q, k, V) = \sum_i \frac{e^{q \cdot k_i}}{\sum_j e^{q \cdot k_j}} v_i$$

(if the query q is close to the 1-hot vector for coordinate i , the output is close to v_i) with masking; different orders are possible.

Extensions include:

- Conditional PixelCNN;
- Hierarchical AR image models, which progressively increase the resolution;
- Generating a greyscale image first, before adding colour.

AR models are very slow: they generate one pixel at a time. They can be sped up by breaking the AR pattern (*scaling AR video models*).

or by caching the activations (WaveNet, fastPixelCNN).

There is no straightforward latent representation (everything is pixelwise), but the *Fisher score*

$$\dot{\ell}(x, \theta) = \nabla_{\theta} \log p_{\theta}(x)$$

can be used. It also allows interpolation.

3. Flow models allow sampling $x \sim p_{\theta}$, probability computation $p_{\theta}(x)$ and also provide a latent representation. They transform the input into a target distribution, $z \sim p_z$, e.g., $z \sim N(0, 1)$.

$$x \longrightarrow \boxed{} \longrightarrow \boxed{} \longrightarrow \boxed{} \longrightarrow a = f_{\theta}(x)$$

In dimension 1, the distribution of x is given by a change of variable, provided f_{θ} is *invertible*,

$$p_{\theta}(x) = p_z(f_{\theta}(x)) \left| \frac{\partial f_{\theta}(x)}{\partial x} \right|$$

and θ can be found by maximizing

$$\sum_i \log p_{\theta}(x_i) = \sum_i \log p_z(f_{\theta}(x_i)) + \log \left| \frac{\partial f_{\theta}(x)}{\partial x}(x_i) \right|.$$

Sampling is straightforward: $z \sim p_z$, $x = f_{\theta}^{-1}(z)$.

In dimension 1, with $p_z = U(0, 1)$, the flow is just the cdf of x , and could be estimated as a mixture of Gaussians.

In dimension 2, this becomes

$$\begin{pmatrix} x_1 \\ x_2 \end{pmatrix} \mapsto \begin{pmatrix} z_1 = f_{\theta}(x_1) \\ z_2 = f_{\theta}(x_1, x_2) \end{pmatrix}$$

$$\begin{aligned} \text{Loss}(\theta) = \sum_i \log p_{z_1}(f_{\theta}(x_1)) + \log \left| \frac{dz_1}{dx_1} \right| + \\ \log p_{z_1}(f_{\theta}(x_1, x_2)) + \log \left| \frac{dz_2}{dx_1} \right|. \end{aligned}$$

For instance, $f_{\theta}(x_1)$ could be the cdf of a mixture of 5 Gaussians and $f_{\theta}(x_1, x_2)$ the cdf of a mixture of 5 Gaussians conditional on x_2 .

In dimension n , notice that sampling from a Bayesian net is a flow: use an *autoregressive flow* (AF).

$$\begin{aligned} x_1 &\sim p_{\theta}(x_1) & x_1 &= f_{\theta}^{-1}(z_1) \\ x_2 &\sim p_{\theta}(x_2|x_1) & x_2 &= f_{\theta}^{-1}(z_2; x_1) \\ x_3 &\sim p_{\theta}(x_3|x_1, x_2) & x_3 &= f_{\theta}^{-1}(z_3, x_1, x_2) \end{aligned}$$

$$p_{\theta}(x) = p(f_{\theta}(x)) \left| \det \frac{\partial f_{\theta}(x)}{\partial x} \right|$$

Instead of learning an invertible mapping $x \mapsto z$, one can learn $z \mapsto x$ (inverse AR flow, IAF): training is now sequential (slow), but sampling parallelizable (fast) (ParallelWaveNet, IAF-VAE).

The loss is now

$$\begin{aligned} \mathbb{E}_{x \sim \text{data}} [-\log p_{\theta}(x)] = \\ \mathbb{E}_{x \sim \text{data}} \left[-\log p_z(f_{\theta}(x)) - \log \left| \det \frac{\partial f_{\theta}(x)}{\partial x} \right| \right] \end{aligned}$$

For *affine flows* (multivariate Gaussians)

$$\begin{aligned} z &= f(x) = A^{-1}(x - b) & z &\sim N(0, 1) \\ x &= Az + b & x &\sim N(b, AA') \end{aligned}$$

the log-likelihood is expensive to compute (since $\partial f / \partial x = A^{-1}$, we need $\det A$).

The *elementwise flow* $x \mapsto (f_\theta(x_1), \dots, f_\theta(x_n))$ is not expressive enough, but could be used for some layers.

NICE and RealNVP split the variables in two

$$\begin{aligned} z_{1:d/2} &= x_{1:d/2} \\ z_{d/2:d} &= d_{d/2:d} \cdot s_\theta(x_{1:d/2}) + t_\theta(x_{1:d/2}) \end{aligned}$$

where s_θ, t_θ are arbitrary neural nets.

Split images using a checkerboard pattern or channels.

Flow++ replaces the affine transformations in RealNVP

$$x_i = z_i \cdot a_\theta(\text{parent}(x_i)) + b_\theta(\text{parent}(x_i))$$

with non-linear transformations, e.g., the cdf (or icdf) of Gaussian or logistic mixtures, or piecewise linear or quadratic functions. If the data is discrete $\mathbf{111}$, we do not want a pdf with peaks $\mathbf{\Delta\Delta\Delta}$, but something closer to a piecewise uniform distribution $\mathbf{\perp\perp\perp}$: add $U(-\frac{1}{2}, +\frac{1}{2})$ to the data (*dequantization*). Also check *Glow*, *FFJORD*.

(To check if a latent coordinate k is independent from the others, take two images $x^{(1)}, x^{(2)}$; compute $z^{(1)}, z^{(2)}$; replace $z_k^{(1)}$ with $z_k^{(2)}$; compute the corresponding image x ; check if it looks real, e.g., with a GAN – this could also be part of the loss function.)

4. With AR and flow models, all variables are observed, but they depend on one another. With **latent variable models**, some variables are hidden, but the observed variables are conditionally independent given the latent variables.

$$\begin{aligned} z &\sim p_z \\ x &\sim p_\theta(x|z) \end{aligned}$$

The likelihood is $p_\theta(x) = \sum_z p_z(z) p_\theta(x|z)$ and the model can be trained as

$$\text{Maximize}_\theta \sum_i \log p_\theta(x^{(i)}) = \sum_i \log \sum_z p_z(z) p_\theta(x^{(i)}|z).$$

If z only takes a small number of values, the objective is tractable, e.g., a mixture of 3 Gaussians:

$$\begin{aligned} z &\sim \text{Unif}\{A, B, C\} \\ x &\sim N(\mu_z, \sigma_z^2). \end{aligned}$$

Prior sampling replaces $\mathbb{E}_{z \sim p_z}[\cdot]$ with the average over a sample $z_k^{(i)} \sim p_z$, but most terms are negligible unless, by chance, z_k is close to a latent representation of x – and things get worse in high dimension: use *importance sampling*. A good proposal distribution would be $q(z) = p_\theta(z|x^{(i)})$, but it is difficult to sample from. Instead, use a variational approach and find $q = N(\mu, \sigma^2)$ close to $p_\theta(z|x^{(i)})$ by minimizing

$$\begin{aligned} \text{KL}(q(z) \parallel p_\theta(z|x^{(i)})) &= \mathbb{E}_{z \sim q} \log \frac{q(z)}{p_\theta(z|x^{(i)})} \\ &= \mathbb{E}_{z \sim q} \log \frac{q(z)}{p_\theta(x^{(i)}|z)p(z)/p_\theta(x^{(i)})} \\ &= \mathbb{E}_{z \sim q} [\underbrace{\log q(z)}_{\text{computable}} - \underbrace{\log p_\theta(x^{(i)}|z)}_{\text{does not depend on } q} - \log p(z)] + \log p_\theta(x^{(i)}). \end{aligned}$$

Instead of finding a distribution q minimizing the KL divergence for each i , use *amortized inference* and solve

$$\text{Minimize}_\phi \sum_i \text{KL}(q_\phi(z|x^{(i)}) \parallel p_\theta(z|x^{(i)}))$$

where q_ϕ is a neural net: $q_\phi(z|x) = N(\mu_\phi(x), \sigma_\phi^2(x))$.

Note that p_θ is part of the model while q_ϕ is merely used for inference. This is the *importance weighted autoencoder* (IWAE).

Find θ and ϕ

$$\begin{aligned} \text{To maximize} \quad & \sum_i \log \frac{1}{K} \sum_k \frac{p_x(z_k^{(i)})}{q(z_k^{(i)})} p_\theta(x^{(i)}|z_k^{(i)}) \\ & - \sum_i \text{KL}(q_\phi(x|x^{(i)}) \parallel p_\theta(z|x^{(i)})) \end{aligned}$$

Where $z_k^{(i)} \sim q_\phi(\cdot|x^{(i)})$

The traditional **VAE** uses $K = 1$.

The VAE loss can also be derived from Jensen's inequality:

$$\begin{aligned} \sum_i \log p_\theta(x^{(i)}) &= \sum_i \log \sum_z p(z) p_\theta(x^{(i)}|z) \\ &= \sum_i \log \sum_z \frac{q(z)}{q(z)} p(z) p_\theta(x^{(i)}|z) \\ &= \sum_i \log \mathbb{E}_{z \sim q} \left[\frac{p(z)}{q(z)} p_\theta(x^{(i)}|z) \right] \\ &\geq \sum_i \mathbb{E}_{z \sim q} \log \frac{p(z)}{q(z)} p_\theta(x^{(i)}|z) \end{aligned}$$

Jensen's inequality, $\log \mathbb{E} X \geq \mathbb{E} \log X$, is an equality if X is constant, i.e., if $q(z) \propto p_\theta(z|x^{(i)})$:

$$\sum_o \log p_\theta(x^{(i)}) = \max_q \sum_i \mathbb{E}_{z \sim q} \log \frac{p(z)p_\theta(x^{(i)}|z)}{q(z)}.$$

This is the *variational lower bound* (VLB, or evidence lower bound, ELBO). To train the model, maximize the VLB wrt both q and θ .

The VAE objective can also be derived by computing $\text{KL}(q(z) \parallel p(z|x))$:

$$\log p(x) = \mathbb{E}_{z \sim q} \left[\log \frac{p(z)p(x|z)}{q(z)} \right] + \text{KL}(q(z) \parallel p(z|x)).$$

The optimization wrt q is tricky because the objective is an expectation wrt q . The *likelihood ratio gradient* (score function, REINFORCE)

$$\nabla_\phi \mathbb{E}_{z \sim q_\phi} [f(z)] = \mathbb{E}_{z \sim q_\phi} [\nabla_\phi \log q_\phi(z) \cdot f(z)]$$

is very noisy (try to minimize $\mathbb{E}_{x \sim N(\mu, 1)} \|x - 5\|^2$: the gradient is $\frac{1}{2}(x - \mu) \|x - 5\|^2$ – each step is in a random direction, but they are slightly longer in the right direction). Whenever possible, the *reparametrization trick* (or *pathwise derivative*) works better:

$$\mathbb{E}_{z \sim N(\mu, \sigma^2)} [f(x)] = \mathbb{E}_{\varepsilon \sim N(0, 1)} [f(\mu + \sigma \varepsilon)]$$

The β -VAE forces the latent representation to be even more Gaussian ($\beta \gg 1$):

$$\text{Loss} = \mathbb{E}_{z \sim q_\phi(z|x)} [\log p_\theta(x|z)] - \beta \cdot \text{KL}(q_\phi(z|x) \parallel p(z)).$$

The VQ-VAE provides a better separation between classes by quantizing the latent space. The VQ-VAE-v2 (current SOTA) uses a hierarchical latent space (with progressive up- and down-sampling) and self-attention; contrary to GANs, it does not suffer from mode collapse.

More complex distributions for $p(x|z)$, e.g., PixelCNN, tend to forget the latent code...

Variational approximation has other uses. Flow++ does not use uniform quantization, which results in piecewise constant distributions, $\square\square\square$, but learns it (*variational dequantization*) \triangleleft .

Mutual information can be approximated as

$$\begin{aligned} I(z; x) &= H(z) - H(z|x) \\ &= H(z) - \mathbb{E}_{(z,x) \sim p(z,x)} [-\log p(z|x)] \\ &= H(z) + E[\log q(z|x) - \log q(z|x) + \log p(z|x)] \\ &= H(z) + E[\log q(z|x)] + \text{KL} \\ &\geq H(z) + E[\log q(z|x)] \end{aligned}$$

5,6. Implicit models learn a mapping $z \mapsto x$ without explicit density estimation – just samples. We can no longer compute $\text{KL}(p_{\text{data}} \parallel p_{\text{model}})$: we will use other distances (MMD, JSD, EMD, etc.)

A **generative adversarial network** (GAN) is a min-max game between a generator and a discriminator

$$\min_G \max_D \mathbb{E}_{x \sim \text{data}} \log Dx + \mathbb{E}_{z \sim p_z} \log(1 - DGz).$$

To evaluate the quality of the generated images, the kernel density estimator (aka *Parzen window density estimator*) does not work well in high dimension. The *inception score* uses a pretrained classifier: the class of each generated image should be easy to recognize ($p(y|x)$ has low entropy) and the classes should be diverse ($p(y)$ has high entropy).

$$\begin{aligned} \text{IS} &= \exp[H(y) - H(y|x)] \\ &= \exp \mathbb{E}_{x \sim \text{generated}} \text{KL}(p(y|x) \parallel p(y)) \end{aligned}$$

It is still susceptible to model collapse. The *Frechet inception distance* (FID) compares the mean and covariance of the features (Inception-v3 pool3) of the real and generated images:

$$d^2 = \|m - m_w\|^2 + \text{tr}(C + C_w - 2(CC_w)^{1/2}).$$

Those evaluation methods are not good enough to be used as objectives, though.

The optimal discriminator is

$$D^*(x) = \frac{p_{\text{data}}(x)}{p_{\text{data}}(x) + p_{\text{generated}}(x)};$$

the objective is then

$$V(G, D^*) = -\log 4 + \text{JSD}(p_{\text{data}} \parallel p_{\text{generated}}).$$

The Jensen-Shannon divergence is between the KL (no mode collapse, blurry) and the inverse KL (mode collapse) divergences. If the discriminator is too good, it saturates (its gradient is zero – uninformative): for the generator loss (only), change the second term from $\log(1 - DGz)$ to $-\log DGz$: the uninformative gradients are no longer for the fake samples but for the real ones. (It is no longer a zero-sum game: the loss is different for G and D .)

DCGAN (deep convolutional GAN) uses mostly convolutions; it allows for vector arithmetic (pose, smile, glasses, gender). When interpolating using a GAN, do not use a straight line (it would go close to the origin, which is a muddy image), but a half-circle away from the origin.

Improved training of GANs introduced a few ideas:

- Feature matching: for some feature f , add

$$\left\| \mathbb{E}_{x \sim \text{data}} [f(x)] - \mathbb{E}_{z \sim \text{noise}} [f(Gz)] \right\|^2$$

to the loss;

- Minibatch discrimination: feed minibatches, rather than individual images, to the discriminator, to spot mode collapse (of just add $\exp - \|fx_i - fx_j\|_1$ to the loss, or to the input, for some feature f);
- Historical averaging: regularize by adding $\|\theta - \frac{1}{T} \sum_t \theta_i\|^2$ to the loss (cf. Cesaro (usually at text time only), TRPO);
- One-sided label smoothing (only for the real data);
- Virtual batch normalization: batch-norm procudes correlated samples: compute the batch statistics using a virtual batch made of the current observation and a fixed reference batch;
- Semi-supervised learning: have the discriminator predict labels, if available, instead of just real vs fake;
- Inception score.

The *Wasserstein GAN* (WGAN) replaces the JSD with the Wasserstein distance

$$\begin{aligned} W(p_{\text{real}}, p_{\text{gen}}) &= \inf_{\gamma \in \Pi(p_r, p_g)} \mathbb{E}_{(x,y) \sim \gamma} \|x - y\| \\ &= \sum_{\|f\|_L \leq 1} \mathbb{E}_{x \sim p_r} [f(X)] - \mathbb{E}_{x \sim p_g} [f(X)]. \end{aligned}$$

To enforce the Lipschitz condition, just clip the weights. There is no classifier: the Lipschitz function is just a “critic”. The gradient is more meaningful, and the model more robust (no need for all those tricks).

WGAN-GP replaces the weight clipping with a gradient penalty $(\|\nabla_x D(x)\|_2 - 1)^2$, evaluated at a random point between a real and a fake sample; there is no batch-norm in the discriminator.

ProGAN progressively increases the resolution.

SNGAN (spectral normalization) uses a *hinge loss*

$$\begin{aligned} L_D &= \mathbb{E}_{x \sim \text{data}} (Dx - 1)_- + \mathbb{E}_{z \sim \text{noise}} (-DGz - 1)_- \\ L_G &= - \mathbb{E}_{z \sim \text{noise}} [DGz], \end{aligned}$$

conditional batchnorm, and enforces the Lipschitz condition using *spectral normalization* of the weight matrices, $W \leftarrow W/\sigma(W)$; the spectral norm (largest singular value) can be approximated with power iteration (one iteration is enough).

The discriminator can use labels in different ways:

SAGAN uses *self-attention*, spectral normalization (in both discriminator and generator) and hinge loss.

BigGAN scales everythingm adds *orthogonal regularization* $\|W'W - I\|_F^2$, but only for the off-diagonal elements $\|W'W \odot (1 - I)\|_F^2$, use the *truncation trick* (truncate the Gaussian $N(0, I)$ at test time to $[-c, c]$) and “standing statistics” (?) for batch-norm.

StyleGAN uses the noise in a different way: the generator starts with a constant input and progressively upscales it, adding noise at each step; there are two types of noises: the style noise, preprocessed by another network, is incorporated at each step; additional Gaussian noise, different at each step, is also added. As with style transfer, StyleGAN uses (adaptive) *instance normalization*.

StyleGAN2 addresses some artefacts in StyleGAN (e.g., water-droplet-like artefacts, very visible in the activations, but less so in the final images) and can compute the latent representation of an image.

The *variational information bottleneck* (VIB) add another encoder before the discriminator,

to reduce the information it receives, with a constraint on the mutual information $I(X; Z) \leq I_c$ or a variational bound on the mutual information

$$\mathbb{E}_x [\text{KL}(p(z|x) \parallel r(z))] \leq I_c.$$

Pix2Pix is a *conditional GAN* (cGAN) used, e.g., to colour black-and-white images, in which the discriminator takes pairs of images to ensure the output is related to the input;

it also uses an autoencoder loss $\text{B\&W} \rightarrow \text{colour} \rightarrow \text{B\&W}$. To reduce the capacity of the discriminator, have it work on patches. Examples include colouring images, turning contours into images, sharpening, turning sketches into photorealistic images (GauGAN), controlling drawing software (learning-to-paint), video (video2video: pose detection to change the person moving or dancing, deep fake adding frames, increasing resolution, etc.)

GANs can also be used for *representation learning*. The *InfoGAN* generator takes as input a code c and noise z to generate an image x ; to ensure that the code is

actually used, maximize the mutual information $I(c, x)$ or a variational lower bound.

$$\begin{aligned} I(c; x) &= I(c; G(z, c)) \\ &= H(x) - H(c|G(z, c)) \\ &= H(c) + \mathbb{E}_{x \sim G(z, c)} \mathbb{E}_{c' \sim p(c'|x)} \log p(c'|x) \\ &\geq H(c) + \mathbb{E}_{x \sim G(z, c)} \mathbb{E}_{c' \sim p(c'|x)} \log q(c'|x) \end{aligned}$$

It can also be used for unsupervised category discovery (with a discrete code).

BiGAN (bidirectional GAN) and BigBiGAN learn “generators” in both direction, between image and latent representation; the discriminator learns to distinguish encoder pairs (x, \hat{z}) from generator pairs (\hat{x}, z) .

Energy-based models

$$p(x) = \frac{1}{Z} e^{-E(x)}$$

are estimated by maximizing

$$\mathbb{E}_{x \sim \text{data}} [\log p_\theta(x)] = \mathbb{E}[-E_\theta(x)] - \log Z(\theta).$$

The partition function Z can be replaced by a variational lower bound.

$$\begin{aligned} \log Z &= \log \sum_x e^{-E_\theta(x)} \\ &= \log \sum_x \frac{q(x)}{q(x)} e^{-E_\theta(x)} \\ &= \log \mathbb{E}_{x \sim q} \left[\frac{e^{-E_\theta(x)}}{q(x)} \right] \\ &\geq \max_\phi \mathbb{E}_{x \sim q_\phi} \left[\log \frac{e^{-E_\theta(x)}}{q_\phi(x)} \right] \\ &\geq \max_\phi \mathbb{E}_{x \sim q_\phi} [-E_\theta(x) + H(q_\phi)]. \end{aligned}$$

The objective is then an *entropy-regularized GAN* (the entropy helps prevent mode collapse).

$$\max_\theta \min_\phi \mathbb{E}_{x \sim \text{data}} [-E_\theta(x)] + \mathbb{E}_{x \sim q_\phi} [E_\theta(x)] - H(q_\phi)$$

The entropy is usually difficult to compute (except for some models, e.g., PixelCNN).

The WGAN optimizes the dual; *optimal transport* GAN directly optimized the primal, e.g., using *implicit MLE*:

- Generate n samples from p_θ ;
- Pick n real images;

- For each real image, pick the “closest” generated image, form some measure of distance (since each real image is matched, we avoid mode collapse);
- Move θ to make them closer.

Adversarial losses also have applications in *transfer learning*,

fairness,

$$\max_{\theta} \text{Loss}(\theta) \text{ such that } \text{Loss}_{\text{sensitive}}(\theta) \leq K$$

or imitation learning (GAIL)

$$\mathbb{E}_{\pi} [\log D(s, a)] + \mathbb{E}_{\pi_{\text{expert}}} [\log(1 - D(s, a))] - \lambda H(\pi),$$

which works better with a variational information bottleneck (VAIL).

7. Self-supervised learning is a form of unsupervised learning which holds part of the data and tasks a neural network to recover it.

Denoising autoencoders add different types of noise (Gaussian, zero, zero-or-one); they make the output constant in directions orthogonal to the data manifold. They can be stacked.

Impainting removes the central region, a random block, or an element (segmentation mask); use a GAN loss in addition to the reconstruction loss to avoid blurry images.

The *split-brain autoencoder* predicts one view of an image from another (e.g., colour from greyscale, $L \mapsto (a, b)$); it works better with quantized colours (pixel-wise classification problem).

One can try to predict the relative position of two patches (include gaps, jitter the patches; chromatic aberration can be a problem: it points to the center of the image),

or reorder them, as a jigsaw problem, or predict by how much an image was rotated (4 rotations work better than more).

Word embeddings predict the center of a window (CBOW) or the context of a word (skipgram, with negative sampling).

contrastive predictive coding (CPC) looks for an encoder E such that the mutual information $I(Ex_1; Ex_2)$ be high if x_1 and x_2 are patches from the same image, and low otherwise. Applications include sound, iamges. language, reinforcement learning; data augmentation is important.

Even if you have data, unsupervised pretraining followed by supervised fine-tuning outperforms supervised training.

Instance discrimination looks for a latent representation in which augmented versions (cropped, flipped, etc.) of the same image are close and different images are far apart: MoCo (keep a buffer of negative examples), SimCLR, MoCo-v2.

8. Use AR models if you need a density – but sampling is slow.

Use VAEs if you need both a latent representation and samples.

Use GANs if you want good quality samples (sharp images), fast-training, or image-to-image translation.

9a. Supervised learning solves

$$\underset{\theta}{\text{Maximize}} \underset{(x,y) \sim \text{data}}{\text{E}} [\log p_{\theta}(y|x)].$$

Semi-supervised learning leverages unlabeled data.

Entropy minimization ensures the classifier is confident on unlabeled data. *Pseudo-labels* are confident predictions, on the unlabeled data, progressively added to the training data.

Label consistency asks that predictions be similar for different augmentations of any given input, e.g., with the π -model

or *temporal ensembling* (the squared difference is with a moving average of past latent representations of the input) or *mean teacher* (instead of keeping a moving average for each input, just keep a moving average of the weights, and compare the latent representations computed with the current and average weights).

An adversarial example $x + r$ can be found as $r = \varepsilon g / \|g\|$, where $g = \nabla_x \log p(y|x; \hat{\theta})$, or

$$r = \underset{\|r\| \leq \varepsilon}{\text{Argmax}} \text{KL}(p(\cdot|x; \hat{\theta}) \| p(\cdot|x+r; \hat{\theta}))$$

(linearize the Kullback-Leibler divergence and use power iteration).

Virtual adversarial training (VAT) makes the forecasts for x and $x + r$, for unlabeled data, close; it performs best.

Unsupervised data augmentation (UDA) (back-translation, image augmentation) improves performance more than random perturbations. *Training*

signal annealing (TSA) helps prevent overfitting on labeled data by masking out high-confidence samples

$$\underset{\theta}{\text{Minimize}} \underset{x,y}{\text{Mean}} - \log p_{\theta}(y|x) \mathbf{1}_{p_{\theta}(y|x) \leq \eta_t}.$$

MixUp creates new, synthetic observations by combining existing ones.

$$\lambda \sim \text{Beta}(\alpha, \alpha)$$

$$\lambda' = \text{Max}(\lambda, \lambda')$$

$$x' = \lambda' x_1 + (1 - \lambda') x_2$$

MixMatch uses MixUp to mix labeled and unlabeled observations, computes the labels by running the classifier on several augmentations of the input, averaging the outputs, and shapening (temperature) the average.

The *noisy student* trains progressively larger models:

- Train a teacher models;
- Train a student model on the original data, and teacher forecasts for unlabeled data, with both input noise (data augmentation) and model noise (dropout, stochastic depth);
- Iterate with a larger student.

9b. Unsupervised distribution alignment tries to find a mapping between two domains, A and B , either as conditional probabilities, $p(a|b)$ and $p(b|a)$, or as maps $A \rightleftharpoons B$, using only unpaired data from A and B . Examples include daylight and night-time images, black-and-white and colour images, segmentation mask and photograph, English and French sentences, image and caption, painting and photograph, etc.

CycleGAN combines *marginal matching*, which approximates the marginals $p(a|b) \approx q_{\theta}(a|b)$, $p(b|a) \approx q_{\theta}(b|a)$ such that

$$q(b) = \underset{a \sim p}{\text{E}} [q(b|a)] \approx p(b)$$

$$q(a) = \underset{b \sim p}{\text{E}} [q(a|b)] \approx p(a)$$

and *cycle consistency*. It can cheat the cycle consistency condition by hiding information (steganography).

DualGAN uses a stochastic mapping $G_{AB} : A \times X \rightarrow B$ instead of $A \rightarrow B$, but the cycle consistency $G)BA(G_{AB}(a, z), z') = a$ makes it ignore z and z' . Instead, the *augmented CycleGAN* learns mappings between $A \times Z$ and $B \times Z$.

Word2vec embeddings for different languages can be aligned with a rotation: approximate marginal matching with adversarial training followed by a refinement of the rotation by solving the exact alignment problem for the top pairs.

Unsupervised machine translation combines word-level alignment, monolingual models (marginal matching), back-translation (cycle consistency).

10. Compression. The *Shannon entropy* is the number of bits needed to transmit information,

$$H(X) = \sum_i p(x_i) \log \frac{1}{p(x_i)}.$$

For any uniquely decodable code C ,

$$\sum_{(s,w) \in C} 2^{-\ell(w)} \leq 1$$

(Kraft-McMillan inequality); conversely, for any lengths satisfying this inequality, there exists a *prefix* code.

The length of a code is at least the entropy, $H(X) \leq \langle \ell \rangle$; there exists a code with average length $\langle \ell \rangle \leq H(X) + 1$. *Huffman coding* (a trie, built bottom up) has length $\ell_i = \lceil -\lg p(x_i) \rceil$; it is optimal.

If we only have an approximation \hat{p} of p , the average length is $\text{KL}(\hat{p}||p) + H(p)$. If the entropy is too high, try conditioning: $H(X|C) \leq H(X)$, e.g., with AR models. The “+1” in $\langle \ell \rangle \leq H(X) + 1$ matters if $H(X)$ is small: use larger chunks. The entropy of the English language is around 1 bit per character.

Arithmetic coding encodes a message as a subinterval of $[0, 1]$: for each new character, split the current interval into subintervals of sizes proportional to the probabilities of each symbol, and pick that corresponding to the new character. To send the final interval, use any number in it.

Asymmetric numeral systems are an alternative to arithmetic coding using integers instead of intervals: partition \mathbf{N} into subsets S_a, S_b , etc., one for each symbol, such that “ S_a contains a proportion $p(a)$ of integers”, and progressively update a state $s \in \mathbf{N}$, starting at $s = 0$, by setting $\text{enc}(s, a)$ to the s th element of S_a .

High-dimensional (discretized) continuous data can be modeled as a mixture of simple distributions, $p(x) = \sum_i p(i)p(x|i)$, using

- Max-mode coding: send $i = \text{Argmax } p(i|x)$ encoded with p , then x encoded with $p(\cdot|i)$; it costs $H(X) + \text{KL}(\text{true}||\text{mixture})$;
- Posterior sampling: use i sampled from $p(\cdot|x)$ instead;
- **Bits-back coding**.

The **Lempel-Ziv** (LZ) compression algorithm looks, in the text seen so far, for the longest match to the string starting at the current position, and outputs its location and length.

11. NLP. The *perplexity* of a language model is the average number of possible next words, *i.e.*, the branching factor – it is between 5 and 10 for free speech, and more constrained, 3 or 4, for translation.

Here are some milestones in the history of language models:

- GloVe, a factorization of the pointwise mutual information matrix,

$$\text{PMI}(x, y) = \log \frac{p(x, y)}{p(x)p(y)},$$

obtained from the co-occurrence matrix;

- Word2vec, another vector embedding, predicting a word from its context (CBOW, continuous bag of words) or the opposite (skipgram);

- Byte pair encoding (BPE, usually up to 32,000 tokens);
- n -gram models with smoothing;
- NPLM, an n -gram model, with vector embeddings and a neural net;
- Skip-thought, skipgram with sentences instead of words (contrary to the word embeddings, the sentence embeddings are not model parameters but are computed from the word embeddings);
- ELMO, contextual word representations from RNNs;
- GPT, contextual word representations with a transformer-based generative model;
- BERT (masking), RoBERTa;
- Electra: BERT-like model (masking) with a discriminator to distinguish real from generated sentences;
- T5, which combines all of the above.

Multitask and metalearning

C. Finn (Stanford, 2020)

2. A *multitask learning* network can take as additional input a description of the task,

or split the parameters into task-specific and shared (or soft-shared: $\lambda \sum \|\theta_t - \theta_{t'}\|$).

There can be *negative transfer* – independent networks may work better.

3. There are three types of metalearning algorithms: black-box, optimization-based and non-parametric.

In black-box algorithms, a first network processes the training data and outputs parameters for the second network, which performs the task.

Optimization-based algorithms, e.g., **MAML** (model-agnostic meta-learning) learn parameters θ such that starting the optimization at θ gives the best performance on the new tasks.

$$\text{Minimize}_{\theta} \sum_{\text{task } i} \text{Loss}(\theta - \alpha \nabla_{\theta} \text{Loss}(\theta, \mathcal{D}_i^{\text{train}}), \mathcal{D}_i^{\text{test}})$$

4. MiniImageNet is a metalearning benchmark for one-shot 5-class image classification.

A *siamese network* checks if two images are of the same class – but training a binary classification model for n -way classification may not be optimal. *Matching networks* learn an embedding on which k -NN performs well. If there are several samples per class, a *prototypical network* embeds them all, computes their averages, and uses k -NN on those averages,

$$p(y = k|x) \propto \exp -d(f_\theta(x), c_k).$$

One can also learn the distance (relation networks) or allow for several prototypes per class (infinite mixture of prototypes, IMP).

5. MAML ensembles are an example of Bayesian metalearning algorithm.

6. Since MAML and black-box meta-learning only need gradients, they can be used with policy gradient – but the variance is high, and it is on-policy. Value-based reinforcement learning (off-policy) is not gradient-based: it is difficult to combine it with MAML.

8. Model-based reinforcement learning learns the dynamics (usually, the same across tasks); *model-predictive control* (MPC) replans after each step, because we may end up in a state slightly different from what the model predicted. Learn either in latent space or in image space (video prediction)

$$(\text{observation}_n, \text{action}_n) \mapsto \text{observation}_n.$$

9. In **life-long learning**, the agent is asked to learn a first task, then a second, and so on, instead of all at the same time. Task order can be known, predictable, or random; task boundaries may be known or not; they can change abruptly or progressively shift.

We want to minimize the *regret*.

There can be positive/negative forward/backward transfer: the current task can make the performance on future/previous tasks better/worse.

The *follow-the-leader* algorithm stores all the data seen so far and trains on it. The *catastrophic forgetting* algorithm takes a gradient step on the current observation and forgets it.

To avoid forgetting previous tasks, keep a small amount of data for each task and add a constraint that the loss on the previous tasks does not get worse.

10. *Generative teaching networks* (GTN) learn how to generate data to train on, to help select the network

architecture – once it is chosen, train on actual data, long enough.

Weight normalization suggests to parametrize the weights as $\mathbf{w} = g \cdot \mathbf{v} / \|\mathbf{v}\|$, $g \in \mathbf{R}_+$ and learn \mathbf{v} and g separately.

Learning to RL (LRL – RL² is similar) learns a RNN $(s, t, a_t) \mapsto a_t$; it is amenable to differential Hebbian learning (“neurons that fire together wire together”) and neuromodulated differentiable Hebbian learning (with eligibility traces).

To avoid catastrophic forgetting when “learning to continuously learn”, ANML uses second network to identify the task and zero out the weights irrelevant for it.

POET and Go-Explore use *goal switching* and automatically generate tasks.

11. *Mutual information* is a measure of dependence

$$\begin{aligned} I(x; y) &= \text{KL}(p(x, y) \parallel p(x)p(y)) \\ &= \underbrace{H(p(y))}_{\text{how hard it is to guess } y} - \underbrace{H(p(y|x))}_{\text{how hard it is to guess } y \text{ knowing } x} \end{aligned}$$

For instance, the *empowerment* is

$$I(s_{t+1}; a_t) = H(s_{t+1}) - H(s_{t+1}|a_t).$$

Some variants of Q -learning

$$Q(s, a) \leftarrow s(s, a) + \text{Max}_{a'} Q(s', a')$$

increase exploration (soft Q -learning, SAC)

$$Q(s, a) \leftarrow s(s, a) + \log \int \exp Q(s', a') da'$$

$$Q(s, a) \leftarrow s(s, a) + \underbrace{\mathbb{E}_{s', a'} [Q(s', a') - \log \pi(a'|s')]}_{\text{entropy}}$$

Soft actor critic (SAC) updates the policy as

$$\pi \leftarrow \underset{\pi}{\text{Argmin}} \text{KL}(\pi(\cdot|s) \parallel \exp Q^{\pi^{\text{old}}}(s, \cdot)).$$

To learn without a reward function, train a VAE to represent the state of the world, pick a state at random, and use it as a goal. To get diverse goals, update the VAE using *weighted MLE*, maximizing $\mathbb{E}[w(x) \log p(x)]$ instead of $\mathbb{E}[\log p(x)]$, e.g., with $w(x) = p(x)^\alpha$, $\alpha \in [-1, 0)$, to increase entropy. Learning $\pi(a|s, \text{goal})$ is equivalent to maximizing $I(s; \text{goal})$.

Intrinsic motivation adds an exploration bonus $-\log p_\pi(s)$ to the reward – but check *state marginal matching* (SMM) instead.

Instead of specifying a goal, give the policy a “skill” z (an integer) and have a discriminator try to guess it

from the subsequent state(s). Policy and discriminator cooperate. This maximizes the mutual information $I(z; s)$. (In hierarchical reinforcement learning, once the skills have been learnt, one can learn a policy that switches between them.)

12. To avoid memorization, add a penalty on the information stored in the parameter (*meta-regularization*).

If there is no explicit boundary between tasks, use the performance of the current model to detect changes or, more generally, BOCPD (Bayesian online change-point detection – it is differentiable: you can backprop through it): MOCA (metalearning with changepoint analysis).

If there is no explicit task, learn a representation of the data (unsupervised: BiGAN, DeepCluster), arbitrarily cluster the data (in different ways), and ask metalearning to learn to distinguish those classes.

If two gradients conflict ($g_1 \cdot g_2 < 0$), project each onto the normal hyperplane of the other (PCGrad: projecting conflicting gradients).

Generative deep learning D. Foster (2019)

1. *Naïve Bayes* models are *generative*; they may work with simple tabular data, but will fail with pixels.

2. To classify images (CIFAR-10), one could try dense layers (200, 150, 10, softmax; ReLU), but convolutions (3×3 , 32, 32₁, 32₂, 64₁, 64₁, dense(128), dropout, dense; leaky ReLU, batchnorm after each layer – I indicate the stride with indices) work better.

3. To generate images (MNIST), we could try an *autoencoder*, but the distribution in the latent space is not centered, far from Gaussian, and unbalanced. Instead, a *variational autoencoder* (VAE, or β -VAE) adds noise to the latent space and forces the distribution to be close to $N(0, 1)$. Check the 1-dimensional distributions in the latent space: after training, they should look Gaussian. You can interpolate between images, or change some attribute, e.g., by adding $\lambda \cdot [\text{avg}(\text{smile}) - \text{avg}(\neg \text{smile})]$ (CelebA).

4. GANs are notoriously difficult to train: they suffer from mode collapse, oscillating loss, uninformative loss (the loss function of the generator changes with time: if the loss increases with time, this may not be worrying, the quality may be improving) and hyperparameters are tricky to select.

The *Wasserstein GAN* (WGAN) removes the log in the objective, makes the critic 1-Lipschitz with weight clipping, and trains the critic to convergence (e.g., 5 steps for each generator step).

Instead of clipping the weights, the *WGAN-GP* uses a gradient penalty, $(\|\nabla_{\text{input}} \text{critic}\| - 1)^2$, where the gradient is evaluated at random averages between generated and real images, and removes the critic batchnorm. Examples include “Quick, draw!”, CIFAR-10 horses and CelebA.

5. A *CycleGAN* uses two generators and two discriminators, with a UNet or ResNet architecture,

instance normalization instead of batch normalization, and a *PatchGAN* discriminator: it does not output a single number, but an 8×8 matrix indicating if each patch is real or generated (what is consistent across patches is the style, rather than the contents: that is what we want to capture).

Neural style transfer combines three losses: for the contents (MSE of the features), the style (MSE of the GRAM matrices of the features, for several layers), and the total variation (actually $L^{1.25}$ instead of L^1); the model uses a pretrained VGG19 and is fitted with L-BFGS-B [why not gradient descent?].

6. To generate text, try an LSTM RNN, or a GRU, or their bidirectional variants, or stack them, after an embedding layer; train with *teacher forcing*; sample with *temperature* [and try *beam search*] (Maluuba NewsQA, to generate answer-question pairs from text).

7. To generate monophonic music (Bach cello suites), use *music21* to process the MIDI files, and stacked LSTMs, outputting pitch-duration pairs one by one.

MuseGAN deals with polyphonic music (Bach chorales); the generator has 4 components, whose output change (or not) with each bar (or track); the discriminator uses 3-dimensional convolutions.

8. The *WorldModel* for reinforcement learning (RL) in OpenAI Gym’s CarRacing game has three components:

- A VAE to process the image: $\text{img}_t \mapsto h_t \mapsto \text{img}_t$;
- An RNN with a *mixture density network* (MDN-RNN), i.e., an LSTM followed by an MDN (which outputs a mixture of 5 Gaussians in each dimension, i.e., parameters $p_1, \dots, p_5, \mu_1, \dots, \mu_5, \sigma_1, \dots, \sigma_5 \in$

- \mathbf{R}^n), which tries to predict the next state, $(a_{t-1}, h_t) \mapsto \hat{h}_{t+1}$;
- A controller $(a_{t-1}, h_t, \hat{h}_{t+1}) \mapsto (a_t, \hat{r}_{t+1})$, fully connected, trained with *CMA-ES*, in parallel (**estool**).

One can train using the MDN-RNN as a model (*in-dream training*) – to reduce overfitting, add a temperature parameter to control model uncertainty and steer the controller towards safer, better understood actions.

9. Transformers are stacked attention layers (no RNN, no CNN), with *positional encoding* and *multihead attention*. BERT is a bidirectional masked language model; GPT2 is unidirectional; MuseNet is unidirectional and uses a *sparse transformer*.

ProGAN progressively increases the resolution of the image during training.

SAGAN uses self-attention (some parts of the image that are far apart, e.g., the background, should be similar).

BigGAN uses a truncated Gaussian ($z \mid |z| \geq \varepsilon$, instead of $z \sim N(0,1)$), to increase diversity, adds the noise to each layer, uses a shared embedding (?), a hierarchical latent space (?), orthogonal initialization ($W'W = I$), orthogonal regularization ($\|W'W - I\|_F^2$ or $\|W'W \odot (1 - I)\|_F^2$), spectral normalization, hinge loss, EWMA of the weights, etc.

StyleGAN is a style transfer network, based on ProGAN, adding the noise to each layer, with *adaptive instance normalization* to match the mean and variance of each feature with those of the desired style.

Machine learning for asset managers M. López de Prado (2020)

1. Applications of machine learning (ML) in finance include existence (of a phenomenon, of information in data), variable importance, causation, dimension reduction, visualization, latent representation, outlier detection, etc.

2. Use random matrix theory (RMT) to denoise correlation matrices, setting the noise eigenvalues to their average (to preserve the trace).

For clustering, try *detoning* – removing the market component (the matrix is then singular, but it is not an issue).

3. Correlation can be turned into a distance as $d = \sqrt{1 - \rho}$ or $d = \sqrt{1 - |\rho|}$ (it is the Euclidean distance between the standardized vectors). The *variation of information* VI is another distance.

$$H(X) = \mathbb{E}_x[-\log p_x] \quad (\text{entropy})$$

$$= \sum_x -p_x \log p_x$$

$$H(X, Y) = \mathbb{E}_{x,y}[-\log p_{xy}]$$

$$H(X|Y) = H(X, Y) - H(Y)$$

$$\text{KL}(p||q) = \mathbb{E}_{x \sim p} \left[-\log \frac{q_x}{p_x} \right] \quad (\text{KL divergence})$$

$$= \sum_x p_x \log \frac{p_x}{q_x}$$

$$H_c(p||q) = \mathbb{E}_{x \sim p} [-\log q_x] \quad (\text{cross-entropy})$$

$$= H(p) + \text{KL}(p||q)$$

$$I(X; Y) = H(X) - H(X|Y) \quad (\text{mutual information})$$

$$= H(Y) - H(Y|X)$$

$$= \sum_{xy} p_{xy} \log \frac{p_{xy}}{p_x p_y}$$

$$= \text{KL}(p_{xy}||p_x p_y)$$

$$= \mathbb{E}_y [\text{KL}(p(x|y) || p(x))]$$

$$= \mathbb{E}_x [\text{KL}(p(y|x) || p(y))]$$

$$\text{VI}(X, Y) = H(X|Y) + H(Y|X)$$

$$= H(X) + H(Y) - 2I(X; Y)$$

$$= 2(H(X, Y) - H(X) - H(Y))$$

$$= H(X, Y) - I(X; Y)$$

$$\widetilde{\text{VI}}(X, Y) = \frac{\text{VI}(X, Y)}{H(X, Y)}$$

$$= 1 - \frac{I(X; Y)}{H(X, Y)}$$

$$\widetilde{\widetilde{\text{VI}}} = 1 - \frac{I(X; Y)}{\text{Max}\{H(X), H(Y)\}}$$

4. Use *k*-means clustering *on the columns* of the distance matrix $\sqrt{1 - \rho}$ (or $\sqrt{1 - |\rho|}$); choose *k* to maximize the *clustering quality* *q* (optimal number of clusters, ONC)

$$q = \frac{\mathbb{E}[S]}{\text{Var}[S]}$$

$$S_i = \frac{b_i - a_i}{\text{Max}(a_i, b_i)}$$

where a_i (resp. b_i) is the average distance between observation x_i and the elements of its cluster (resp.,

of the nearest cluster). Compute the clustering quality for each cluster; recluster those below average (just once) and keep the new clustering if quality improves.

5. Instead of forecasting labels based on time, tick, volume or price bars,

$$\begin{cases} +1 & \text{if } r > \tau \\ 0 & \text{if } |r| \leq \tau \\ -1 & \text{if } r < -\tau, \end{cases}$$

use a *trippel barrier*

$$\begin{cases} +1 & \text{profit-taking barrier} \\ -1 & \text{stop-loss barrier} \\ 0 & \text{time-out barrier} \end{cases}$$

or *trend scanning*: whether each observation is in an up/down trend or not, by looking at the minimum p -value of linear regressions on $[t, t + T]$, for various T .

For bet sizing:

- Assume the Sharpe ratio is a standard Gaussian and bring it back to $U(-1, 1)$;
- Given n binary predictors, their average under $H_0 : p = \frac{1}{2}$ is known; bring it back to $U(-1, 1)$.

6. To measure feature importance, check:

- p -values;
- Shapley values;
- Accumulated local effects (ALE);
- Mean increase impurity: weighted information gain, from a random forest;
- Mean decrease accuracy: drop in accuracy after shuffling the values of a variable.

Replace the accuracy with:

- The negative log-likelihood of the true labels;
- The probability-weighted accuracy,

$$\frac{\sum_n \mathbf{1}_{\text{correct}} \times (p_n^{\max} - 1/K)}{\sum_n (p_n^{\max} - 1/K)}$$

where K is the number of classes and p_n^{\max} the probability, from the model, of the most likely class.

To deal with multicollinearity, cluster the features.

7. Numeric instability, in portfolio construction, is due to the condition number of the precision matrix V^{-1} ; it is worse when there are highly correlated assets. It is usually dealt with by regularization (Black-Litterman), constraints, or better estimates of the concentration matrix. *Nested clustered optimization* (NCO) denoises (RMT) and clusters (ONC) the covariance matrix, computes optimal portfolios withing each cluster, and then the inter-cluster optimal portfolio.

8. To limit selection bias under multiple testing, estimate the FDR and the FWER from

$$\begin{aligned} \text{FPR} \quad \alpha &= \frac{\text{FP}}{\text{TN} + \text{FP}} \\ \text{FNR} \quad \beta &= \frac{\text{FN}}{\text{TP} + \text{FN}} \\ \theta &= \frac{\text{TP} + \text{FN}}{\text{TN} + \text{FP}} \end{aligned}$$

Approximations of the distribution of

- The sample Sharpe ratio;
- The maximum sample Sharpe ratio after k trials.

help define a *deflated Sharpe ratio*.

Use clustering to estimate the effective number of trials.

9. To limit overfitting, test on synthetic data, using

- Resampling: cross-validation, (sequential) bootstrap and their variants;
- Monte Carlo: parametric, GAN, VAE.

Probabilistic foundations of statistical network analysis H. Crane (2018)

A *random graph* is a graph-valued random variable.

3. We rarely observe the whole graph, but only some *sample* of it: it is not always straightforward to infer properties of the population graph from those of the sample graph (*consistency*), and this depends a lot on how the network was sampled – *vertex sampling* (which tends to generate empty subgraphs, if the population graph is large and sparse), *edge sampling* (a list of edges, e.g., when you intercept communications), *snowball sampling* (pick k nodes at random and consider their radius- r egonets), *hyperedge sampling* (collaboration, e.g., co-author networks) or *path sampling* (traceroute, to study the internet).

4. Common models include:

- Erdos-Renyi: $P(Y_{ij} = 1) = p$;
- Barabasi-Albert (preferential attachment);
- Exponential random graph model (ERGM),

$$P(Y = y) \propto \exp \sum_i \theta_i T_i(y)$$

where the T_i are features (sufficient statistics); ERGMs do not work well with sampled networks;

- Graphons, $P(Y_{ij} = 1) = \phi(U_i, U_j)$, where $U_i \stackrel{\text{iid}}{\sim} U(0, 1)$ and $\phi : [0, 1]^2 \rightarrow [0, 1]$ or, in closed form

$$P(Y = y) = \int \prod_{i \neq j} \phi(u_i, u_j)^{y_{ij}} (1 - \phi(u_i, u_j))^{1 - y_{ij}} du$$

- Sparse graphon, $\phi_n(u, v) = \rho_n^{-1} w(u, v)$, for graphs of size n , where ρ_n^{-1} is the edge density (e.g., $\rho_n = n$ – this allows sparse graphs, which are impossible with graphons, but not power law degree distributions)
- Stochastic block model (SBM) $P(Y_{ij} = 1) = 1 - \exp \theta_i \theta_j w(k(i), k(j))$ degree-corrected SBM $P(Y_{ij} = 1) = 1 - \exp \theta_i \theta_j \log \phi_{k(i), k(j)}(U_i, U_j)$
- Graphex: an exchangeable point process on $[0, \infty)^2$

$$Y(A) = \#\{a \in A : a \in Y\}, \quad A \subset [0, \infty)^\infty,$$

where $(t, t') \in Y$ is a link between t and t' (users are identified by their registration timestamp)

6. Some of those models are *vertex-exchangeable*: the distribution is invariant under permutation of the vertices. More generally, exchangeable random graphs are continuous mixtures of graphons (Aldous-Hoover theorem). This generalizes de Finetti's theorem: if $(X_n)_{n \geq 1}$ is an exchangeable sequence of random variables with values in $\{0, 1\}$ then, there exists $f : [0, 1]^2 \rightarrow [0, 1]$ such that X has the same distribution as Y defined by

$$\begin{aligned} U_n &\stackrel{\text{iid}}{\sim} U(0, 1) & n \geq 0 \\ Y_n &= f(U_0, U_n) & n \geq 1 \end{aligned}$$

i.e., it is a continuous mixture of iid sequences $f_u(U_n) = f(u, U_n)$.

8. *Relatively exchangeable* models only requires that the distribution be invariant under some permutations of the vertices, for instance, generalized SBM

$$\begin{aligned} P(Y_{ij} = 1) &= \phi_{k(i), k(j)}(U_i, U_j) \\ k : \mathbf{N} &\rightarrow \llbracket 1, k \rrbracket \\ \phi_{k_1, k_2} : [0, 1]^2 &\rightarrow [0, 1] \\ U_i &\stackrel{\text{iid}}{\sim} U(0, 1) \end{aligned}$$

where k indicates the class of each node. Relative exchangeability can be relative to another network:

$$P(Y_{ij} = 1) = \phi_{G|_{\{i, j\}}}(U_i, U_j).$$

More generally, consider k -ary relations, for various k 's, $X_1, \dots, X_r, X_j : \mathbf{N}^{a_j} \rightarrow \mathcal{X}_j$, for instance

- $a_1 = 1$, $\mathcal{X} = \llbracket 1, k \rrbracket$, for the SBM;
- $a_1 = 2$, $\mathcal{X} = \{0, 1\}$ for graph exchangeability;
- $a_1 = 1$, $\mathcal{X} = \mathbf{R}^d$ for latent space models.

Under reasonable assumptions, relative exchangeable random graphs are continuous mixtures of

$$P(Y_{ij} = 1) = \phi_{X_1|_{\{i, j\}}, \dots, X_r|_{\{i, j\}}}(U_i, U_j) \quad U_i \stackrel{\text{iid}}{\sim} U(0, 1).$$

9. An edge-exchangeable random graph is an exchangeable sequence of ordered pairs (exchangeable modulo vertex renaming). If \mathcal{P} is the set of vertices, an *interaction propensity process* is a sequence of iid random variables with values in $\mathcal{P} \times \mathcal{P}$,

$$P[X_k = (r, s)] = f_{r, s}.$$

Examples include the vertex component model $f_{ij} = f_i^{\text{out}} f_j^{\text{in}}$ or the (preferential attachment) *Hollywood model* (which does not generate a graph but a sequence of edges). Edge-exchangeable graphs are continuous mixtures of interaction propensity processes.

One can also consider *relative edge exchangeability* $P[X_i = (r, s)] = f_{r, s}^{k(i)}$, $k : \mathbf{N} \rightarrow \llbracket 1, k \rrbracket$. The notion of exchangeability (and the Hollywood model) can be extended to hyperedges (collaboration networks (IMDb, coauthors): the interaction propensity process is a probability distribution on $\text{fin } \mathcal{P}$, the set of finite multisets of elements of \mathcal{P} : $P[X_i = 1] = f_x$, $x \in \text{fin } \mathcal{P}$) and paths.

11. To model dynamic networks, one often makes a simplifying Markov assumption, or even a *projective Markov* assumption ($(G_t)_t$ is Markov on $\{0, 1\}^{N \times N}$, and so are its restrictions). The *temporal ERGM* is

$$P(Y_{t+1} = y' | Y_t = y) \propto \exp[\eta \cdot T(y, y')].$$

A *rewiring process* samples a new rewiring map

$$W : \begin{cases} \{0, 1\}^{N \times N} & \longrightarrow & \{0, 1\}^{N \times N} \\ Y_t & \longmapsto & Y_{t+1} \end{cases}$$

for each t .

A *graph-valued Lévy process* is defined by

- $Y_0 = 0 \in \{0, 1\}^{N \times N}$;
- Stationary increments $Y_{t+s} \triangle Y_t \stackrel{d}{=} Y_s$;
- Independent increments: $Y_{t_0} \triangle Y_{t_1}, Y_{t_1} \triangle Y_{t_2}, \dots, Y_{t_{k-1}} \triangle Y_{t_k}$ independents

It can be constructed as $Y_0 = 0$, $Y_{t+1} = Y_t \triangle Z_{t+1}$, $Z_{t+1} \sim \mu$, for some distribution μ on $\{0, 1\}^{N \times N}$ (or using a rewiring process).

Deep reinforcement learning hands-on M. Lapan (2020)

1. While the inputs of supervised learning algorithms are pairs (x, y) , where y is the value to predict from x , reinforcement learning uses tuples (s, a, r, s') , where s is the current state, a the action chosen by the agent, r the (immediate) reward and s' the next state, and tries to find the best action for any given state (an action that may not have been chosen by the agent) for the sum of the discounted rewards (and not just the immediate reward).

Challenges of RL include:

- The best action is not known;
- Delayed rewards;
- Non-iid observations;
- Exploitation vs exploration.

2. OpenAI Gym provides RL environments. Some of the environments require the commercial MuJoCo physics simulator (PyBullet is a free alternative, slower with an unpleasant API).

There is no sklearn-like standard Python library for RL algorithms: check OpenAI Baselines (Tensorflow, with a declarative interface), ptan (used by the book), catalyst, etc.

4. The RL algorithm taxonomy distinguishes between:

- **Policy-based** (we directly try to find the best policy, i.e., a map from states to actions – it could be stochastic) vs **value-based** (we try to estimate the

value of each state, *i.e.*, the cumulated reward we would get if we started in a given state and acted optimally – from there, we can find the optimal policy); there are also hybrid algorithms, estimating both policy and value function, each helping improve the other;

- **On-policy** (the training data was generated by the current best estimate of the policy) vs **off-policy** (the training data was generated by some other policy, *e.g.*, an old policy, or a policy modified to explore more).
- **Model-based** (we use the data to estimate the dynamics of the environment) vs **model-free** (we do not) – RL usually refers to searching for an optimal policy for an unknown MDP, only accessible through observations: if the MDP is known, this is an easier **planning** problem.

The **cross-entropy method** (CEM) is the simplest policy-based RL algorithm: it learns to repeat actions that performed well.

- Start with a random policy;
- Act according to this policy;
- Keep the best 30% episodes;
- Train a new policy to replicate what the agent did in those episodes.

This works in simple environments, such as CartPole, but even for FrozenLake, a few adjustments are needed:

- Larger batches (successful episodes are rarer);
- Keep successful episodes in memory for longer;
- Decrease the learning rate; train for longer.

5. For a known MDP, the value of a state $V(s)$, or of a state-action pair $Q(s, a)$, satisfies the **Bellman equation**,

$$V(s) = \max_a E[r + \gamma V(s')] \\ Q(s, a) = E[r + \gamma \max_{a'} Q(s', a')].$$

6. For an unknown MDP, the update

$$Q(s, a) \leftarrow r + \gamma \max_{a'} Q(s', a')$$

is a bit too violent: it completely discards the previous value of $Q(s, a)$... (Tabular) Q-learning uses:

$$\text{target} \leftarrow r + \gamma \max_{a'} Q(s', a') \\ Q(s, a) \leftarrow (1 - \lambda)Q(s, a) + \lambda \text{target}$$

Deep Q-learning (DQN) minimizes

$$\text{Loss} = [Q(s, a) - (r + \gamma \max_{a'} Q(s', a'))]^2.$$

As often with RL, it does not work in practice without a few adjustments:

- Use ε -greedy, with ε decreasing, to explore enough at the beginning;
- Use a replay buffer (fixed-size, or prioritized) to have enough diversity;

- Training is unstable because we are “chasing our tail” ($Q(s, a)$ and $Q(s', a')$ are too close): use a *target network*, and only update it from time to time;
- To ensure the Markov property, keep the previous state(s) in memory.

8. DQN can (should) be improved on:

- N -step DQN (this is no longer really off-policy: we assume that the intermediate action was optimal – but if you only look 2 or 3 steps ahead, it is almost off-policy)

$$Q(s_t, a) = r_t + \gamma \max_a Q(s_{t+1}, a) \\ = r_t + \gamma r_{t+1} + \gamma^2 \max_a Q(s_{t+1}, a) \\ = \dots$$

- Double DQN: since DQN tends to overestimate Q (because of the Max), use the other network to choose the optimal action

$$Q(s_t, a) = r_t + \gamma \max_a Q(s_{t+1}, a) \quad \text{Bellman} \\ Q(s_t, a) = r_t + \gamma \max_a Q'(s_{t+1}, a) \quad \text{DQN (target network)} \\ Q(s_t, a) = r_t + \gamma Q'(s_{t+1}, \text{Argmax}_a Q'(s_{t+1}, a)) \quad \text{Same formula} \\ Q(s_t, a) = r_t + \gamma Q'(s_{t+1}, \text{Argmax}_a Q(s_{t+1}, a)) \quad \text{Double DQN}$$

- Noisy networks: instead of taking actions completely at random to explore, add noise to the network weights, with learned variance (Bayesian FC layer; use a low-rank parametrization for the matrix of variances);
- Prioritized replay buffer: prioritize samples with a larger loss, *i.e.*, train more on data that surprises you (the observations are no longer iid: use sample weights);
- Dueling DQNs separately estimate the value of the state and the advantage of the action,

$$Q(s, a) = V(s) + A(s, a);$$

to ensure that the average advantage is zero, use

$$Q(s, a) = V(s) + A(s, a) - \text{Mean}_a A(s, a)$$

- Categorical (distributional) DQN: replace expectations with distributions (histograms, 51 bins).

9. To speed up the computations:

- Only compute the gradient when it is needed (not for the target or to select actions) (`detach()`);
- Only build the computation graph when it is needed (`torch.no_grad()`);
- Use larger batches: sample from several (identical) environments;
- Play and train in separate processes.

10. DQN could be used to design an intraday trading strategy: the state could be the current position and the previous 1-minute bars OHLC prices, the actions “buy” or “sell”, the reward the after-transaction-cost (realized, or unrealized) P&L. Do not expect the strategy to perform well out-of-sample.

[For some reason, all the applications of RL in finance use DQN. (My report on end-to-end portfolio construction used policy-based RL.)]

11. So far, we have focused on the value function, $V(s)$ or $Q(s, a)$, but what we really want is the policy. For small, discrete action spaces, we can easily solve the optimization problem

$$\underset{a}{\text{Maximize}} Q(s, a)$$

but for large or infinite action spaces, it is more problematic.

The **policy gradient** is

$$\begin{aligned} J &= \mathbb{E}[Q(s, a)] \\ \nabla_{\theta} J &= \mathbb{E}_{\pi_{\theta}}[Q(s, a) \nabla_{\theta} \log \pi_{\theta}(a|s)] \\ &= \mathbb{E}_{\pi_{\theta_1}}[Q(s, a) \nabla_{\theta_2} \log \pi_{\theta_2}(a|s)] \\ &= \nabla_{\theta_2} \mathbb{E}_{\pi_{\theta_1}}[Q(s, a) \log \pi_{\theta_2}(a|s)] \\ \text{Loss} &= -Q(s, a) \log \pi(a|s). \end{aligned}$$

(Note that there is no log in the definition of J , but there is one in the definition of the loss: the gradients are nonetheless the same, because the parameter θ in the expectation is fixed when we differentiate the loss, but not when we compute the expectation of J .)

The cross-entropy method is a policy gradient method with $Q(s, a) = 0$ or 1 .

REINFORCE uses the returns as Q :

$$\text{Loss} = - \sum_t G_t \log \pi(a_t|s_t).$$

However:

- The variance is *very* high: use a baseline, e.g., a constant, such as the average discounted reward, or moving average (use a **deque**), or an estimate of $V(s)$;
- Full episodes are required: we could use $Q(s, a) = r + \gamma V(s')$, with another network to estimate V (Actor-Critic), or unroll a few steps of the Bellman equation, especially if γ is not too high;
- There is not enough exploration (there is some at the beginning, because the policy is stochastic): add an *entropy bonus*, $H(\pi)$;
- The samples are correlated (and we cannot increase the replay buffer, because policy gradient methods are on-policy): use parallel environments to generate enough samples.

In practice:

- Use a baseline;
- Add an entropy bonus;
- Unroll 10 steps of the Bellman equation;
- Use parallel environments;
- Clip the gradients;
- Monitor the KL divergence between the current and previous policy (spikes are a bad sign), the L^{∞} and L^2 norm of the gradients, the components of the loss.

12. If all the Q -values are positive, the optimization of

$$\text{Loss} = -Q(s, a) \log \pi(a|s)$$

will try to move the network towards each action encountered, whether good or bad, but it will move slightly less towards bad actions. In contrast, if the Q -values are sometimes positive and sometimes negative, the optimization will move towards the good actions, and away from the bad – it will move less, and in more consistent directions.

This can be ensured with a *baseline*.

The **Advantage-Actor-Critic** (A2C) method makes the baseline state-dependent, $V(s)$:

- The *actor* computes the policy, $\pi(a|s)$;
- The *critic* computes the state value function, $V(s)$.

There are 3 losses (pay attention to their signs!): policy, value and entropy.

13. SGD works better with iid observations, but interacting with the environment gives correlated observations:

- For off-policy methods (such as DQN), use a huge replay buffer;
- For on-policy methods (such as policy gradient), use parallel environments (this is not sample-efficient).

There are two types of parallelism for RL (Asynchronous advantage actor critic, **A3C**):

- In data-level parallelism, the workers are in charge of the interactions between agent and environment, and everything else (loss, gradient, SGD) is centralized;
- In gradient-level parallelism, the workers also compute their contributions to the loss and the gradient.

14. RL (self-critical sentence training, SCST) can be used to generate text, e.g., in a chatbot, asking a customer more details about her query, and directing her to the correct page. It has several advantages over maximum likelihood estimation:

- It allows for several unrelated outputs, e.g., different translations of the same sentence, different answers to the same question – the “average” of those outputs is unlikely to be a good answer;
- We can maximize the score we want, e.g., BLEU – it does not need to be differentiable.

$$\text{MLE} : \mathbb{E}_{x \sim \text{data}} [\log p_{\text{model}}]$$

$$\text{REINFORCE} : \mathbb{E}_{\substack{s \sim \text{data} \\ a \sim \pi}} [Q(s, a) \log \pi(a|s)]$$

The rewards are too sparse to use REINFORCE directly: first pre-train with MLE (traditional seq2seq), then fine-tune with REINFORCE.

As baseline, use a greedy decoder to get a BLEU score estimate of the whole sentence.

15. The state space can be complex: for instance,

TextWorld is a grid world of which we are only given a textual description, which can be processed by an LSTM before being fed to a DQN.

16. One could also attempt to use RL to generate GUI actions from a textual description such as “Click on ‘Close’”, “Open collapsed groups and click on the link with ‘foobar’”, “select yesterday’s date using the date picker tool”, “tick checkboxes containing ‘foobar’”, etc.

17. A2C has three ingredients:

- The REINFORCE gradient,

$$\nabla J = \nabla_{\theta} \log \pi_{\theta}(a|s)(R - V_{\theta}(s));$$

- The baseline, $V_{\theta}(s)$, which minimizes the MSE with the value from the Bellman equation;
- An entropy bonus.

If the action space is continuous, represent the policy as a Gaussian distribution, parametrized by μ and σ^2 .

(Deep) Deterministic policy gradient (**DDPG**) is similar, but with a deterministic policy – so far, the policies in policy gradient (PG) methods were stochastic.

$$\nabla_{\theta} Q(s, \mu(s)) = \nabla_a Q(s, \mu(s)) \cdot \nabla_{\theta} \mu(s)$$

Note that the critic, $Q(s, a)$, is not used as in A2C: in A2C, it was optional (it was just there to reduce the variance – without it we get the Reinforce algorithm). Here, it is needed: we will train end-to-end using its gradient. Contrary to A2C, DDPG is off-policy.

Since the policy is deterministic, something else is needed to explore, e.g., adding iid noise to the actions, or using an Ornstein-Uhlenbeck process

$$dx = \theta(\mu - x)dt + \sigma dW$$

(but this requires the agent to be stateful and does not seem to improve on iid noise).

(Distributed) distributional (deep deterministic) policy gradients (**D4PG**) adds the usual DQN improvements to DDPG:

- Distribution of Q -values instead of Q -value, with the cross-entropy loss to compare the two distributions;
- n -step Bellman equation;
- Prioritized replay buffer;
- iid noise.

18. For actual robots (you can put a PyBoard, a few sensors, a few servos, on a 3D-printed frame), train them (with DDPG) in a simulator and hope the trained model also works on the robot. [Meta-learning is a more recent approach, but it requires more computation power on the robot.]

19. Small changes in the model can lead to large changes in the policy: that is why we were monitoring the KL divergence between the distribution of actions between consecutive steps. Instead of just monitoring it, trust region methods constrain it.

Proximal policy optimization (**PPO**)

- Replaces the objective $J_{\theta} = E[\log \pi_{\theta}(a_t|s_t)A_t]$ with $J_{\theta} = E[r_t \cdot A_t]$, where the importance weights are

$$r_t = \frac{\pi_{\theta_{\text{new}}}(a_t|s_t)}{\pi_{\theta_{\text{old}}}(a_t|s_t)}$$

$$\pi_{\theta_{\text{new}}}(a_t|s_t)/\pi_{\theta_{\text{old}}}(a_t|s_t)$$

- Clips the importance weights to $(1 - \epsilon, 1 + \epsilon)$;
- Replaces the advantage

$$A_t = -V(s_t) + r_t + \gamma r_{t+1} + \dots + \gamma^{T-t+1} r_{T-1} + \gamma^{T-1} V(s_T)$$

with

$$A_t = \sigma_t + (\gamma\lambda)\sigma_{t+1} + \dots + (\gamma\lambda)^{T-t+1}\sigma_{T-1}$$

where $\sigma_t = r_t + \gamma V(s_{t+1}) - V(s_t)$.

Trust region policy optimization (**TRPO**) uses the discounted visitation probability

$$\rho_{\pi}(s) = P[s_1 = s] + \gamma P[s_2 = s] + \dots,$$

defines the loss as

$$E[G] + \sum_s \rho_{\pi}(s) \sum_a \tilde{\pi}(a|s) A(s, a)$$

where G is the discounted reward, $\tilde{\pi}(a|s)$ the argmax policy, adds a constraint $KL(\theta_{\text{old}}||\theta) \leq \delta$, and uses the conjugate gradient (CG) method to solve the resulting constrained optimization problem.

ACKTR (A2C using K-FAC trust region) combines A2C, Kronecker-factored (K-FAC) second-order optimization, and trust regions.

Soft actor-critic (SAC) – currently the preferred approach for continuous control) uses

- Entropy regularization: add an entropy bonus to each reward, to encourage actions that will lead to more exploration in the long term;
- Clipped double- Q trick: learn two networks to predict the Bellman Q -value, and use the minimum, to deal with Q -value over-estimation.

There are 4 networks: π , V , Q_1 , Q_2 .

20. Population-based optimization algorithms are not sample-efficient, but eminently parallelizable.

Genetic algorithms (GA):

- Randomly perturb the current policies;
- Keep the best ones;
- Iterate.

Evolutionary strategies:

- Fit a Gaussian distribution to the parameters of the current population of policies;
- Sample from it;
- Keep the best ones;
- Iterate.

Evolutionary strategies (**CMA-ES**):

- Randomly perturb the current policy, in several ways;
- Compute the fitness of the resulting policies;

- Modify the original policy weights by adding the same noise, but rescaled proportionally to the fitness – you can use the PyTorch optimizers (not just plain descent): they just need something that looks like a gradient.

21. So far, we achieved exploration with ε -greedy policies (for value-based methods) or an entropy bonus (for policy-based methods). But taking isolated random actions may not be sufficient to explore other regions of the search space: several steps may be needed.

Noisy networks (Bayesian neural nets) add noise to the weights, with a learned variance. This may look similar to ε -greedy, but the noise is added to the weights, not the network output.

Count-based methods add a reward for rarely-visited states, c/\sqrt{N} (as UCB, for bandits). If there are many states, or if the state space is continuous, use a density estimator, or a learned state embedding, or a hashing function.

Curiosity-driven exploration does not use the reward from the environment at all, but a measure of novelty.

Prediction-based methods measure the novelty of a state by attempting to predict something from the environment: if prediction is easy, the state is not that new and does not warrant more exploration. As intrinsic reward, one could even use the ability of a (trained) neural network to predict the output from another one (untrained, randomly initialized) (more generally, the

same idea, distillation of a random neural net, can be used for outlier detection).

22. Model-based methods are more sample-efficient.

For instance, imagination-augmented agents (I2A) train an environment model $(s, a) \mapsto (r, s')$ and generate trajectories from it. They use two policies, the learned one, and a distilled version to generate trajectories, and use an RNN to compute a latent representation of the generated trajectories to add them to the input of the policy.

23. For two-player games (tic-tac-toe, chess, go), the minimax algorithm can rarely expand the full tree. Instead:

- Expand it using the current best policy (**MCTS**: Monte Carlo Tree Search); only the first moves are stochastic;
- Progressively update the value of the nodes, as in value iteration;
- Train a model on those partially expanded trees, as if they were fully expanded;
- From time to time, compare the performance of the two models (the trained one, and that used to expand the tree), and update the latter.

AlphaGo Zero uses a variant of MCTS.

24. Attempts to solve the Rubik's Cube with self-play (ADI, autodidactic iterations) were not convincing.

25. RL also applies to (competing or collaborating) multi-agent systems (MARL).

***Multiplicative interactions
and where to find them***

S.M. Jayakumar et al. (ICLR 2020)

Try replacing concatenation with *multiplication* – gating, hypernetworks, dynamic convolutions, attention, etc. can be expressed as multiplications. More generally, replace linear maps $(x, z) \mapsto W[x; z] + b$ with bilinear ones $(x, z) \mapsto z'Wx + z'U + Vx + b$ (W is then a 3-dimensional tensor).

***Gradients as features
for deep representation learning***

F. Mu et al. (ICLR 2020)

The gradient of the output wrt the parameters provides a latent representation of the input.

***Enhancing adversarial defense
by k -winners-take-all***

C. Xiao et al. (ICLR 2020)

The gradient of the loss wrt the input is used to mount adversarial attacks. One way to thwart those attacks is to use “obfuscated gradients”, *i.e.*, non-differentiable layers (differentiable wrt the parameters, for training, but not wrt the input).

But non-differentiable layers can be approximated, in the backward pass, with differentiable ones. Prefer non-differentiable layers that cannot easily be approximated by smooth functions, such as the k -winners-take-all: $\phi_k(y)_j = y_j$ if y_j is in the k largest components of y , $\phi_k(y)_j = 0$ otherwise. The loss surface, in weight space, is smooth almost everywhere (so the network is still easy to train) but in input space, it is not (so searching for adversarial examples is more problematic).

***Jacobian adversarially regularized
networks for robustness***

A. Chan et al. (ICLR 2020)

For images, the gradient of the loss wrt the input is itself an image, which can help tell how robust a model is: for robust models, it looks like the input, *i.e.*, like an actual picture, while for non-robust models, it looks like noise. During training, adding a discriminator to make this gradient image look more like a picture improves robustness (since the colours are off, add a 1-layer CNN to make the Jacobian look more like a real image).

Meta-learning with warped gradient descent

S. Flennerhag et al. (ICLR 2020)

WarpGrad learns a gradient preconditioner (as in the natural gradient, but learned, and non-linear) in the meta-learning phase – it is fixed when the final tasks are learned.

***Truth or backpropaganda? An empirical
investigation of deep learning theory***

M. Goldblum et al. (ICLR 2020)

Many commonly-held beliefs about neural networks, only proved for unrealistic architectures, such as deep linear networks, are actually wrong in general: there are sub-optimal local minima, low L^2 norm local minima need not be better, low-rank models need not be better or more robust (maximizing the rank actually works better). In spite of this, neural networks work well, thanks to their initialization.

***Piecewise linear activations substantially
shape the loss surfaces of neural networks***

F. He et al. (ICLR 2020)

ReLU networks divide the input space into “cells”; in each cell, the local minima are connected, but there are spurious minima.

***Bounds on over-parameterization
for guaranteed existence of descent paths
in shallow ReLU networks***

A. Sharifnassab et al. (ICLR 2020)

We already knew that sufficiently over-parametrized shallow ReLU networks were easy to train (the loss landscape has the “descent path property”). The converse is true: when a network is not sufficiently over-parametrized, the optimization can easily get stuck (there are “local cup minima”).

***Evaluating the search phase
of neural architecture search***

K. Yu et al. (ICLR 2020)

Evaluating network architecture search (NAS) algorithms is tricky, and they do not seem to perform much better than random search. They are biased towards fast-converging cells (shallow and wide), which do not guarantee better generalization.

NAS evaluation is frustratingly hard

A. Yang et al. (ICLR 2020)

***Understanding architectures learnt
by cell-based neural architecture search***

Y. Shu et al. (ICLR 2020)

Network architecture search (NAS) algorithms are biased towards fast-converging cells (shallow and wide), which do not guarantee better generalization.

***Understanding and robustifying
differentiable architecture search***

A. Zela et al. (ICLR 2020)

Architectures that do not generalize correspond to a sharper minimum of the loss function: stop when the largest eigenvalue of the Hessian (on a random validation minibatch) starts to increase. Alternatively, increase the regularization of the inner problem, to lower the curvature.

***Neural oblivious decision ensembles
for deep learning on tabular data***
S. Popov et al. (ICLR 2020)

Many traditional machine learning algorithms can be used as layers of deep neural networks, either as is, if they are differentiable, or after regularization if they involve discrete choices. For instance, in *oblivious decision trees* (decision trees which use the same features and thresholds at each tree level), one can use soft thresholds, *i.e.*, replace $x_i > b$ with $\sigma((\sum \lambda_i x_i - b)/s)$, and sparsemax instead of softmax for sparsity. Those layers can be stacked (NODE).

***Meta-learning acquisition functions for
transfer learning in Bayesian optimization***
M. Volpp et al. (ICLR 2020)

In GP-based Bayesian optimization, replace the acquisition function with a neural network, trained on similar objective functions; train with RL (no gradient needed).

***Learning space partitions
for nearest neighbor search***
Y. Dong et al. (ICLR 2020)

Many classical algorithms rely on some heuristic to speed them up: in particular this is the case of search algorithms (A*, DPLL, etc.), which explore a tree or a graph, and need to choose which node to explore next. Those heuristics can be replaced with a neural net.

Approximate nearest neighbour search often relies on space partition, often dependent on data (LSH, k -means (quantization), hyperplane partitions). Use supervised learning to find better partitions (neural LSH): compute the k -NN graph of the data; find a balanced partition (combinatorial graph partitioning, KaHIP); use a deep neural net to assign each point of \mathbf{R}^n to a partition. At query time, use the neural net to find the most likely bins, and search them for the nearest neighbour.

Learning to link
M.F. Balcan et al. (ICLR 2020)

Use a neural net to predict the best hyperparameters (of hierarchical clustering).

***Neural network branching
for neural network verification***
J. Lu and M.P. Kumar (ICLR 2020)

Use a graph neural net (GNN) to find branch-and-bound heuristics.

Explanation by progressive exaggeration
S. Singla et al. (ICLR 2020)

Counterfactuals are a way of explaining the forecasts of a model: minimal changes to the input to change the output (adversarial examples). They are usually

computed as an optimization problem, but one could use a neural network to automatically compute them.

The counterfactual explanation should look real: use a discriminator. Also add a self-consistency loss (if the output is the age of a person from a picture, making it 10 years older, and then 10 years younger, should recover the initial image).

Mathematical reasoning in latent space
D. Lee et al. (ICLR 2020)

There are three main types of logic: propositional logic (and, or, not operators, but no quantifiers: SAT solvers, such as minisat), first-order logic (with quantifiers over variables: SMT solvers, e.g., z3), and higher-order logic (with quantifiers over variables, functions and propositions: theorem provers, such as coq, agda, isabelle). HOL Light is an interactive theorem prover, with a database of 19,000 mathematical statements, covering algebra, topology, calculus, and measure theory. Like most theorem provers, it relies on rewrite rules – but it is very time-consuming to check which rules can be applied, and where they lead to.

With a graph neural net, one can learn an embedding that helps tell if a rewrite rule applies to a given statement (by taking the scalar product of the embeddings) and perform approximate reasoning, by moving several steps in the latent space.

***Learning heuristics for quantified boolean
formulas through reinforcement learning***
G. Lederman et al. (ICLR 2020)

Learned constraint solver heuristics outperform hand-crafted ones. A formula in conjunctive normal form (CNF) can be represented as a bipartite graph, whose nodes are terms and variables, which can be fed to a graph neural net (GNN).

***Deep symbolic superoptimization
without human knowledge***
H. Shi et al. (ICLR 2020)

To simplify expressions, in a compiler, one can use reinforcement learning to select which rules to apply among a set of predefined rewrite rules. To avoid the dependence on rules provided by humans, model the expressions as trees, compute node (or rather sub-tree) embeddings (with a tree LSTM), select a subtree (with a neural network), decode it using a tree LSTM with attention, replace the subtree with the new one and start again. Train with Reinforce and curriculum learning with increasingly long expressions.

***CLN2INV: learning loop invariants
with continuous logic networks***
G. Ryan et al. (ICLR 2020)

Automated program verification struggles with loops: the loop invariants still have to be specified by humans – once provided, the SMT solver can do its job.

One can use neural networks to guide the search for invariant formulas from recorded execution traces, after relaxing logical formulas into continuous logic networks (CLN) (and progressively tightening the relaxation during the optimization).

***Oblique decision trees
from derivatives of ReLU networks***
G.H. Lee and T.S. Jaakkola (ICLR 2020)

An *oblique decision tree* is a decision tree whose decision nodes are linear classifiers (*i.e.*, of the form $w'x < \alpha$ instead of $x_i < \alpha$). Locally constant neural networks model oblique decision trees, in a parsimonious way (N neurons suffice for 2^N nodes); they can be obtained as the gradient of a ReLU network, further processed with another neural net.

***PCMC-Net:
feature-based pairwise choice markov chains***
Alix Lhéritier (ICLR 2020)

Traditional *choice models* (multinomial logit, random utility models) do not account for human idiosyncrasies: independence of irrelevant alternatives, regularity (increasing the choice set does not change the ranking). *Pairwise choice Markov chain* (PCMC) models are more general: they use a Markov chain whose transition matrix models the preference between pairs of alternatives and consider its stationary distribution. If there are too many alternatives, use a neural net to approximate the transition matrix and compute the stationary distribution. Application: airline itinerary choice

***Higher-order function networks for learning
composable 3D object representations***
E. Mitchell et al. (ICLR 2020)

Hypernetworks are neural networks computing the weights of another network. They can be used to design input-dependent networks, for instance to apply a different decoder for each type of object when reconstructing it from a cloud of points.

***Neural epitome search
for architecture-agnostic network compression***
D. Zhou et al. (ICLR 2020)

Hypernetwork to uncompress, on the fly, the weights of a neural network.

***You only train once:
loss-conditional training of deep networks***
A. Dosovitskiy and J. Djolonga (ICLR 2020)

Hypernetworks can be used to generate a family of image compression models, using

$$\text{compression} + \lambda \cdot \text{reconstruction}$$

as loss, with the weights depending on λ .

Continual learning with hypernetworks
J. von Oswald et al. (ICLR 2020)

Hypernetworks can also be used for continual learning, preventing catastrophic forgetting by computing an embedding of the task, computing the new weights from that embedding, with a constraint that the weights of the previous tasks to remain fixed.

***Generalization bounds
for deep convolutional neural networks***
P.M. Long and H. Sedghi (ICLR 2020)

Neural networks may appear too expressive to lead to good generalization, but the training procedures do not stray far from the initialization, considerably reducing the risk of overfitting. Increasing the number of parameters decreases the distance from initialization.

***Learning to balance: Bayesian meta-learning
for imbalanced and out-of-distribution tasks***
H.B. Lee et al. (ICLR 2020)

The goal of meta-learning, or “learning to learn”, is to be able to learn a new task with little data (*few-shot learning*) and only a few steps of gradient descent. MAML (model-agnostic meta learning) is one of the popular algorithms for this: it learns a good initialization, from which new tasks can be learned quickly.

To account to task imbalance, class imbalance and distribution shift, in meta-learning (MAML),

- Use sample and task statistics to recognize these;
- Feed them to a neural net to compute the step size and number of steps (more and smaller steps for larger tasks – the gradients are larger and there is more information to extract), and the shift to apply to the initial parameters (to account for distribution shift).

***Meta dropout: learning to perturb
latent features for generalization***
H.B. Lee et al. (ICLR 2020)

To improve the decision boundaries in few-shot learning (MAML), learn input-dependent data augmentation (multiplicative noise, at each layer).

***Empirical Bayes transductive meta-learning
with synthetic gradients***
S.X. Hu et al. (ICLR 2020)

MAML learns a weight initialization that can be used for any new task. Instead, leverage the unlabeled data of the new task to choose that initialization.

***Rapid learning or feature reuse? towards
understanding the effectiveness of MAML***
A. Raghu et al. (ICLR 2020)

MAML uses an outer loop to find a good initialization, and an inner loop, on a few samples, to adapt that

initialization to the new task. Comparing the representations learned across several tasks shows that only the last layer changes: MAML relies on feature reuse. To speed things up, only train the last layer in the inner loop (ANIL).

Transferring optimality across data distributions via homotopy methods

M. Gargiani et al. (ICLR 2020)

In transfer learning, progressively deform the source task to the target task (with a simple convex combination).

Cross-domain few-shot classification via learned feature-wise transformation

H.Y. Tseng et al. (ICLR 2020)

In few-shot classification, try to make the feature distribution, for the new task, more diverse, with a “feature-wise transformation layer”.

Scalable and order-robust continual learning with additive parameter decomposition

J. Yoon et al. (ICLR 2020)

In continual learning, separate shared parameters from task-specific parameters.

Sliced Cramer synaptic consolidation for preserving deeply learned representations

S. Kolouri et al. (ICLR 2020)

To prevent catastrophic forgetting in sequential learning, one could keep track of some of the inputs of the previous tasks, and add a penalty to ensure their latent representations are kept. Instead, try to preserve the *distribution* of those latent representations.

An exponential learning rate schedule for deep learning

Z. Li and S. Arora (ICLR 2020)

There are countless learning rate schedules: decreasing, triangular, cosine, etc. Even weirder ones work, such as an exponentially increasing one (yes, increasing, not decreasing: multiply the learning rate by $1+c$, $c > 0$, at each iteration) – this assumes the presence of normalizing layers, which make the loss function scale-invariant.

The tapered exponential schedule has an exponential growth in each phase, and a small drop at the end of each phase, before moving to a lower growth rate.

Budgeted training: rethinking deep neural network training under resource constraints

M. Li et al. (ICLR 2020)

If your training budget is limited and known in advance, linearly decreasing the learning rate, down to zero, may be good enough.

Rethinking the hyperparameters for fine-tuning

H. Li et al. (ICLR 2020)

What matters is not really the learning rate, but the *effective learning rate*, $\eta/(1-m)$, which combines learning rate and momentum.

Revisiting self-training for neural sequence generation

J. He et al. (ICLR 2020)

Semi-supervised learning often works as follows: train a teacher network on real data; train a student network on data labeled by the teacher; fine-tune the student on real data; iterate (the student becomes teacher).

Dropout is important (noisy self-training).

Contrastive representation distillation

Y. Tian et al. (ICLR 2020)

Distillation is similar, but instead of matching the output of the teacher network, *i.e.*, the class labels, the student network tries to match the logits. Instead, one could try to match the features, one layer before, after mapping them to the same vector space (they have different dimensions), using the cosine distance.

DeepHoyer: learning sparser neural network with differentiable scale-invariant sparsity measures

H. Yang et al. (ICLR 2020)

Instead of the lasso sparsifying regularizer, try the **Hoyer-square** regularizer $H(w) = \|w\|_1^2 / \|w\|_2^2$ (or the group Hoyer). It is differentiable (like L^1) and scale-invariant (like L^0); it still trims small values, but preserves large ones.

Padé activation units: end-to-end learning of flexible activation functions in deep networks

A. Molina et al. (ICLR 2020)

The activation functions (ReLU, sigmoid, tanh, etc.) are usually fixed. Instead, we can choose a flexible parametrization, that allows a large variety of shapes, and learn the activation functions. The *Padé approximations*, *i.e.*, rational functions (quotients of polynomials)

$$g_{\theta}(x) = \frac{\sum_{i=0}^m \theta_i x^i}{1 + \left| \sum_{j=1}^n \theta_{m+j} x^j \right|}$$

are often used by computers in numerical computations (e.g., for special functions). A random variant adds a small uniform noise to θ .

Effect of activation functions on the training of overparametrized neural nets

A. Panigrahi et al. (ICLR 2020)

Most theoretical studies assume ReLU activations. Experiments suggest that non-smooth activation functions (e.g., ReLU, ELU) lead to faster convergence (than swish, tanh). The situation improves with depth.

**Order learning
and its application to age estimation**
K. Lim et al. (ICLR 2020)

Here is another way of adding (robustness to) nonlinearities to a neural net: do not output an absolute value (age, distance, pitch, score, etc.), but compare inputs, with a siamese network; at test time, the numeric value can be computed by interpolation.

This approach can be combined with clustering, if there are distinct groups in the input requiring different models: train separate models for random clusters, update cluster membership from the model performance, iterate.

**Geometric analysis
of nonconvex optimization landscapes
for overcomplete learning**
Q. Qu et al. (ICLR 2020)

Overcomplete dictionary learning looks for $A \in \mathbf{R}^{n \times m}$ and $X \in \mathbf{R}^{m \times p}$ such that $Y = AX$. Since the problem has many symmetries, it is non-convex, but if all minima are equivalent, and if the saddle points are not flat, it can be solved efficiently. We can require A to be row-orthonormal, and column-near-orthogonal, *i.e.*, impose an upper bound on the absolute value of the correlation (*i.e.*, cosine) of any two columns. To get one column of A , solve

$$\begin{array}{ll} \text{Find} & q \in \mathbf{S}^{n-1} \\ \text{To minimize} & -\|q'Y\|_4^4 \end{array}$$

(in the over-complete case, use the spikiness, L^4 , rather than L^1).

With pre-conditioning, this can be generalized to *convolutional dictionary learning* (A is no longer near-orthogonal): $y_i = \sum_k a_k \otimes x_{ki}$, where $y_i, a_k, x_{ki} \in \mathbf{R}^n$, with x_{ki} sparse

Examples include phase retrieval, low-rank matrix recovery, phase synchronization, shallow/linear neural net, sparse blind deconvolution, etc.

**Short and sparse deconvolution:
a geometric approach**
Y. Lau et al. (ICLR 2020)

**Understanding l^4 -based dictionary learning:
interpretation, stability, and robustness**
Y. Zhai et al. (ICLR 2020)

The L^4 norm, or “spikiness”, can be used instead of the L^2 or L^1 norms, for instance, for dictionary learning:

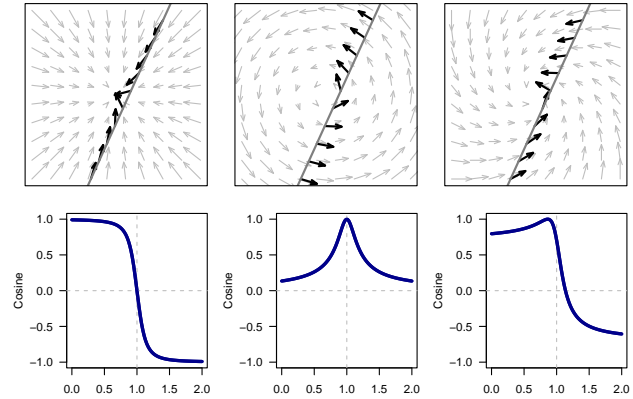

$$\begin{array}{ll} \text{Find} & A \in O_n \\ \text{To maximize} & \|AY\|_4^4 \end{array}$$

**A closer look at the optimization landscapes
of generative adversarial networks**
H. Berard et al. (ICLR 2020)

Consider the cosine similarity between the *game vector field* v , *i.e.*, the concatenation of the gradients of the generator and discriminator, and the linear path $(\theta_t)_{t \in [0,1]}$ between the initial and final parameters.

$$c_t = \cos(\theta_1 - \theta_0, v(\theta_t))$$

Plotting c_t (and $\|v(\theta_t)\|$) for $t \in [0.5, 1.5]$ reveals two possible behaviours: attraction (decreasing) and rotation (bump at 1).

**An inductive bias for distances: neural nets
that respect the triangle inequality**
S. Pitis et al. (ICLR 2020)

When learning a distance function, we want it to satisfy the triangle inequality. Deep metric learning often learns an embedding and then computes the Euclidean distance in that latent space – but not all metrics can be computed in that way.

A *DeepNorm* network is

$$\begin{array}{l} h_i = g_i(W_i h_{i-1} + U_i x) \\ \|x\| = h_k \end{array}$$

where $h_0 = 0$, $W_1 = 0$, the W_i are non-negative, g is convex and positive homogeneous, *e.g.*,

$$\begin{array}{l} g(u) = \alpha \text{relu}(u) + \beta u \\ \max \text{ReLU}(x, y) = [\max(x, y), \alpha \text{relu}(x) + \beta \text{relu}(y)] \end{array}$$

where $\alpha, \beta \geq 0$.

Wide Mahalanobis norms are of the form

$$\|x\| = \text{MaxMean}_i(\|W_i x\|_2)$$

$$\text{MaxMean}(x_1, \dots, x_n) = \alpha \text{Max}(x_1, \dots, x_n) + (1 - \alpha) \text{mean}(x_1, \dots, x_n).$$

Deep batch active learning by diverse, uncertain gradient lower bounds
J.T. Ash et al. (ICLR 2020)

Active learning approaches can be uncertainty-based (for small batches) or diversity-based (for larger batches). They can be combined: use the gradient of the loss (for the most likely label) wrt the parameters as a representation of the unlabeled examples, and sample using a determinantal point process (DPP) or (less expensive) k -means++.

Accelerating SGD with momentum for over-parameterized learning
C. Liu and M. Belkin (ICLR 2020)

Nesterov momentum provably accelerates (full) gradient descent, but not stochastic gradient descent. Instead, try

$$\begin{aligned} w_{t+1} &\leftarrow u_t - \eta_1 \nabla f(u_t) \\ u_{t+1} &\leftarrow (1 + \gamma) w_{t+1} - \gamma w_t + \eta_2 \nabla f(u_t) \end{aligned}$$

Variance reduction with sparse gradients
M. Elibol et al. (ICLR 2020)

The SpiderBoost gradient,

$$g_{n+1} = g_n + \nabla f_n(\theta_n) - \nabla f_n(\theta_{n-1}),$$

where f_n is the loss on the n th batch, can be approximated with sparse updates, only computing a random subset of the coordinates with the largest variance (sparse forward and backward passes).

Coherent gradients: an approach to understanding generalization in gradient descent-based optimization
S. Chatterjee (ICLR 2020)

Models trained with gradient descent (GD) generalize well (even though they could just memorize their input) because strong gradient directions (common to many observations) are kept and weak gradients cancel out. It is possible to perturb GD to suppress weak gradients (cf. random forests).

Stochastic weight averaging in parallel: large-batch training that generalizes well
V. Gupta et al. (ICLR 2020)

Start training with large batches, but stop early; then, train on small batches, in parallel; finally average the weights.

Why not to use zero imputation? correcting sparsity bias in training neural networks
J. Yi et al. (ICLR 2020)

Replacing missing values with 0 changes the scale of the output of the first layer; rescale the input accordingly (as with dropout).

ProxSGD: training structured neural networks under regularization and constraints
Y. Yang et al. (ICLR 2020)

Although the L^1 norm is a sparsifying constraint, SGD cannot push the weights to exactly zero – it cannot enforce hard constraints. Replace the gradient step

$$\begin{aligned} g &\leftarrow \nabla_x f(x) + r(x) \\ \hat{x} &\leftarrow \hat{x} - \alpha g \end{aligned}$$

with a proximal step

$$\begin{aligned} g &\leftarrow \nabla_x f(x) \\ \hat{x} &\leftarrow \underset{x \in X}{\text{Argmin}}(x - \hat{x})' g + \frac{1}{2} \|x - \hat{x}\|^2 + r(x) \end{aligned}$$

When the penalty r is the L^1 norm, the proximal operator is soft-thresholding.

Identity crisis: memorization and generalization under extreme overparameterization
C. Zhang et al. (ICLR 2020)

To study how overparametrized models generalize, look at extreme situations, such as learning with just one sample (learning the constant map) and learning the identity map. Shallow networks are better at learning the identity map, deeper networks are better at learning the constant map.

Deep double descent: where bigger models and more data hurt
P. Nakkiran et al. (ICLR 2020)

The *double descent* phenomenon is visible for:

- test error vs model size;
- test error vs epoch.

Gradient descent maximizes the margin of homogeneous neural networks
K. Lyu and J. Li (ICLR 2020)

Deep neural nets are too expressive and should overfit. They work because gradient methods have an implicit bias towards maximum-margin solutions.

Unbiased contrastive divergence algorithm for training energy-based latent variable models
Y. Qiu et al. (ICLR 2020)

Contrastive divergence (CD), used to train energy-based models (EBM) such as restricted Boltzman machines (RBM), uses a biased gradient estimator (a small, fixed, number of MCMC steps) and may diverge. *Unbiased MCMC* can provide an unbiased gradient estimator (by using a random number of MCMC steps).

Mixout: effective regularization to finetune large-scale pretrained language models
C. Lee et al. (ICLR 2020)

Drop-connect sets some of the weights to zero. Instead, set them to the weights of a pre-trained network.

Self-supervised learning of appliance usage
C.Y. Hsu et al. (ICLR 2020)

To detect causality in weakly-related data streams, such as total energy consumption of a home over time, and people's location in the home (approximate, from Wifi perturbations), try to predict one from the other (the cause from the consequence: location given energy event): when prediction is possible, the two are related.

SELF: learning to filter noisy labels with self-ensembling
D.T. Nguyen et al. (ICLR 2020)

With low-quality (crowd-sourced) training data, some of the labels may be incorrect. Only train on reliable labels: to identify them, compare the predictions of the current model and that a few epochs ago: more reliable labels have more stable predictions.

DivideMix: learning with noisy labels as semi-supervised learning
J. Li et al. (ICLR 2020)

To identify noisy observations, one can model that noise: the per-sample loss is then a two-component mixture (noisy samples have a larger loss). One can then discard the noisy labels and use semi-supervised learning. To avoid confirmation bias, train two networks, each filtering the other's noise.

Simple and effective regularization methods for training on noisily labeled data with generalization guarantee
W. Hu et al. (ICLR 2020)

To deal with label noise, one could add a penalty for the distance to the initialization parameters, or actually model the noise by adding trainable auxiliary variables. For a wide neural net, these are equivalent to kernel *ridge* regression with a neural tangent kernel.

AugMix: a simple data processing method to improve robustness and uncertainty
D. Hendrycks et al. (ICLR 2020)

Traditional data augmentation applies one transformation to the image. Instead, apply several, and mix

the results (with a weighted DAG); add a consistency penalty to the loss to ensure that different augmentations yield the same result.

ReMixMatch: semi-supervised learning with distribution matching and augmentation anchoring
D. Berthelot et al. (ICLR 2020)

MixMatch performs semi-supervised learning by training on the labeled data, running the model on many augmentations of the unlabeled data, and using the resulting label distribution. ReMixMatch enforces consistency among augmentations, makes the label distribution close to that of the training set, and adds a self-supervised loss (rotation prediction).

Robust training with ensemble consensus
J. Lee and S.Y. Chung (ICLR 2020)

To make a network more robust, we can train it on the $(100 - e)\%$ observations with the smallest loss (as with a truncated regression).

Identify noisy examples among those small-loss examples by perturbing the network: if an image was not noisy (learned by generalization), the prediction does not change, but if it was noisy (learned by memorization), it changes.

An ensemble of neural nets, obtained by adding noise, at test time, to the input or to the network (e.g., with dropout), or by taking the same network from previous epochs (a "self-ensemble") is more robust than a single network.

Self-labelling via simultaneous clustering and representation learning
Y.M. Asano et al. (ICLR 2020)

Jointly learn a representation and a clustering (or labeling) of the data, with a constraint that each label be used the same number of times, by iteratively computing the optimal labeling (optimal transport) and training a classifier.

Use data augmentation. You can learn several clusterings (classification heads – cf. DeepCluster) at the same time.

RaPP: novelty detection with reconstruction along projection pathway
K.H. Kim et al. (ICLR 2020)

Autoencoders can be used to detect anomalies: their reconstruction error is large. Do not only compare the input and the output of the network, feed the output back to the input, and also compare the intermediate layers: if the autoencoder is

also compare $g_1(x)$ and $g_1(\hat{x})$, $g_2(g_1(x))$ and $g_2(g_1(\hat{x}))$ etc.

***Robust subspace recovery layer
for unsupervised anomaly detection***
C.H. Lai et al. (ICLR 2020)

Auto-encoders can be used for anomaly detection: the reconstruction error is larger than usual. But auto-encoders are not robust to outliers: add a *robust subspace recovery* layer $z \mapsto Az$ between the encoder and the decoder, which projects to an even lower-dimensional subspace, with $\|AA' - I\|$ and $\|z - A'Az\|_2$ as penalties.

***Classification-based anomaly detection
for general data***
L. Bergman and Y. Hoshen (ICLR 2020)

A similar idea can be applied to many other models: for out-of-distribution samples, the error is often larger. For instance, GOAD picks M random affine transformations, transforms the data with them, and tries to recover which transformation was used: the prediction accuracy is an anomaly score.

***Input complexity
and out-of-distribution detection
with likelihood-based generative models***
J. Serrà et al. (ICLR 2020)

Likelihood can be used to identify out-of-distribution datasets – but the distribution of those likelihoods can be higher than for the training set (it is easier), or lower (more difficult). The likelihood is correlated with the complexity of the data (Kolmogorov complexity, approximated by a lossless compression algorithm). Compensate for this relation:

$$S(x) = -\text{LogLik}(x) - \text{Complexity}(x).$$

This can be interpreted as a likelihood ratio test.

Novelty detection via blurring
S. Choi and S.Y. Chung (ICLR 2020)

Random network distillation (RND) takes two networks: a randomly-initialized, fixed network g , and a network f trained to replicate g on the training data. Since they only match on the training data, their difference $\|f(x) - g(x)\|$ is larger for out-of-distribution samples. Blurring the data (RND trained on both raw and blurred data) helps.

White noise analysis of neural networks
A. Borji and S. Lin (ICLR 2020)

Titration (progressively adding noise to images and checking the output, or the confusion matrix) can help understand classification biases

***Feature interaction interpretability: a case
for explaining ad-recommendation systems
via neural interaction detection***
M. Tsang et al. (ICLR 2020)

Detect interactions via feature perturbation, and use them for sparse feature crossing.

Detecting extrapolation with local ensembles
D. Madras et al. (ICLR 2020)

To see if a model is extrapolating (and if the forecasts are unreliable), train several models (with the same structure) and check if they agree. This can be done with a single model as well: at the local minimum, changing the weights in the direction of the smallest eigenvalues of the Hessian of the loss does not change the loss much, and provides a “self-ensemble” of models.

***Conservative uncertainty estimation
by fitting prior networks***
K. Ciosek et al. (ICLR 2020)

To estimate the uncertainty of a neural network, train several networks, with different random initializations, and check if they match.

***Towards neural networks
that provably know when they don't know***
A. Meinke and M. Hein (ICLR 2020)

Our models do not really model $P[y|x]$, but $P[y|x, \text{in-distribution}]$. We can actually estimate $P[y|x]$ with Bayes's formula.

***Quantifying point-prediction uncertainty
in neural networks
via residual estimation with an i/o kernel***
X. Qiu et al. (ICLR 2020)

Given a trained neural net, train another neural net to predict the uncertainty of the forecasts

$$(x, \hat{y}) \mapsto \|y - \hat{y}\|^2.$$

***Distance-based learning from errors
for confidence calibration***
C. Xing et al. (ICLR 2020)

To estimate the uncertainty of a prediction from a classifier, cluster the observations in each class, and use the distance to the cluster center. Use a neural network to approximate those uncertainty estimates.

Ensemble distribution distillation
A. Malinin et al. (ICLR 2020)

There are two types of uncertainty:

- Data uncertainty: the classes overlap, or we are too close to the decision boundary;
- Knowledge uncertainty: out-of-distribution observation, *i.e.*, we are too far from the training data.

The situation can be estimated from an ensemble of models:

- If the models are all unsure, we are close to the decision boundary;
- If the models are sure but disagree, the data is out-of-distribution;
- If the models are sure and agree, that is fine.

Do not distill a single teacher model into a student one, nor the mean of an ensemble of teacher models, but both mean and diversity of the ensemble, using Dirichlet distributions.

A constructive prediction of the generalization error across scales
J.S. Rosenfeld et al. (ICLR 2020)

Predict the generalization error by fitting a model

$$\text{test error} \sim \log(\#\text{samples}) + \log(\#\text{parameters}).$$

Pitfalls of in-domain uncertainty estimation and ensembling in deep learning
A. Ashukha et al. (ICLR 2020)

Before comparing (ensembles of) models (with the log-likelihood, or the Brier score), ensure the models are calibrated. To assess an ensembling technique (which may produce dependent models), compute the equivalent number of independent models (for instance, an ensemble of 100 dropout variants of a models could be equivalent to 2 independently-trained models). Test-time augmentation works well.

Unrestricted adversarial examples via semantic manipulation
A. Bhattad et al. (ICLR 2020)

Computer vision neural networks can be trained to be robust to adversarial attacks, in the sense that images close to the input will give the same output, where closeness is measured with the L^∞ or L^2 norm.

But this leaves enough room for photo-realistic attacks, manipulating colour and texture or adding barely perceptible shadows.

Breaking certified defenses: semantic adversarial examples with spoofed robustness certificates
A. Ghiasi et al. (ICLR 2020)

The robustness certification radius is not a good measure of robustness: we can find attacks that look like natural images, get misclassified, but have a large certification radius. The shadow attack changes the luminosity of each pixel, as if there were a shadow on the image; add a penalty to make it smooth (no edges), and another to keep the change small.

A target-agnostic attack on deep models: exploiting security vulnerabilities of transfer learning
S. Rezaei and X. Liu (ICLR 2020)

Many models are built from publically-available pre-trained networks: only the head of the network is unknown to the attacker. Inputs with a single very large activation provide good adversarial attacks.

Transferable perturbations of deep feature distributions
N. Inkawhich et al. (ICLR 2020)

Using the latent feature distributions, from the intermediate layers, leads to more transferable attacks.

Thieves on sesame street! model extraction of BERT-based APIs
K. Krishna et al. (ICLR 2020)

If a model, trained by fine-tuning a publically-available pre-trained model (e.g., BERT – the availability of the pre-trained model is important) on proprietary data, has a public API (e.g., Google Translate), it is (economically) possible to extract it, by feeding it data (e.g., random words, with no grammatical structure, or Wikipedia excerpts), collecting the results, and training a new model. This model stealing attack allows intellectual property theft, (white-box) adversarial attacks, and data leakage.

Defences include API watermarking (for 0.1% of the queries, return an incorrect answer and store the input/answer pair) and membership classification (recognize out-of-distribution inputs and return random data), but they only work on naive adversaries.

Prediction poisoning: towards defenses against DNN model stealing attacks
T. Orekondy et al. (ICLR 2020)

To protect a trained model $f : x \mapsto y$ against stealing attacks, try to perturb the attacker's gradient: do not return $y = f(x)$, but $y + \delta$, where δ is small, $|\delta| < \varepsilon$ and maximizes the angle between the gradients $\nabla \text{Loss}(y)$ and $\nabla \text{Loss}(y + \delta)$.

EMPIR: ensembles of mixed precision deep networks for increased robustness against adversarial attacks
S. Sen et al. (ICLR 2020)

Low-precision networks are less accurate but more robust to adversarial attacks than full-precision ones: use an ensemble of both.

Enhancing transformation-based defenses against adversarial attacks with a distribution classifier
C. Kou et al. (ICLR 2020)

To defend against adversarial attacks, one can use data augmentation at test time, *i.e.*, feed several altered images to the classifier, and use a majority vote – but accuracy degrades. Instead, train the model that will actually be used, the model including the data augmentation.

Defending against physically realizable attacks on image classification
T. Wu et al. (ICLR 2020)

Training against rectangular occlusion attacks improves robustness to physically realizable attacks.

Skip connections matter: on the transferability of adversarial examples generated with resnets
D. Wu et al. (ICLR 2020)

Replace the skip connection $z_1 = z_0 + f(x_0)$ gradient $1 + f'$ with $1 + \gamma f'$, $\gamma < 1$: the resulting network is more robust to transferred (black-box) adversarial attacks.

Adversarial Lipschitz regularization
D. Terjék (ICLR 2020)

Lipschitz regularization is usually implemented with a gradient penalty. The Lipschitz regularization, $E[|f(y) - f(x)| / |y - x|]$, tends to diverge when estimated using pairs of points from a minibatch: instead, use adversarial examples, $y = x + r$, $|r| \leq \varepsilon$ (one could also use a gradient penalty, as in WGANs).

Consistency regularization for generative adversarial networks
H. Zhang et al. (ICLR 2020)

The gradient penalty (Lipschitz) adds a computational overhead. Use *consistency regularization* (as in semi-supervised learning – deformed images should have the same output) on the discriminator instead of the Lipschitz constraint (gradient penalization, spectral normalization) (CR-GAN)

Intriguing properties of adversarial training at scale
C. Xie et A. Yuille (ICLR 2020)

Removing clean images from the training set makes the model more robust to adversarial attacks. Clean

images and adversarial examples seem to come from different distributions: in the BatchNorm layers, use different statistics for the clean and adversarial inputs (mixture batch normalization), or use a non-batch normalization (e.g., group norm).

Deeper networks are more robust.

Universal approximation with certified networks
M. Baader et al. (ICLR 2020)

Interval analytics can provide ℓ^∞ robustness certification (robustness to ℓ^∞ adversarial examples) but, for arbitrarily-trained networks, the intervals are often too large. However, for any function, there exists a ReLU network approximating it and whose ℓ^∞ robustness can be proved by interval analysis.

Adversarially robust representations with smooth encoders
T. Cemgil et al. (ICLR 2020)

VAEs are not robust to adversarial perturbations; the encoder is to blame: train it adversarially. The adversarial training searches for an input image, close to the initial input, but with latent representation as far away (for the Wasserstein distance) as possible. To check that the output is also robust, use a classifier (detecting the presence of glasses, of a smile, etc.) and try to change the predicted class.

Sign bits are all you need for black-box attacks
A. Al-Dujaili and U.M. O'Reilly (ICLR 2020)

Most attacks require an estimate of the gradient of the network wrt to its input, which requires $O(n)$ queries. Looking for the sign of the gradient (an element of $\{\pm 1\}^n$ instead of \mathbf{R}^n) still requires $O(n)$ queries, but an adversarial attack is often found much earlier.

Sign-OPT: a query-efficient hard-label adversarial attack
M. Cheng et al. (ICLR 2020)

Understanding the limitations of conditional generative models
E. Fetaya et al. (ICLR 2020)

Discriminative models are not robust to outliers and adversarial attacks. Generative models do not necessarily fare better: with MNIST digits on CIFAR background, images interpolated between digits have a higher log-likelihood (because there is more content in the background, more entropy unrelated to the class).

Data-independent neural pruning via coresets
B. Mussay et al. (ICLR 2020)

Prune the weights of a neural network by keeping those with the highest importance (if there are several outputs, take the maximum of the importances) and then fine-tuning.

***Provable filter pruning
for efficient neural networks***
L. Liebenwein et al. (ICLR 2020)

Pruning is usually empirical (no guarantees), and only looks at the weights, not the data. Instead, look at the contributions of a neuron to the activations of the next layer.

***Lookahead: a far-sighted alternative
of magnitude-based pruning***
S. Park et al. (ICLR 2020)

Magnitude-based pruning (discarding low weights) does not take into account the connectivity of the network: if a large-weight edge is only connected to small-weight edges, it may not be that important, and could also be discarded – taking into account the previous and next layer can change which edges seem important: prune weights that are small and/or connected to small weights. More formally, do not prune W_k into \tilde{W}_k to minimize $\|W_k x - \tilde{W}_k x\|_2$ but to minimize $\|W_{k+1} W_k W_{k-1} x - W_{k+1} \tilde{W}_k W_{k-1} x\|_2$.

***Comparing rewinding and fine-tuning
in neural network pruning***
A. Renda et al. (ICLR 2020)

After pruning a network, one usually fine-tunes it, but, since the network is now different, the optimal hyperparameters are no longer the same: they have to be re-estimated. *Rewinding* the weights (*i.e.*, using old weights) or just the learning rate, before fine-tuning, works as well as hyperparameter tuning.

***The intriguing role of module criticality
in the generalization of deep networks***
N.S. Chatterji et al. (ICLR 2020)

Rewind a layer (only one) back to its initialization: the impact is sometimes visible, sometimes not. This suggests that some layers are more important than others; this can be explained by the loss landscape, the path from the initialization to the final weights, which looks like a tunnel for some layers (less important), or like a funnel (more important). The width of that funnel (network criticality) is related to generalization.

Dynamic model pruning with feedback
T. Lin et al. (ICLR 2020)

Pruning can be done before training, after training, several times during training, or dynamically during training, potentially reactivating prematurely pruned weights). This can be done with a binary mask on the weights (use the mask in the forward pass, but not in the backward pass; the mask can change at each step) or a threshold vector (layer-wise, filter-wise or neuron-wise).

***Dynamic sparse training:
find efficient sparse network from scratch
with trainable masked layers***
J. Liu et al. (ICLR 2020)

Instead of training, pruning and fine-tuning a network, learn both the weights and a threshold vector (layer-wise, filter-wise or neuron-wise).

***Signal propagation perspective for pruning
neural networks at initialization***
N. Lee et al. (ICLR 2020)

Surprisingly, it is possible to prune the network before training, by looking at the change in loss when removing a parameter, which can be computed as a gradient, $\nabla_c \text{Loss}(c \odot w)$ evaluated at $c = \mathbf{1}$, where $c \in \{0, 1\}^m$ is the mask. This works better if the singular values of the weights matrices of each layer (strictly speaking, the singular values of the jacobian of each layer) are close to 1.

***One-shot pruning of recurrent neural networks
by jacobian spectrum evaluation***
S. Zhang and B.C. Stadie (ICLR 2020)

For efficient backward/forward propagation in a RNN, we want the eigenvalues of $J_t = \partial h_t / \partial h_{t+1}$ to be close to 1, but they are initially small: only keep the weights likely to help maximize $\chi = \sum_t \mathbb{E} \|J_t\|_F$, *i.e.*, those with the largest value of $|\partial_\theta \chi|$ (set the others to 0, permanently). (the weights are pruned before training, the first time they see the data: it is a sparse initialization)

***Batch-shaping for learning
conditional channel gated networks***
B.E. Bejnordi et al. (ICLR 2020)

To reduce the energy consumption of a neural net, only use part of it, with a gating mechanism to choose which features to compute.

Depth-adaptive transformer
M. Elbayad et al. (ICLR 2020)

Sequence-to-sequence models have more and more parameters; they can be shrunk by distillation or structured pruning. Instead, reduce the model in a sample-specific way: add exits at each level of the decoder, and a halting mechanism.

***Triple wins: boosting
accuracy, robustness and efficiency together
by enabling input-adaptive inference***
T.K. Hu (ICLR 2020)

Multi-output networks seem more robust to adversarial attacks.

***Gradient L^1 regularization
for quantization robustness***
M. Alizadeh et al. (ICLR 2020)

Neural networks can be trained to be more robust to post-training quantization (a bounded, additive perturbation) by adding an L^1 penalty for the gradient of the loss (wrt the weights).

Robust learning with jacobian regularization
J. Hoffman et al. (ICLR 2020)

***Additive powers-of-two quantization:
an efficient non-uniform discretization
for neural networks***
Y. Li et al. (ICLR 2020)

Quantization (after clipping) can be uniform (write the number with k bits), power-of-two (less precision for larger numbers), or sum of powers of two, $q = 2^x + 2^y + 2^z$ (with k terms).

Learned step size quantization
S.K. Esser et al. (ICLR 2020)

To learn layer-specific quantization, with gradient descent, use the floor function in the forward pass, and relax it to the identity in the backward pass (using a different function in the forward and backward pass, to deal with locally constant functions, is a common trick). Rescale the step size with the size of each bin.

***Mixed precision DNNs:
all you need is a good parametrization***
S. Uhlich et al. (ICLR 2020)

In mixed precision DNN, the bitwidth is different for each layer, for the weights and the activations. For the uniform and pow-2 quantization schemes, do not directly estimate the bitwidth: parametrize the quantization with the maximum and the stepsize (the gradients are better-behaved). To train the model, add a penalty for the total memory required for the weights and activations; for the backward pass, set the derivative of the floor function to 1.

***Precision gating:
improving neural network efficiency
with dynamic dual-precision activations***
Y. Zhang et al. (ICLR 2020)

Dynamic quantization computes most features in low precision and a few (input-dependent) important ones in high precision, using a gating mechanism (precision gating).

***BinaryDuo: reducing gradient mismatch
in binary activation network
by coupling binary activations***
H. Kim et al. (ICLR 2020)

Binary neural nets, *i.e.*, neural nets whose weights and activations are ± 1 , are difficult to train. Approaches

include coupling them with a higher-precision network, or using a surrogate, such as a stochastic binary neural net. To reduce the gradient mismatch problem: train coupled binary and ternary models; then decouple them and fine-tune the binary one.

***Critical initialisation in continuous
approximations of binary neural networks***
G. Stamatescu et al. (ICLR 2020)

Train a continuous surrogate for the binary neural net: a stochastic binary neural net.

***Kaleidoscope: an efficient, learnable
representation for all structured linear maps***
T. Dao et al. (ICLR 2020)

To reduce the number of parameters in a neural net, one can use structured matrices instead of arbitrary, dense matrices: low-rank, sparse, Kronecker-factored, DFT, etc. Those matrices are products of sparse matrices, and they can be obtained from **butterfly matrices** (block matrices, whose blocks are diagonal); the construction encodes a recursive divide-and-conquer structure. The sparsity pattern is fixed, and learnable with gradient descent.

Reformer: the efficient transformer
N. Kitaev et al. (ICLR 2020)

The reformer is a memory-efficient variant of the transformer, using **reversible residual** layers (there is no longer any need to keep all the activations in memory), and locality-sensitive hashing (LSH) to locate and compute the largest elements of $\text{softmax}(Q'K)$ (which is almost sparse).

***Lite transformer
with long-short range attention***
Z. Wu et al. (ICLR 2020)

The attention matrix can be decomposed into local attention (dense, close to the diagonal) and global attention (sparse, off-diagonal): one can use a lower-dimensional attention mechanism for the global part, and a CNN for the local part.

***ELECTRA: pre-training text encoders
as discriminators rather than generators***
K. Clark (ICLR 2020)

Instead of masked pretraining, pretrain with replaced token detection. The replacements come from a small BERT, trained at the same time. (The model only requires 4 GPU-day.)

***ALBERT: a lite BERT for self-supervised
learning of language representations***
Z. Lan et al. (ICLR 2020)

Albert is a smaller BERT-like model, with a projection between the 1-hot word encodings and their vector embeddings, to reduce the number of parameters, shared parameters across layers, a sentence-order prediction loss, no dropout (there is enough data: it is not needed), and more data.

***FSPool: learning set representations
with featurewise sort pooling***
Y. Zhang et al. (ICLR 2020)

Transformer-based language models present visible patterns (vertical or horizontal lines, rectangles) in their self-attention heatmaps, which can be used to construct parse trees.

***Poly-encoders: transformer architectures
and pre-training strategies
for fast and accurate multi-sentence scoring***
S. Humeau et al. (ICLR 2020)

To decide if two sentences follow one another, the *bi-encoder* feeds each to a transformer and uses the scalar product of the outputs as score. The *cross-encoder* (BERT) feeds both sentences to a transformer (and can use cross-sentence attention) and directly outputs a score. The bi-encoder is less accurate, but much faster. The *poly-encoder* feeds the candidate sentence to a transformer that outputs a query, feeds the context to a transformer that outputs a sequence of states, and uses an attention mechanism to combine query and states.

***Are transformers universal approximators
of sequence-to-sequence functions?***
C. Yun et al. (ICLR 2020)

Transformers are universal approximators of continuous, permutation-equivariant sequence-to-sequence functions. Transformers with positional encoding are universal approximators of continuous sequence-to-sequence functions.

***Tree-structured attention
with hierarchical accumulation***
X.P. Nguyen et al. (ICLR 2020)

The attention mechanism can be generalized to hierarchical structures, e.g., parsed sentences.

***On the relationship between
self-attention and convolutional layers***
J.B. Cordonnier et al. (ICLR 2020)

Transformers (self-attention with positional encoding) also work for images: they can compute convolutions (you need as many heads as there are pixels in the receptive field).

***Multi-scale representation learning for spatial
feature distributions using grid cells***
G. Mai et al. (ICLR 2020)

The (1-dimensional) positional encoding used in transformers can be generalized to 2 dimensions, and it can be learned: Space2Vec is an embedding $(x, y) \mapsto$ latent representation.

***Neural text generation
with unlikelihood training***
S. Welleck et al. (ICLR 2020)

Standard language models produce too many frequent tokens and too few rare tokens. This may be due to maximum likelihood estimation: add an *unlikelihood* penalty to explicitly penalize negative tokens, defined as tokens previously used in the sentence.

The curious case of neural text degeneration
A. Holtzman et al. (ICLR 2020)

Text-generation models (e.g., GPT2), relying on beam search, generate text less surprising than humans do. Instead of beam search, which is an approximation of maximum likelihood, use sampling, but discard the most unlikely words, not by retaining the top- k proposals, but by retaining the top- p (probability mass) ones ($p = 0.95$).

***Towards verified robustness
under text deletion interventions***
J. Welbl et al. (ICLR 2020)

Language models suffer from undersensitivity: deleting parts of a sentence can make a model more confident, because it exploits shallow clues (negation, premise-only entailment, etc.). To avoid those problems, ensure that removing words does not increase the probability, e.g., with interval bound propagation (IBP).

***BERTScore:
evaluating text generation with BERT***
T. Zhang et al. (ICLR 2020)

Text generation evaluation metrics are often based on n -grams (BLEU, ROUGE, METEOR, chrF), but they struggle with synonyms. More recent metrics (Meant, YiSi, BERTScore) are based on embeddings. BERTScore computes the BERT embeddings of the two sentences (generated and reference), then all the cosine similarities; it then greedily matches the words (in each directions, to separate precision from recall) averages the similarities, and computes an F_1 score.

***Improving neural language generation
with spectrum control***
L. Wang et al. (ICLR 2020)

The word embeddings of current language models do not span the whole available space; this can be seen in the distribution of the singular values. Instead of learning an embedding $x \mapsto Wx$ from 1-hot-encoded vectors, learn its SVD decomposition $W = U\Sigma V'$, with penalties to enforce the orthogonality of U and V and to make the k th singular value close to $ck^{-\gamma}$ or $c_1 \exp(-c_2 k^\gamma)$

Mirror-generative neural machine translation
Z. Zheng et al. (ICLR 2020)

Non-parallel (*i.e.*, monolingual) data can help train better NMT systems, *e.g.*, using back-translation (translated sentences should sound idiomatic). The 4 models (source and target language models, and the translation models in both directions) can be linked with a VAE whose latent variable models the contents of the sentence, trained iteratively (one direction at a time).

Logic and the 2-simplicial transformer
J. Clift et al. (ICLR 2020)

Attention can be generalized to higher-order relations (between 3 objects instead of 2): use two keys instead of one, and replace the scalar product of query and key with the tetrahedron volume

$$\langle a, b, c \rangle = (a \cdot b)c - (a \cdot c)b + (b \cdot c)a.$$

***Strategies for pre-training
graph neural networks***
W. Hu et al. (ICLR 2020)

To limit negative transfer in graph neural nets, pre-train both node embedding (predict (masked) node labels, or context) and graph embeddings (various supervised tasks: attribute prediction, structural similarity).

***Composition-based multi-relational
graph convolutional networks***
S. Vashishth et al. (ICLR 2020)

To process knowledge graphs with GNN, learn both node and edge embeddings.

***InfoGraph: unsupervised and semi-supervised
graph-level representation learning
via mutual information maximization***
F.Y. Sun et al. (ICLR 2020)

There are two common representations of graphs:

- Graph kernels decompose graphs into substructures/motifs and counts them;
- Graph2vec compute node embeddings, and aggregates them (*cf.* word2vec, doc2vec).

InfoGraph uses graph convolutions, and a discriminator, fed with pairs of graph and subgraph representations, to decide if they are from the same graph. For semi-supervised learning, use two encoders, one with the supervised loss, one with the unsupervised one, and keep them close to one another by maximizing the mutual information between their activations – this can be done by a discriminator, fed with a representation from each encoder, and deciding if they correspond to the same graph (*cf.* student/teacher networks).

***What graph neural networks cannot learn:
depth vs width***
A. Loukas (ICLR 2020)

Message-passing GNNs are not universal, unless nodes have uniquely identifying features, and $\text{depth} \times \text{width} = \Omega(n^2)$ (the exponent is lower for some tasks).

PairNorm: tackling oversmoothing in GNNs
L. Zhao and L. Akoglu (ICLR 2020)

GNNs achieve best performance with 1 or 2 layers – adding more layers leads to vanishing gradients, overfitting, and “oversmoothing”.

***Learning deep graph matching
with channel-independent embedding
and Hungarian attention***
T. Yu et al. (ICLR 2020)

The attention mechanism can also be generalized to graph neural nets (GNN).

***Learning to retrieve reasoning paths over
wikipedia graph for question answering***
A. Asai et al. (ICLR 2020)

When searching for the answer of a question in a text database (*e.g.*, Wikipedia), the paragraph containing the answer may not have a lot of overlap (often measured at the word level, *e.g.*, tf-idf): multi-hop reasoning may be needed. Use an RNN to learn the path in the graph.

***Differentiable reasoning
over a virtual knowledge base***
B. Dhingra et al. (ICLR 2020)

Question answering over text often requires combining information from several sources. The traditional approach (retrieve the relevant documents, understand them, answer) struggles with such multi-hop questions: we do not know which documents to retrieve until we have partially answered the question.

Encode entities as vectors and relations as sparse matrices; use BERT to measure the similarity between relations and mentions; information retrieval can then be done with sparse matrices products and approximate k -NN queries.

***You can teach an old dog new tricks!
On training knowledge graph embeddings***
D. Ruffinelli et al. (ICLR 2020)

Implementation details (knowledge graph embedding) matter: small tricks can make old models (whose training did not use them) look as good as recent models (whose training did).

***Graph constrained reinforcement learning
for natural language action spaces***
P. Ammanabrolu and M. Hausknecht

Reinforcement learning algorithms struggle with the discrete but very large action space of text adventure games such as Zork. Use a knowledge graph representing (what we know of) the game world, with a graph attention network (GAT), to trim down the search space (Verb Object1 Object2).

***Query2box: reasoning over knowledge graphs
in vector space using box embeddings***
H. Ren et al. (ICLR 2020)

To answer first-order logic queries on a knowledge graph, model entities as points (in latent space), and queries as boxes (or unions of boxes); relations map entities to boxes, e.g., (S,V,?) or (?,V,O).

***Tensor decompositions
for temporal knowledge base completion***
T. Lacroix et al. (ICLR 2020)

The ComplEx model

$$X_{i,j,k} = \langle U_i, V_j, \bar{U}_k \rangle$$

is a low-rank tensor completion model, for knowledge bases, often used with a nuclear 3-norm regularizer. It can be generalized to temporal knowledge bases,

$$X_{i,j,k,t} = \langle U_i, V_j, \bar{U}_k, T_t \rangle$$

or (temporal and non-temporal predicates)

$$X_{i,j,k,t} = \langle U_i, \tilde{V}_j + V_j \odot T_t, \bar{U}_k \rangle,$$

with a temporal regularizer

$$\sum \|T_{t+1} - T_t\|_p^p.$$

***LambdaNet: probabilistic type inference
using graph neural networks***
J. Wei et al. (ICLR 2020)

Computer code (untyped Python, TypeScript) can be parsed into a tree (an abstract syntax tree, AST), which can be fed to a graph neural net and a pointer network, for various prediction tasks: type inference, bug detection, etc.

The compiler can provide more links to add to the graph.

***Hoppity: learning graph transformations
to detect and fix bugs in programs***
E. Dinella et al. (ICLR 2020)

A (Javascript) program can be represented as an abstract syntax tree (AST), which a graph neural net can turn into a latent representations. A bugfix is a graph edit, represented by a sequence of operations.

***Towards a deep network architecture
for structured smoothness***
H. Habeeb and O. Koyejo (ICLR 2020)

CNNs gather information from fixed neighbourhoods: instead, the “fixed grouping layer” (FGL) uses neighbourhoods defined by data, e.g., with some clustering algorithm (fMRI data) or external data (industries, in finance), and ensures that the receptive fields do not span group boundaries.

***Deep 3D pan
via adaptive t-shaped convolutions
with global and local adaptive dilations***
J.L.G. Bello and M. Kim (ICLR 2020)

The filters used by convolutions need not be square: for some applications, T-shaped ones make sense.

***Denoising and regularization via exploiting
the structural bias of convolutional generators***
R. Heckel and M. Soltanolkotabi (ICLR 2020)

An auto-encoder (U-Net) trained on a single image ($n = 1$) first learns the image, then the noise – early stopping provides denoising. This comes from the linear upsampling, which fits the smooth part (low frequency) before the noise.

Adjustable real-time style transfer
M. Babaeizadeh and G. Ghiasi (ICLR 2020)

***Robust and interpretable blind image denoising
via bias-free convolutional neural networks***
S. Mohan et al. (ICLR 2020)

Bias-free CNNs are better at denoising.

***Neural symbolic reader: scalable integration
of distributed and symbolic representations
for reading comprehension***
X. Chen et al. (ICLR 2020)

Language models (BERT) cannot easily answer simple questions requiring arithmetic computations. Adding specialized modules (addition, subtraction, count, span, negation, etc.) does not allow compositionality and does not generalize well to new problems. The neural semantic reader extracts the structure of the text and the question, turns the question into a program, and runs it on the parsed text.

Neural arithmetic units

A. Madsen and A.R. Johansen (ICLR 2020)

Neural networks are good at interpolation, but not at extrapolation: arithmetic expressions perform better. For instance, the neural arithmetic logic unit (NALU) is defined as

$$\begin{aligned}w &= \tanh \times \text{sigmoid} && (\text{sign and scale}) \\a &= \sum w_i x_i && (\text{sum}) \\b &= \exp \sum w_i \log(|x_i| + \varepsilon) && (\text{product}) \\g &= \text{sigmoid} && (\text{gate}) \\y &= ga + (1 - g)b && (\text{output})\end{aligned}$$

But it does not consistently find the correct solution (and negative numbers are a problem). Instead, the neural arithmetic unit, biases w towards -1, 0 and +1, and uses an actual multiplication, with a gating mechanism to select what to multiply.

What can neural networks reason about? K. Xu et al. (ICLR 2020)

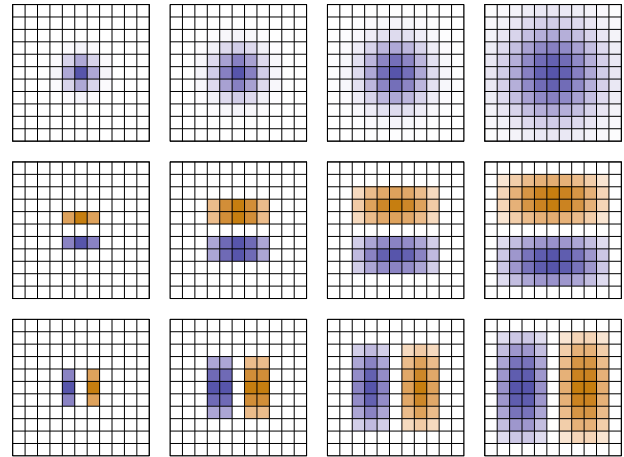

A given neural network architecture (e.g., GNN) has an implicit prior on the structure of the computations/algorithm it learns: it will more easily learn algorithms aligned with that structure. The GNN nested loops (loop over the nodes, loop over the neighbours, apply some function) are aligned with dynamic programming algorithms: this explains their success. They do not work for NP-complete problems, though: try “neural exhaustive search” (NES) instead.

Learn to explain efficiently via neural logic inductive learning Y. Yang and L. Song (ICLR 2020)

Neural networks can be used to explain an image by mapping its elements (e.g., car, wheel, window, etc.) to vectors, and relations to matrices, and using an attention mechanism to find first-order-logic formulas matching the scene.

Scale-equivariant steerable networks I. Sosnovik et al. (ICLR 2020)

CNNs are translation-equivariant, but not scale-equivariant. Use a predefined basis of filters, at different scales, and learn a (scale- and rotation-independent) linear combination of them.

B-spline CNNs on Lie groups E.J. Bekkers (ICLR 2020)

DeepSphere: a graph-based spherical CNN M. Defferrard et al. (ICLR 2020)

Co-attentive equivariant neural networks: focusing equivariance on transformations co-occurring in data D.W. Romero and M. Hoogendoorn

Group equivariant CNNs apply the same filter after the various actions of a (discrete) group. Add an attention mechanism to identify co-occurring actions.

On universal equivariant set networks N. Segol and Y. Lipman (ICLR 2020)

\mathfrak{S}_n -equivariant affine maps are of the form $X \mapsto XA + \mathbf{1}\mathbf{1}'XB + \mathbf{1}c'$ (DeepSets). If $B = 0$, each row of the input is transformed in the same way (PointNet).

Pure and spurious critical points: a geometric study of linear networks M. Trager et al. (ICLR 2020)

The geometry of the weight space differs from that of the function space: one can distinguish between critical points in function space (“pure”) and those only in parameter space (“spurious”). For linear networks and quadratic loss, spurious critical points are saddle points and there are no bad minima: all local minima are global, even if the network has a bottleneck layer – in this case, the map is not full rank, and the space of such maps, the *determinantal variety*, is non-convex and non-smooth.

Efficient Riemannian optimization on the Stiefel manifold via the Cayley transform J. Li et al. (ICLR 2020)

If a matrix W is skew symmetric, then $(I + W)(I - W)^{-1}$ is orthogonal (Cayley transform). The paths

$Y(\alpha) = (1 - \frac{1}{2}\alpha W)^{-1}(1 + \frac{1}{2}\alpha W)X$, or their iterative approximation $Y(\alpha) = X + \frac{1}{2}\alpha W(X + Y(\alpha))$, allow for Riemannian optimization on the Stiefel manifold (the space of orthogonal matrices) – orthogonal weight matrices improve learning, accuracy and robustness.

On the need for topology-aware generative models for manifold-based defenses
U. Jang et al. (ICLR 2020)

Generative models assume that the distribution in the latent space is a standard Gaussian – in particular, the data manifold is contractible. In reality, it could be more complex – in particular, there could be several connected components.

AE-OT: a new generative model based on extended semi-discrete optimal transport
D. An et al. (ICLR 2020)

The optimal transport map from a uniform distribution to a multi-modal one can be discontinuous and can lead to mode collapse. It is the gradient of the Brenier potential, which is continuous and convex: directly learn the Brenier potential (in a latent representation),

Deep orientation uncertainty learning based on a Bingham loss
I. Gilitschenski et al. (ICLR 2020)

The Bingham distribution, on the hypersphere, is

$$p(x) \propto \exp(x' M Z M' z)$$

where $x \in \mathbf{S}^{d-1}$, $M \in O(d)$ and $Z \in \mathbf{R}^{d \times d}$ is diagonal. To estimate the orientation of an object, as a unit quaternion, have a neural network estimate M (with Gram-Schmidt orthonormalization) and Z , and use the log-likelihood as loss function. The normalizing constant is difficult to compute: use a pre-computed look-up table and a radial basis function (RBF) interpolator.

Neural Tangents: fast and easy infinite neural networks in Python
R. Novak et al. (ICLR 2020)

Neural-Tangents provide infinitely-wide layers, as a drop-in replacement for `stax`, the `jax` neural network library. Since these are Gaussian processes, they do not scale well with dataset size.

Harnessing the power of infinitely wide deep nets on small-data tasks
S. Arora et al. (ICLR 2020)

The neural tangent kernel (NTK) works better than random forests on the UCI dataset, and better than ResNets on small datasets (10 to 100 samples).

DDSP: differentiable digital signal processing
J. Engel et al. (ICLR 2020)

DDSP provides digital signal processing operations (oscillators, filters, etc. – everything you would do in an audio editor such as Audacity or with a music programming language such as ChuckK), as TensorFlow layers (non-reproducible) examples include removing the reverb (or extracting it to add it to another recording) or changing the timbre (violin→flute, human→violin).

BackPACK: packing more into backprop
F. Dangel et al. (ICLR 2020)

BackPACK is a PyTorch library to compute more quantities during back-propagation:

- the individual gradients from a mini-batch (for instance to identify which samples are informative and which are not, for importance sampling),
- the variance of the gradients in a mini-batch (to monitor the signal-to-noise ratio and increase the batch size if needed),
- a Fisher information matrix approximation.

Also check: `PyHessian`, `JAX` (or `Zygote`, in Julia) (both forward and backward AD, AD through arbitrary programs: loops, conditionals).

DiffTaichi: differentiable programming for physical simulation
Y. Hu et al. (ICLR 2020)

At stability's edge: how to adjust hyperparameters to preserve minima selection in asynchronous training of neural networks?
N. Giladi et al. (ICLR 2020)

To ensure stability in (centralized) asynchronous SGD, rescale the learning rate: learning rate $\propto 1/\text{delay}$.

Gap aware mitigation of gradient staleness
S. Barkai et al. (ICLR 2020)

Distributed stochastic gradient descent can rely on:

- Ignoring synchronization problems;
- Waiting until all the workers have finished;
- Staleness awareness: divide the learning rate by the delay: $\eta \mapsto \eta/(\tau + 1)$, but this over-penalizes old gradients;
- Gap-awareness: use the gap (minimum number of updates needed to move from the previous to the current parameters):

$$1 + \frac{\|\theta_t - \theta_{t-\tau}\|}{\eta \cdot \mathbb{E}[\nabla \text{loss}]}$$

Decentralized deep learning with arbitrary communication compression
A. Koloskova et al. (ICLR 2020)

ChocoSGD combines decentralized SGD with (lossy) communication compression: do not send everything,

do not send accurate numbers, but keep track of the cumulated errors, to send them later, once they have accumulated.

SQIL: imitation learning via reinforcement learning with sparse rewards
S. Reddy et al. (ICLR 2020)

Imitation learning suffers from distribution shift: if the agent ends up away from the trajectory, it no longer knows what to do. Adversarial approaches (e.g., GAIL) use a discriminator, separating expert from agent trajectories, but GAN training is unstable. Instead of learning a reward function, set the reward of the expert actions to 1, those of the agent to 0, put both in the replay buffer, and use off-policy learning (e.g., soft actor critic).

Optimistic exploration even with a pessimistic initialisation
T. Rashid et al. (ICLR 2020)

Optimistic initialization does not work well with function approximation. Use optimistic Q-values:

$$Q^+(s, a) = Q(s, a) + C/(N(s, a) + 1)^M.$$

Dynamical distance learning for semi-supervised and unsupervised skill discovery
K. Hartikainen et al. (ICLR 2020)

RL problems often have sparse rewards: the agent only receives a reward when it reaches the goal. Learn a distance function, measuring how many time steps away two states are, on trajectories for the current policy. Then, use minus this distance as a reward, to improve the policy.

This generalizes the discounted state value function, which can be seen as a measure of the distance to the final goal – instead of the distance between arbitrary states.

Imitation learning via off-policy distribution matching
I. Kostrikov et al. (ICLR 2020)

ValueDICE is an alternative to DAC, GAIL, based on the *Donsker-Varadhan* representation of the KL divergence

$$\text{KL}(p||q) = \max_{f: X \rightarrow \mathbf{R}} \mathbb{E}_{x \sim p} [f(x)] - \log \mathbb{E}_{x \sim q} [e^{f(x)}].$$

Implementation matters in deep RL: a case study on PPO and TRPO
L. Engstrom et al. (ICLR 2020)

Apparently insignificant code-level optimization (value-clipping, reward-clipping, Adam annealing, orthogonal initialization, etc.) have a large impact – more than the choice of algorithm (e.g., PPO vs TRPO).

Explain your move: understanding agent actions using specific and relevant feature attribution
N. Puri et al. (ICLR 2020)

To explain the action chosen by an agent, perturb the state features and re-compute the Q-value: if it changes a lot (in absolute value, and/or relatively to the Q-values of the other actions), the feature was important.

Disagreement-regularized imitation learning
K. Brantley et al. (ICLR 2020)

To limit the compounding error problem in behavioural cloning, add a penalty term to stay close to the expert distribution.

RIDE: rewarding impact-driven exploration for procedurally-generated environments
R. Raileanu and T. Rocktäschel (ICLR 2020)

Reward actions that have a large impact on the environment, measured by the L^2 norm of the difference between the latent state representations. To focus on unforeseen/surprising consequences, train a model to predict the next (latent) state from the current state and the action. To focus on changes we can actually control, train a model to predict the action from the current and next state.

Toward evaluating robustness of deep reinforcement learning with continuous control
T.W. Weng et al. (ICLR 2020)

Threat models in reinforcement learning include:

- Observation manipulation (before the agent receives it);
- Action manipulation (after the agent chooses it).

To prevent those threats, one could learn the dynamics, identify unsafe states, and avoid them – but performance degrades a lot.

Keep doing what worked: behavior modelling priors for offline reinforcement learning
N. Siegel et al. (ICLR 2020)

When learning from a fixed replay buffer, with no new trajectories, avoid actions that would lead away from the explored portions of the state-action space, by putting a prior on the policy, to make it close to those in the buffer – or, better, close to the actions that worked.

Model-based reinforcement learning for biological sequence design
C. Angermueller et al. (ICLR 2020)

To find biological sequences x maximizing $f(x)$ (the result of some wet-lab experiment result), use reinforcement learning, where the actions select the next character of the (fixed-length) sequence, and we only receive

a reward, $f(x)$, at the end. Add a penalty to increase diversity.

Harnessing structures for value-based planning and reinforcement learning
Y. Yang et al. (ICLR 2020)

Represent the Q -value as a matrix, state \times action (after discretization, if needed): quite often, it is low-rank. Use such a low-rank matrix in planning or reinforcement learning.

The ingredients of real-world robotic reinforcement learning
H. Zhu et al. (ICLR 2020)

Real-world reinforcement learning faces three problems:

- No resets (the robot could get stuck – or could reach the goal, from which the optimal action is to do nothing): learn a perturbation agent;
- High-dimensional observations (images) instead of low-dimensional state: learn a low-dimensional representation of the state, with a VAE;
- No reward: train a classifier to recognize the goal (from a set of example images).

Behaviour suite for reinforcement learning
I. Osband et al. (ICLR 2020)

bsuite provides a set of experiments and metrics (exploration, generalization, credit assignment, scalability, etc.) to test and compare RL algorithms (like MNIST for RL). It can also generate a 1-page L^AT_EXsummary, to add to your paper.

Evolutionary population curriculum for scaling multi-agent reinforcement learning
Q. Long et al. (ICLR 2020)

In multi-agent reinforcement learning, start with small populations, and progressively increase the size. The model, for each agent, should be applicable to an arbitrary number of inputs (number of enemies, resources). When increasing the population size, we do not only want agents that perform well when the population size is N : they should also be good initializations for population size $2N$ – use an evolutionary strategy, with k groups of agents, and keep those performing best at size $2N$. Application: grassland game (grass, sheep, wolves).

Demystifying inter-class disentanglement
A. Gabbay and Y. Hoshen (ICLR 2020)

To disentangle class (e.g., identity, in a face recognition system) from content (pose), learn separate class and content embeddings but, to avoid information leakage, have the class embedding be the same for all members of that class.

Learning representations for binary-classification without backpropagation
M. Lechner (ICLR 2020)

Backpropagation is biologically implausible. Alternatives include: Hebbian learning, Target propagation, Feedback alignment (FA), direct feedback alignment (FDA), monotone DFA.

Reconstructing continuous distributions of 3D protein structure from Cryo-EM images
E.D. Zhong (ICLR 2020)

Each Cryo-EM (electron microscopy) image contains only one molecule, in a random orientation and location, but they may not all be in the same configuration. We usually try to cluster them. Instead, assume the configurations form a 2-dimensional manifold. For the orientation and location of the molecule in each image, use an optimization over $SO(3) \times \mathbb{R}^2$

Intrinsically motivated discovery of diverse patterns in self-organizing systems
C. Reinke et al. (ICLR 2020)

To find interesting and diverse patterns in a self-organizing system (snowflakes, animal skin patterns, or, as in this example, the continuous game of life – time and space are still discrete, but the values are in $[0,1]$), start with a random initial state and look after 200 steps.

To ensure diversity in the output, learn a latent representation (8-dimensional VAE) of the outputs; pick a point at random in this latent space; find an input whose output is close to that point; iterate (and retrain the VAE once in a while).

Since random noise tends to generate global patterns rather than local ones, use patterns from a CPPN (compositional pattern-producing network) as inputs.

Learning compositional Koopman operators for model-based control
Y. Li et al. (ICLR 2020)

Koopman operator theory takes a non-linear dynamical system $x_{n+1} = F(x_n)$ and finds an embedding into a higher-dimensional space $y = g(x)$ such that the dynamics become linear $y_{n+1} = Ky_n$. Systems made of many parts are often modeled (and controlled) with interaction graphs. Those two approaches can be combined, the graph structure corresponding to a block Koopman matrix.

SNODE: spectral discretization of neural ODEs for system identification
A. Quaglini et al. (ICLR 2020)

Separate the neural ODE “find θ so that x defined by $\dot{x}(t) = f_\theta(t, x(t))$, $x(t_0) = y_0$ minimizes $\int \text{Loss}(t, x(t))dt$ ”, into two:

- Find a function x minimizing the loss;

– Find θ so that this x approximately solves the ODE.
Estimate the derivative \dot{x} by expressing x with Legendre polynomials. This is much faster than using an ODE solver.

***On robustness
of neural ordinary differential equations***
H. Yan et al. (ICLR 2020)

Neural ODEs are more robust to noise than CNNs with residual connections

$$\begin{aligned}\dot{z}(t) &= f_\theta(z(t), t) \\ z(0) &= z_{\text{in}} \\ z(1) &= z_{\text{out}}\end{aligned}$$

For time-invariant steady neural ODE (TisODE)

$$\dot{z}(t) = f_\theta(z(t))$$

one can add a further robustness penalty.

***Deep audio priors emerge from
harmonic convolutional networks***
Z. Zhang et al. (ICLR 2020)

Auto-encoders (U-Net) can denoise images, but not sound: replace the convolutions with **harmonic convolutions** (a form of dilated convolutions): do not use $[(1 - \varepsilon)f, (1 + \varepsilon)f]$ as neighbourhood of frequency f , but $\{f, 2f, 3f, \dots, 12f\}$.

***On the steerability
of generative adversarial networks***
A. Jahanian et al. (ICLR 2020)

One can learn transformations (rotation, translation, zoom, colour changes, etc.) in the latent space of GANs, to some extent (not beyond the training distribution).

***Controlling generative models
with continuous factors of variations***
A. Plumerault et al. (ICLR 2020)

Yet another attempt to control the output of a GAN: size, orientation, colour, etc.

Real or not real, that is the question
Y. Xiangli et al. (ICLR 2020)

The Realness GAN considers that samples are not fully real or fully fake, and optimizes

$$\max_G \min_D \mathbb{E}_{x \sim \text{data}} \text{KL}(A_1 \| D(x)) + \mathbb{E}_{x \sim \text{fake}} \text{KL}(A_0 \| D(x))$$

where A_0 and A_1 are random variables (e.g., $A_0 \sim \text{Beta}(5, 1)$, $A_1 \sim \text{Beta}(1, 5)$).

***Dynamic time lag regression:
predicting what & when***
M. Chandorkar et al. (ICLR 2020)

The dynamic time-lag regression $y(t + g(x_t)) = f(x_t)$ (with f and g unknown) has a closed-form log-likelihood. It has applications in astronomy (solar wind prediction).

***Intensity-free learning
of temporal point processes***
O. Shchur et al. (ICLR 2020)

When modeling temporal point processes (TPP), instead of using an RNN to compute the estimate the intensity function λ_t , estimate the density function of the time until the next event, with normalizing flows (to transform a Gaussian density into the desired density) or a Gaussian mixture.

***Variational autoencoders for highly
multivariate spatial point processes intensities***
B. Yuan et al. (ICLR 2020)

Instead of modeling the intensity function λ , model the density $h(x) = \lambda(x) / \int \lambda$ (this is how one can sample from the process: first sample the number of points N , from a Poisson distribution, then sample N points, iid, from h), with a VAE.

***On solving minimax optimization locally:
a follow-the-ridge approach***
Y. Wang et al. (ICLR 2020)

The nonconvex-nonconcave minimax problem

$$\min_x \max_y f(x, y)$$

can be solved with the follow-the-ridge algorithm, which requires second-order information (the gradient is zero along the ridge).

$$\begin{aligned}x_{t+1} &\leftarrow x_t - \eta \nabla_x f(x_t, y_t) \\ y_{t+1} &\leftarrow y_t - \eta \nabla_y f(x_t, y_t) + \eta H_{yy}^{-1} H_{yx} \nabla_x f(x_t, y_t)\end{aligned}$$

***Gradientless descent:
high-dimensional zeroth-order optimization***
D. Golovin et al. (ICLR 2020)

When the gradient of the function to minimize is not available, gradient-less methods (moving in a random direction if it improves the objective) outperform gradient-approximating ones such as accelerated random search (ARS),

$$x \leftarrow x - \varepsilon \frac{f(x + hv) - f(x)}{h} v$$

for a random unit vector v .

***On mutual information maximization
for representation learning***
M. Tschannen et al. (ICLR 2020)

When learning a latent representation, we want the latent representation to be simpler (lower-dimensional) but to keep as much information as possible from the input. This can be achieved by maximizing the mutual information $MI(x, g(x))$ between the input x and the latent representation $g(x)$ (InfoMax). Modern variants maximize $MI(g(x_1), g(x_2))$, where x_1 and x_2 are different parts of the same image (e.g., top and bottom). The mutual information is maximum if g is bijective, and is invariant by bijections – it is unlikely to find good representations. However, the approximations of MI used (NCE, noise contrastive estimation, or NWJ) are not invariant under bijections, and prefer (hard-to-invert maps that are) good representations.

***Understanding the limitations of variational
mutual information estimators***
J. Song and S. Ermon (ICLR 2020)

***Learning robust representations
via multi-view information bottleneck***
M. Federici et al. (ICLR 2020)

If we know that two images correspond to the same label (but do not know the label), we can still learn a latent representation by maximizing the mutual information between the latent representations of the two images (to keep what is common and discard what is not) and minimizing the divergence between the distributions of those latent representations (in the case of a VAE). For isolated images, use data augmentation.

Rényi fair inference
S. Baharlouei et al. (ICLR 2020)

Try the Rényi correlation

$$\rho(X, Y) = \sup_{\substack{f, g \\ E f(X) = E g(Y) = 0 \\ E f(X)^2 = E g(Y)^2 = 1}} [f(X)g(Y)]$$

instead of mutual information (for discrete variables, it is tractable, especially when one is binary). To make a model fairer (classifier or clustering), add a penalty for the Rényi correlation between the output and the protected attribute.

Overlearning reveals sensitive attributes
C. Song and V. Shmatikov (ICLR 2020)

Sensitive attributes can be censored using adversarial training (it should be impossible to predict the sensitive attribute from the latent representation) or information theory (by minimizing the mutual information between the latent representation and the sensitive attribute). Unfortunately, such censoring is either inefficient or harmful to the model.

***Training individually fair ML models
with sensitive subspace robustness***
M. Yurochkin et al. (ICLR 2020)

A model is *individually fair* if it is robust to sensitive perturbations.

***Understanding why neural networks
generalize well through GSNR of parameters***
J. Liu et al. (ICLR 2020)

The one-step generalization ratio is the ratio of the change in test loss over the change in training loss.

The gradient signal-to-noise ratio is the ratio of the squared norm of the mean gradient over the variance of the gradients computed on individual samples; it measures if the gradients of the different samples agree.

If the gradients are consistent across samples, the GSNR and OSGR are large, and the model generalizes well.

***Stable rank normalization for improved
generalization in neural networks and GANs***
A. Sanyal et al. (ICLR 2020)

The generalization gap depends on (the product of) the spectral norms of the weight matrices (Lipschitzness) and (the sum of) their stable ranks.

The *stable rank* of a matrix W with singular values σ_i 's is

$$\text{srank}(W) = \frac{\|W\|_F^2}{\|W\|_2^2} = \frac{\sum \sigma_i^2}{\sigma_1^2} \leq \text{rank}(W)$$

***Deep probabilistic subsampling
for task-adaptive compressed sensing***
I.A.M. Huijben et al. (ICLR 2020)

Gumbel max sampling

$$\underset{i}{\text{Argmax}} \log p_i + g_i, \text{ for } g_i \sim \text{Gumbel}(0, 1)$$

can be made differentiable by replacing the argmax with a softmax (with temperature), and trained to decide which Fourier frequencies to sample to best help classify or reconstruct an input image.

***A function space view of bounded norm
infinite width ReLU nets: the multivariate case***
G. Ongie et al. (ICLR 2020)

The r -norm measures the representation cost of a function

$$R(f) = \liminf_{\varepsilon \rightarrow 0} \inf_{\theta} \{\|\theta\|^2 : \|h_{\theta} - f\| \leq \varepsilon\}$$

where h_{θ} is a 1-hidden-layer infinite-width ReLU network. It can be characterized as $R(f) = c \cdot \|\mathcal{R}(-\Delta)^{(d+1)/2} f\|_1$ where Δ is the Laplacian and \mathcal{R} the Radon transform. In dimension 1: $R(f) = \int |f''|$. It is not a RKHS norm (as with the NTK). Some functions have infinite $R(f)$, even though they are well approximated with 2-hidden-layer networks.

***Knowledge consistency
between neural networks and beyond***
R. Liang et al. (ICLR 2020)

Given two trained networks performing the same task, compare their latent representations x_A , x_B as follows:

- Try to express x_B as a linear transformation of x_A ;
- Try to express the residuals as a 1-layer non-linear transformation of x_A ;
- Try to express the residuals as a 2-layer non-linear transformation of x_A ;
- The residuals are then noise.

This gives a decomposition of the latent representation, which can help spot unreliable features, measure overfitting, and compress networks.

***Functional vs. parametric equivalence
of ReLU networks***

M. Phuong and C.H. Lampert (ICLR 2020)

The function computed by a (ReLU) network is invariant under: permutation of neurons, rescaling (of two layers, with inverse scaling factors). These are the only function-preserving transformations: the *fold-sets* of a ReLU network provide enough constraints on the

weights.

***Stochastic AUC maximization
with deep neural networks***
M. Liu et al. (ICLR 2020)

AUC maximization can be formulated as a min-max problem, non-convex and concave, solvable with the approximate proximal point method (APPM).

***Playing the lottery with rewards and multiple
languages: lottery tickets in RL and NLP***
H. Yu et al. (ICLR 2020)

The “lottery ticket hypothesis” is not limited to image classification: it also seems to hold in NLP and RL.

Deep equilibrium models S. Bai et al. (NeurIPS 2019)

A deep neural network with *weight-tied*, input-injected layers computes the repeated application of a function $z_{i+1} = f_{\theta}(z_i, x)$; it converges (in practice) to an equilibrium point $z^* = f_{\theta}(z^*, x)$. **Deep equilibrium (DEQ)** models find this equilibrium by root finding rather than iteration. They can replace deep neural networks (TrellisNet, universal transformer) with 1-layer networks: they are more memory-efficient.

List-decodable linear regression S. Karmalkar et al. (NeurIPS 2019)

List-decodable models are robust methods returning, not one estimator, but a list of estimators, with a good one ($\|\hat{\alpha} - \alpha^*\| < \varepsilon$) with high probability. They allow for adversarial outliers, and contamination beyond 50%.

Legendre memory units: continuous-time representation in recurrent neural networks A. Voelker et al. (NeurIPS 2019)

Strided recurrent neural nets can account for long-term dependencies, with Legendre polynomials: they are an alternative to LSTMs. [They also do hardware, and have implemented their RNN as a spiking neural net.]

Neural networks with cheap differential operators R.T.Q. Chen and D. Duvenaud (2019)

The divergence $\text{div} \cdot f = \sum \partial f_i / \partial x_i$ of a neural net $f : \mathbf{R}^d \rightarrow \mathbf{R}^d$ only requires the diagonal of the Jacobian. It can be efficiently computed by *hollow networks*

(the Jacobian can easily be separated into diagonal and non-diagonal parts, your deep learning framework can be asked to only compute the gradient of the diagonal).

Applications include fixed point iterations, normalizing flows.

Kernel instrumental variable regression R. Singh et al. (NeurIPS 2019)

To learn a causal relation in presence of confounding variables, regression is biased: it gives a prediction, not a *counterfactual prediction*.

Use an instrumental variable Z (which influences X but not directly Y) and 2SLS:

$$X \sim Z$$

$$Y \sim \hat{X}(Z) \quad \text{estimated on disjoint samples.}$$

Replace the linear regressions with kernel ridge regressions. Asymmetric sample splitting is important, with more observations in the first stage, and even more if the relation $Z \rightarrow X$ is less smooth. DeepIV is preferable if there is enough data (10,000 observations) and the relation is complex.

Adversarial samples are not bugs, they are features A. Ilyas et al. (NeurIPS 2019)

Take a dataset with cats and dogs, train a model, replace each sample with an adversarial example, and flip the labels accordingly, and learn a new model: it works well on the test set. The new model uses non-robust features that generalize well.

Quantum entropy scoring for fast robust mean estimation and improved outlier detection Y. Dang et al. (NeurIPS 2019)

PCA is a good way to find outliers, $\text{score}(x_i) = \langle x_i, \text{PCA}_k \rangle$, but it only detects outliers in one direction at a time: it is not ideal in high dimension. *Quantum entropy scoring* (QUE) replaces PCA with regularized PCA

$$W = \underset{\text{tr } U=1, U \succcurlyeq 0}{\text{Argmax}} \quad \alpha \langle U, \Sigma \rangle + \text{tr}(U \log U)$$

$$\text{score}(X) = \langle XX', W \rangle$$

Uniform convergence may be unable to explain generalization in deep learning V. Nagarjan and J.Z. Kotler (NeurIPS 2019)

To explain why overparametrized models generalize well, we can use uniform convergence to find bounds of the form

$$\text{generalization gap} \leq O \left(\frac{\text{effective model size}}{\text{training set size}} \right)$$

where the effective model size accounts for the bias of the training algorithm (SGD). Those bounds are too loose or require unreasonable assumptions. They do not even behave like the generalization gap: they increase with the training set size (it is in the denominator but also hidden in the numerator, e.g., with the norm of the weights), while the generalization gap decreases.

Deep learning models can learn complex boundaries, which hurt uniform convergence bounds [and look like a bonanza for adversarial attackers] but not generalization.

Estimation of the Lipschitz constant of deep neural networks (M. Fazlyab et al.) (NeurIPS 2019)

Computing the Lipschitz constant of a neural net is NP hard: we can only hope to find approximations or bounds. Taking the product of the (matrix) norms of the weights is overly conservative. The Lipschitz constant can be expressed as the solution of a nonconvex optimization problem whose relaxation is a semidefinite program (solved with CVX and Mosek).

Robustness is one application: low-Lipschitz networks are more robust – conversely, networks trained with robust algorithms have a lower Lipschitz constant.

Data-dependent sample complexity of deep neural networks via Lipschitz augmentation C. Wei et al. (NeurIPS 2019)

Regularizers can be designed in a principled way, based on theoretical upper bounds of the generalization error, but those bounds are loose. The following data-dependent bound

$$\text{generalization} \leq \frac{\text{jacobian norm} \times \text{hidden layer norm}}{\text{margin} \times \sqrt{\text{training set size}}} + \text{lower-order terms}$$

where the Jacobian norm is the L^∞ norm of the Jacobian wrt the weights, the hidden layer norm is the L^∞ norm of the activations (on the training set), the margin is minimum, over the training set, of the difference between the first two logits, suggests to use the *Jacobian* as a regularizer (for the hidden layer norm, just use BatchNorm or LayerNorm).

Scalable global optimization via local Bayesian optimization D. Erikson et al. (NeurIPS 2019)

Thompson sampling can be used as an acquisition function for Bayesian optimization: sample a function from the posterior and estimate its minimum [?]. It is parallelizable: just sample k functions. In higher dimensions (beyond 10), do not try to find a global approximation of the objective, but just a *local* one.

Expand/shrink the region based on progress (trust-region-based Bayesian optimization, TuRBO).

Code available.

Uncertainty on asynchronous time event prediction M. Biloš et al. (NeurIPS 2019)

The forecast for the next event should change with time and account for uncertainty (it should not be a point in the simplex, but a distribution on it). Model continuously evolving distributions over the simplex with:

- Dirichlet distribution parameters evolving with a basis function decomposition;
- Logistic-normal parameters evolving with a weighted Gaussian process.

Applications include anomaly detection.

Variational Bayesian optimal experimental design A. Foster et al. (NeurIPS 2019)

An informative experimental design reduces entropy. The expected information gain $\text{EIG}(d) = E_y[H[P(\theta)] - P[p(\theta|y, d)]]$ is intractable: use variational inference.

Poisson mini-batching for Gibbs sampling with convergence rate guarantees R. Zhang and C. DeSa (NeurIPS 2019)

When using Gibbs sampling on subsets of variables, *i.e.*, when sampling from $x_i|x_J$ instead of $x_i|x_I$, $J \subsetneq I$, a Metropolis-Hastings rejection step is needed to correct the bias. Instead, add an *auxiliary Poisson variable* for each factor to control if it is used – it is unbiased, even without MH.

Parameter estimation in particle Gibbs sampling A. Wigren et al. (NeurIPS 2019)

To fit SEIR (suceptible-exposed-infected-recovered) models for humans and mosquitoes, use Gibbs sampling: sample from $x|\theta, y$, then $\theta|x, y$. Sampling

from $x|\theta, y$ is difficult: use a particle filter. To reduce the correlation, marginalize what can easily be marginalized (conjugate distributions), either by hand or using a *probabilistic programming* such as `birch`, which uses a particle filter with delayed sampling.

Causal confusion in imitation learning
P. de Haan et al. (NeurIPS 2019)

A self-driving car, trained with imitation learning, could learn to pay attention to the brake indicator to decide when to brake, rather than the road... Adding more information (dashboard, history, etc.) can increase causal confusion and lead to poorer real-world performance.

Compute a latent state with a VAE; consider all possible causal graphs from the latent stated, encoded by binary masks; train each of them (train them together, with the mast as input). Run the models on new data (via interventions: change some past action and see what happens) and pick the best (look at the states independently).

Learning to control self-assembling morphologies: a study of generalization via modularities
D. Pathak et al. (NeurIPS 2019)

Dynamic graph networks combines several identical neural nets (with shared weights) into a graph, the output of one being sent to the input of the next ones.

Graded meta policy search
R. Mendonca et al. (NeurIPS 2019)

In meta-learning, learn *local policies*, for the training tasks, and combine them with supervised learning to deal with the whole tasks.

Using a logarithmic mapping to enable lower discount factors in reinforcement learning
H. van Seijen et al. (NeurIPS 2019)

In practice (with function approximation) only discount factors close to 1 work well. Poor performance seems to come from large differences in the action gaps between states

$$\Delta(s) = Q^*(s, a^*) - Q^*(s, \tilde{a}),$$

where a^* is the optimal action and \tilde{a} that chosen by the algorithm.

Logarithmic Q-learning replaces Q with $\log Q$; it is possible to get the correct optimum in spite of $E[\log X] \leq \log EX$.

Hindsight credit assignment

A. Harutyunyan et al. (NeurIPS 2019)

Do not use time for credit assignment, estimate $P(a|x, f(\tau))$, where a is a past action, x a past state and $f(\tau)$ a future outcome.

$$Q(x, a) = r(x, a) + \mathbb{E}_{\tau} \left[\sum \gamma^k \frac{P(a|x, X_k)}{\pi(a|x)} R_k \right]$$

$$\begin{aligned} P(a|x, y) &> P(b|x, y) && \text{more direct path} \\ P(c|y, z) &= \pi(c|y) && \text{any action will do} \end{aligned}$$

Weight-agnostic neural networks
A. Gaier and D. Ha (NeurIPS 2019)

Look for neural network architectures that work well without training.

To simplify the search, use a shared weight (yes, only one parameter: all the weights of all the layers are the same), random. Start with minimal networks of the form

and modify them by inserting nodes, adding connections, or changing activation functions.

The performance is decent on reinforcement learning problems, competitive with SOTA models after training, for much smaller networks.

Those architectures contain implicit priors.

Asymmetric valleys: beyond sharp and flat local minima
H. He et al. (NeurIPS 2019)

According to popular belief, flat minima generalize better. But the loss landscape could be flat in some directions and sharp in others.

Prefer solutions biased towards the flat side – they generalize better; they can be obtained by averaging the solutions on the SGD path.

**UniXGrad: a universal, adaptive algorithm
with optimal guarantees
for constrained optimization**
A. Kavis et al. (NeurIPS 2019)

Gradient descent

$$x_{n+1} = x_n - \alpha \nabla f(x_n)$$

could be replaced by an “implicit” step,

$$x_{n+1} = x_n - \alpha \nabla f(x_{n+1})$$

which can be approximated with two explicit steps

$$\begin{aligned} y_{n+1} &= x_n - \alpha \nabla f(x_n) \\ x_{n+1} &= x_n - \alpha \nabla f(x_{n+1}). \end{aligned}$$

The *MirrorProx* algorithm adds a generalized projection wrt a Bregman divergence.

$$\begin{aligned} y_t &= \underset{y}{\operatorname{Argmin}} \langle y, \nabla f x_{t-1} \rangle + \alpha D_R(y, x_{t-1}) \\ x_t &= \underset{x}{\operatorname{Argmin}} \langle x, \nabla f y_t \rangle + \alpha D_R(x, x_{t-1}) \\ D_R(x, y) &= Rx - Ry - \langle \nabla R y, x - y \rangle \\ R(x) &= \frac{1}{2} \|x\|^2 \end{aligned}$$

The UniXGrad algorithm evaluates the gradients $\nabla f x_{t-1}$ and $\nabla f y_t$ at weighted averages \bar{x}_{t-1} and \bar{y}_t of the previous points $y_1, \dots, y_{t-1}, x_{t-1}$ and y_1, \dots, y_t . and uses an adaptive learning rate, defined with the sum of the gradient differences $\|\nabla f \bar{x}_{t-1} - \nabla f \bar{y}_t\|^2$.

**Sinkhorn barycenters with free support
via Frank-Wolfe algorithm**
G. Luise et al. (NeurIPS 2019)

To compute the average between probability distributions (for the Sinkhorn divergence, *i.e.*, entropic optimal transport), assume $a^* = \sum a_i \delta_{x_i}$, with the x_i ’s fixed and estimate the a_i ’s. Instad, do not fix the x_i ’s, but add them one by one, and do not re-estimate the previous coefficients.

Learning dynamic polynomial proofs
A. Fawzi et al. (NeurIPS 2019)

Given a polynomial P , prove that $\forall x \in [0, 1]^n P(x) \geq 0$, using a reinforcement learning agent, trained with DQN, with unsupervised dense rewards, accounting for symmetries.

**Generative modeling by estimating
gradients of the data distribution**
Y. Song and S. Ermon (NeurIPS 2019)

Generative models are usually implicit, only providing a sampling procedure (e.g., GANs) or explicit, directly modeling a probability distribution function (e.g., VAE), but these need to be normalized. Instead,

model the *score function* $\nabla_x \log p(x)$. It can be estimated from data (integration by parts, score matching).

$$\begin{aligned} \text{Fisher divergence} &= \frac{1}{2} \mathbb{E}_{x \sim \text{data}} \|\nabla_x \log p_{\text{data}}(x) - s_\theta(x)\| \\ &= \mathbb{E}_{x \sim \text{data}} \left[\frac{1}{2} \|s_\theta(x)\|_2^2 + \operatorname{tr} \nabla_x s_\theta(x) \right] \end{aligned}$$

It is necessary to add some noise:

- At least a very small amount, because the data lies on a low-dimensional manifold (or, even, is discrete), to help convergence;
- A larger amount of noise to have a better estimate of the score in low-density regions – but this leads to noisy samples.

The *noise-conditional score network* trains a single model for all levels of noise (the level of noise is one of the inputs). One can sample from a score function using *Langevin dynamics*; progressively reduce the amount of noise while sampling (*annealed Langevin dynamics*).

**Implicit generation and modeling
with energy-based models**
Y. Du and I. Mordatch (NeurIPS 2019)

Energy-based models (EBM)

$$p_\theta(x) \propto \exp -E_\theta(x)$$

can be trained with contrastive divergence

$$\begin{aligned} \mathcal{L}(\theta) &= \mathbb{E}_{x \sim \text{data}} [-\log p_\theta(x)] \\ \nabla \mathcal{L} &= \mathbb{E}_{x \sim \text{data}} [\nabla E_\theta(x)] - \mathbb{E}_{x \sim p_\theta} [\nabla E_\theta(x)] \end{aligned}$$

and sampled from with Langevin dynamics.

**Residual flows
for invertible generative modeling**
R.T.Q. Chen et al. (NeurIPS 2019)

The *invertible ResNet* $f : x \mapsto x + g(x)$ is invertible if g has Lipschitz constant less than 1 (enforced by spectral normalization) and its inverse can be computed by fixed point iterations. To compute

$$\log |\det \nabla_x f| = \sum \frac{(-1)^k}{k} \operatorname{tr} J_g(x)^k,$$

use the **Russian roulette estimator** which replaces the infinite sum with an unbiased estimator, computed as a weighted sum of a random number of terms.

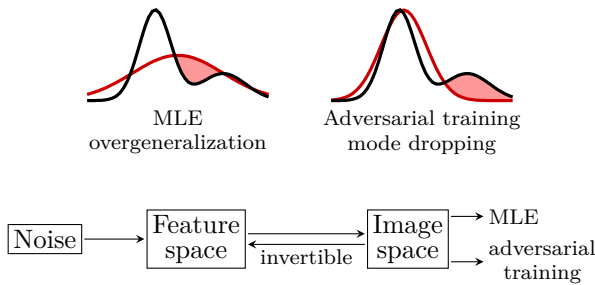

The *lipswish* activation is Lipschitz.

$$\begin{aligned} \text{swish}(x) &= x \cdot \text{sigmoid}(x) \\ \text{lipswish}(x) &= \text{swish}(x)/1.1 \end{aligned}$$

Hype: a benchmark for human eye perceptual evaluation of generative models
S. Zhou et al. (NeurIPS 2019)

Use crowdsourcing to evaluate the quality of a generative model, by measuring the time needed by humans to decide if an image is real or fake, either by showing the image for a limited amount of time, progressively increased or decreased depending on performance (“adaptive staircase procedure”, from psychometrics) or by letting the user choose how long they need. It costs \$60 and takes 60 minutes per model. It was tested on WGAN-GP, ProGAN, SN-GAN, BEGAN, BigGAN.

Adaptive density estimation for generative models
T. Lucas et al. (NeurIPS 2019)

Maximum likelihood estimators (MLE) and adversarial training have complementary advantages and drawbacks: combine them into a hybrid approach to ensure both dataset coverage and sample quality.

Emergence of object segmentation in perturbed generative models
A. Bielski and P. Favaro (NeurIPS 2019)

Unsupervised object segmentation is possible: add a random shift to the foreground and mask: the reconstructed image should still look real.

Faster width-dependent algorithm for mixed packing and covering LPs
D. Boob et al. (NeurIPS 2019)

A mixed packing-covering linear program (MPC-LP) is of the form

$$\begin{array}{ll} \text{Find} & x \in [0, 1]^n \\ \text{Such that} & Px \leq \mathbf{1} \\ & Cx \geq \mathbf{1} \quad \text{where } P, C \geq 0. \end{array}$$

The corresponding *saddle point problem* is

$$\text{Minimize}_{x \in [0, 1]^n} \text{Max}_{\substack{y \in \Delta_p \\ z \in \Delta_q}} L(x, y, z).$$

It is often solved by minimizing the *primal-dual gap* f , with a strong convex penalty ϕ ,

$$\text{Minimize}_w f(w) + \phi(w)$$

with *Nesterov's dual extrapolation*. Replace strong convexity

$$\phi\left(\frac{u+v}{2}\right) \leq \frac{1}{2}[\phi(u) + \phi(v)] - \frac{1}{2}\|u-v\|$$

with a weaker notion, area convexity,

$$\phi\left(\frac{u+v+t}{3}\right) \leq \frac{1}{3}[\phi(u) + \phi(v) + \phi(t)] - \frac{1}{3\sqrt{3}}(v-u)'M(u-t).$$

For instance, $\gamma(x, y) = xy \log x + 2y \log y$, on $[0, 1]^2$.

Sparse logistic regression learns all discrete pairwise graphical models
S. Wu et al. (NeurIPS 2019)

Logistic regression, with an ℓ_1 (or $\ell_{2,1}$) penalty, can recover the structure of a graphical model, such as the Ising (binary) model

$$P(z) \propto \exp \left[\sum_{i,j} A_{ij} z_i z_j + \sum_i \theta_i z_i \right] \quad z \in \{\pm 1\}^n.$$

Smoothing structured decomposable circuits
A. Shih et al. (NeurIPS 2019)

Circuits (aka *sum-product networks*) describe probability distributions and allow efficient computation of likelihood partition function, marginals, etc. provided they are smooth.

A circuit is *smooth* if the children of any \oplus gate use the same variables. It is easy to ensure, but the algorithm is quadratic; it can be sped up by representing groups of variables as intervals.

Tractable probabilistic models
V. van den Broeck et al. (UAI 2019)

Combining generative and discriminative models for hybrid inference
V.G. Satorras et al. (NeurIPS 2019)

Use a neural network to add a correction term to Kalman-like algorithms.

Fast and accurate least mean squares
A. Maalouf et al. (NeurIPS 2019)

The average of n points in \mathbf{R}^d is a convex combination of $d + 1$ of those points; such a representation can be obtained recursively, by putting the points in $d + 1$ (random) groups and computing their means (Caratheodory theorem).

Transform the least mean square (LMS) problem $\text{Argmin}_x \|Ax - b\|_2^2 + g(x)$:

$$\|Ax - b\|_2^2 = [x - 1] \begin{bmatrix} A' \\ b' \end{bmatrix} [A \ b] \begin{bmatrix} x \\ -1 \end{bmatrix} = [x - 1] P' P \begin{bmatrix} x \\ -1 \end{bmatrix}.$$

The covariance matrix $\frac{1}{n} P' P = \frac{1}{n} \sum p_i p_i'$ is the average of n points, $p_i p_i'$ in \mathbf{R}^{d^2} : it can be replaced with a convex combination of $d^2 + 1$ points (useful if $d^2 + 1 \ll n$)

Fast structure learning with modular regularization
G. VerSteeg et al. (NeurIPS 2019)

To recover the dependence structure among a large number of variables from a small number of observations, assume that each observed variable has a single latent parent.

The *total correlation*

$$\begin{aligned} \text{TC}(\mathbf{X}) &= \sum_i H(X_i) - H(\mathbf{X}) \\ &= \text{KL}(\text{joint} \parallel \text{product of marginals}) \end{aligned}$$

aka multivariate mutual information (it generalizes $H(X; Y) = H(X) + H(Y) - H(X, Y)$) can be used to characterize graphical models such that

$$\begin{aligned} \forall i \neq j \quad Z_i \perp\!\!\!\perp Z_j & \quad (\text{latent}) \\ \forall i \neq j \quad X_i \perp\!\!\!\perp X_j \mid \mathbf{Z} & \quad (\text{observed}) \end{aligned}$$

by $\text{TC}(X|Z) + \text{TC}(Z) = 0$. For a “modular” model (each X_i depends on a single Z_j), it suffices to add $\forall i \text{TC}(Z|X_i) = 0$.

To fit those models, set $Z = WX + \varepsilon$, $\varepsilon \sim N(0, \text{diag}(\eta))$ and solve

$$\underset{W}{\text{Minimize}} \text{TC}(X|Z) + \text{TC}(Z) + \text{penalty},$$

where the penalty makes the $\text{TC}(Z|X_i)$ small and cancels out computationally expensive terms.

This can also be applied to large correlation matrices in finance: we recover industry classifications.

Numpy and Pytorch code available: **LinearCorex**, **T-Corex**.

Principal component projection and regression in nearly linear time through asymmetric SVRG
Y. Jin and A. Sidford (NeurIPS 2019)

Principal component projection and PCR are usually done by explicit computation of the eigenvectors or through polynomial approximations of the sign function. Instead, use a *rational approximation* (Zolotarev). It is also possible to reduce the variance of the estimates by expanding the eigenvalue problem to higher dimensions. The algorithm is almost linear in $\text{nnz}(A)$.

PIDForest: anomaly detection via partial identification
P. Gopalan et al. (NeurIPS 2019)

The *sparsity* of a region C is

$$\text{sparsity}(C) = \frac{\text{volume}(C)}{\# \text{ points in } C}.$$

Anomalies can be partially identified (PID) with their PID score:

$$\text{score}(x) = \max_{\substack{C \in \mathcal{C} \\ x \in C}} \text{sparsity}(C),$$

which can be efficiently approximated with a random forest.

A neurally plausible model learns successor representation in partially observable environments
E. Vertez and M. Sahani (NeurIPS 2019)

The **successor representation** (SR), the expected discounted future state occupancy,

$$M(s, s') = E \left[\sum_{k \geq 0} \gamma^k \mathbf{1}_{s_{t+k}=s'} \mid s_t = s \right]$$

is a hybrid between model-based and model-free RL. The *successor features* replace state occupancy with state features.. If the reward function changes, one can use the SR to compute the value function – but it does not work with noisy observations. To represent the distribution (belief) on the current state, use the *distributed distributional code* (DDC)

$$\mu = E_{s \sim p} [\psi(s)] \quad M(\mu) = E \left[\sum_{k \geq 1} \gamma^k \psi * s_{t+k} \mid \mu_t = \mu \right]$$

Learning reward machines for partially observable RL
R.T. Icarte et al. (NeurIPS 2019)

A *reward machine* (RM) is an automaton-based reward function. It can be used as a memory for POMDP problems. Learning a RM is a discrete optimization problem.

Scene representation networks: continuous 3D structure aware neural scene representation
V. Sitzmann et al. (NeurIPS 2019)

From a 2D image, use a *hypernetwork* to learn a *scene representation network*, which can be fed to a *neural renderer* to generate images from other points of view. The SRN maps positions to the properties (colour, shape, etc.) at that position/voxel; contrary to voxel-based representations there are no discretization artefacts. The neural renderer uses *ray marching* (look for objects closest to the camera on each ray from the camera), sped up by predicting the distance to the nearest object from the camera in each direction.

A condition number for joint optimization of cycle-consistent networks
L.J. Guibas et al. (NeurIPS 2019)

A *mapping graph* is a graph (V, E) , with a set D_u associated to each vertex and a mapping $D_u \rightarrow D_v$ associated to each edge $u \rightarrow v$. It is *cycle-consistent* if the composition of the mappings along any cycle is the identity (as with CycleGAN or back-translation).

Cascade RPN: delving into high quality region proposal network with adaptive convolution
T. Vu et al. (NeurIPS 2019)

Probabilistic watershed: sampling all spanning forests for seeded segmentation and semi-supervised learning
E.F. Sanmartín et al. (NeurIPS 2019)

Poincaré recurrence, cycles and spurious equilibria in gradient descent-ascent for non-convex non-concave zero-sum games
E. Vlatakis (NeurIPS 2019)

Gradient descent-ascent does not always work or non-convex non-concave zero-sum games (GANs, etc.): they suffer from spurious equilibria, cycles, and divergence.

Graph-based discriminators: sample complexity and expressiveness
R. Livni and Y. Mansour (NeurIPS 2019)

To compare two distributions from their samples, use and *integral probability measure* (IPM)

$$\text{IPM}(p_1, p_2) = \sup_{h \in H} \left| \mathbb{E}_{x \sim p_1} h(x) - \mathbb{E}_{x \sim p_2} h(x) \right|, \quad H \subset \{0, 1\}^X$$

or a more powerful *graph-based discriminator*

$$\text{IPM}(p_1, p_2) = \sup_{g \in G} \left| \mathbb{E}_{x, y \sim p_1} g(x, y) - \mathbb{E}_{x, y \sim p_2} g(x, y) \right|,$$

for $G \subset \{0, 1\}^{X \times X}$.

Learning by abstraction: the neural state machine
D. Hudson and C. Manning (NeurIPS 2019)

Neural nets can get the right answer for the wrong reason. The *neural state machine* is a differentiable graph-based model outputting a *scene graph*, used as a state machine, with objects (with attribute – colour, shape, etc – given by several embeddings) as nodes and relations (e.g., relative positions) as edges. A question about the scene (visual question answering, VQA) is translated into a sequence of instructions, which are then run on the state machine.

Batched multi-arm bandits
Z. Gao (NeurIPS 2019)

In the batched multi-arm bandit problem, one chooses k arms, gets the results, and plays again. The grid (k) can be imposed or chosen.

Are sample means in multi-arm bandits positively or negatively biased?
J. Shin et al. (NeurIPS 2019)

The sample mean (of a fixed arm, at a fixed time) is negatively biased for ϵ -greedy, UCB, Thompson thresholding. But for the chosen arm and a stopping time:

- Negatively biased under optimistic sampling;
- Positively biased under optimistic stopping;
- Positively biased under optimistic choosing.

SIC-MMAB: synchronization involves communication in multi-player multi-arm bandits
E. Boursier (NeurIPS 2019)

In the *multi-player MAB*, the reward is zero in case of a collision. If the collisions are observed and the players can communicate, the regret for M players is

$$\sum_{k > M} \frac{\log T}{\mu_M - \mu_k}.$$

If they cannot communicate, this does not change: if they are synchronized, they can use the collisions to exchange bits of information. If they are not synchronized (if they do not start at the same time) and do not observe the collisions (only the zero rewards), this is trickier.

Recovering bandits

C. Pike-Burke and S. Grunewalder (2019)

Bandits are often used for product recommendation, but you do not want to recommend a sofa to someone who has just bought one – you should wait. In *recovering bandits*, the reward is a function of the time since the arm was last played, modeled as a Gaussian process. They require some strategic thinking: if you expect a good arm's reward to increase, you may want to wait and play a less good arm for the time being. UCB and Thompson sampling can be modified into d -step look-ahead strategies.

Strategizing against no-regret learners

Y. Deng et al. (NeurIPS 2019)

Mean-based algorithms can be fooled: play a suboptimal action long-enough to trick your opponent into thinking it is optimal for you, then play the actual optimal solution for as long as it takes your opponent to realize they were duped.

No-regret algorithms include EXP3, multiplicative weights, follow the perturbed leader.

Time-accuracy tradeoffs for learning a ReLU with respect to Gaussian marginals

S. Goel et al. (NeurIPS 2019)

ReLU regression looks for w such that $y \approx \text{relu}(w'x)$. If $x \sim N(0, 1)$, a shallow neural net with stochastic gradient descent learns w .

Small ReLU networks are memorizers: a tight analysis of memorization capacity

C. Yun et al. (NeurIPS 2019)

A 2-layer fully-connected ReLU network can memorize N points with $\Theta(\sqrt{N})$ nodes (vs $\Theta(N)$ for a 1-layer neural net).

On making stochastic classifiers deterministic

A. Cotter et al. (NeurIPS 2019)

To solve a non-convex constrained problem, e.g. with fairness constraints

$$\begin{array}{ll} \text{Find} & \theta \\ \text{To minimize} & g_0(\theta) \\ \text{Such that} & \forall i g_i(\theta) \leq 0 \end{array}$$

look for Nash equilibrium of the Lagrangian

$$\mathcal{L}(\theta, \lambda) = g_0(\theta) + \sum \lambda_i g_i(\theta).$$

There might be no pure Nash equilibrium, but there is a mixed one, giving rise to a *stochastic classifier* (alternatively update θ and λ , and put a uniform distribution on the trajectory).

To transform a stochastic classifier into a deterministic one, one could use thresholding $\hat{f} = \mathbf{1}_{f \geq 1/2}$, but the performance can be very different (for instance if $f \equiv 0.51$). Instead, use *hashing* (cf the difference between thresholding and dithering for images), which fakes stochasticity – it replaces stochasticity with arbitrariness.

One can try to interpolate between thresholding and hashing: partition the samples into different regions and use a different threshold in each.

Cold case: the lost MNIST digits

C. Yadov and L. Bottou (NeurIPS 2019)

MNIST was not the whole data: 50,000 samples were discarded (computers were less powerful, then): aMNIST adds them back and provides some metadata.

Testing set rot is real: MNIST classifiers perform less well on the new data than on the initial dataset – however, the ranking of the classifiers remains unchanged.

Optimal sparse decision trees

X. Hu et al. (NeurIPS 2019)

It is possible to compute the *optimal sparse decision tree* (with a penalty on the number of nodes), in time (often) linear in the number of samples and features, with a proof of optimality (in time exponential in the number of features). Code available.

Optimizing generalized rate metrics with three players

H. Narasimhan et al. (NeurIPS 2019)

We often need to train models with *fairness constraints*, e.g., $|\text{precision}(G_1) - \text{precision}(G_2)| \leq \varepsilon$,

$$\begin{array}{ll} \text{Find} & \theta \\ \text{To minimize} & \psi(R_1(\theta), \dots, R_k(\theta)) \\ \text{Such that} & \forall i \psi_i(R_1(\theta), \dots, R_k(\theta)) \leq 0 \end{array}$$

where the R_k 's are prediction rates, *i.e.*, expectations of counts (FPR, etc.) on subsets of the data. Introduce slack variables

$$\begin{array}{ll} \text{Find} & \theta, \xi \\ \text{To minimize} & \psi(\xi_1, \dots, \xi_k) \\ \text{Such that} & \forall i \xi_i \geq R_i(\theta). \end{array}$$

The Lagrangian formulation

$$\begin{array}{ll} \text{Minimize} & \psi(\xi) - \lambda'(\xi - R(\theta)) \\ \theta, \xi & \lambda \geq 0 \end{array}$$

is a 3-player game: use the exact solution for x_i , SGD for λ , and SGD with surrogates for $R_k(\theta) \leq \tilde{R}_k(\theta)$.

There is a TensorFlow constrained optimization (TFCO) library.

***This looks like that: deep learning
for interpretable image recognition***
C. Chen et al. (NeurIPS 2019)

Attention is not sufficient to explain what a convnet sees: it only tells where, not what. Add a *prototype layer*, which learns prototypes and outputs how similar each prototype is to a given patch; combine the prototype scores into output logits.

Paradoxes in fair machine learning
(NeurIPS 2019)

Fairness in machine learning is often defined as some quantity, e.g., odds, being equal among all groups (for some predefined protected attributes). Fairness in *fair division* relies on a few axioms, e.g.,

- Resource monotonicity: adding more resources makes everyone better off;
- Population monotonicity: adding more people makes everyone worse off.

Adding resource monotonicity to equal odds does not impact efficiency; adding population monotonicity does.

***Multicriteria dimensionality reduction
with applications to fairness***
T. Tantipongpipat et al. (NeurIPS 2019)

PCA is not fair: the reconstruction error need not be the same for all groups (for instance, face reconstruction for males is easier than for females). Instead, consider optimization problems of the form

$$\text{Minimize}_{P \text{ projection}} g(f_1(P), \dots, f_k(P))$$

where $f_i(P)$ is the reconstruction error for group i and g some aggregation function (e.g., sum, for PCA). For instance

$$\begin{aligned} &\text{Minimize}_P \text{Max}_{i \in [1, k]} \left(\text{Max}_Q \|A_i Q\|_F^2 - \|A_i P\|_F^2 \right) \\ &\text{Maximize}_P \prod \|A_i P\|_F^2. \end{aligned}$$

***Implicit regularization
in deep matrix factorization***
S. Arora et al. (NeurIPS 2019)

Deep neural networks generalize well, even with no regularization – it is widely believed that SGD provides implicit regularization.

The matrix completion problem is often solved with a nuclear norm penalty

$$\text{Minimize}_W \sum_{(i,j) \in \Omega} (w_{ij} - b_{ij})^2 + \lambda \|W\|_*$$

but a deep matrix approximation (yes, a deep *linear* network) performs better

$$\text{Minimize}_{W_1, \dots, W_N} \sum_{(i,j) \in \Omega} [(W_N W_{N-1} \cdots W_1)_{ij} - b_{ij}]^2$$

(no regularization).

In deeper networks, small singular values move more slowly with gradient descent, while larger singular values move faster: the longer gaps between singular values give a low-rank matrix.

***SGD on neural networks learns
functions of increasing complexity***
D. Kalimeris et al. (NeurIPS 2019)

Stochastic gradient descent (SGD) starts to learn an “essentially linear” classifier (its performance can be explained by a linear classifier) and then increasingly complex models.

When does label smoothing help?
R. Müller et al. (NeurIPS 2019)

Label smoothing replaces hard targets  with soft targets : this ensures that observations are close to their prototypes (weights of the last layer) and far from the others – the clusters are tighter.

Neural networks are over-confident: temperature scaling and label smoothing can help calibrate them.

Label smoothing is bad for distillation: the model no longer knows how different the classes are.

***Splitting steepest descent
for growing neural architectures***
L. Wu et al. (NeurIPS 2019)

To build smaller neural nets, progressively split neurons into several copies.

Positional normalization
B. Li et al. (NeurIPS 2019)

Normalization variants:

The moments (μ, σ) used for the normalization contain information: re-inject them later in the network.

Variance reduction for matrix games
Y. Carmon et al. (NeurIPS 2019)

In zero-sum games

$$\text{Min}_{x \in \mathcal{X}} \text{Max}_{y \in \mathcal{Y}} f(x, y),$$

\mathcal{Y} can be seen as constraints (GAN) or uncertainty (robust optimization).

Examples of bilinear games $\text{Min}_x \text{Max}_y y' A x$ include *matrix games* ($\mathcal{X} = \mathcal{Y} = \text{simplex}$), SVM (\mathcal{X} Euclidean, \mathcal{Y} simplex) and linear regression ($\mathcal{X} = \mathcal{Y} = \text{Euclidean}$).

**Provably robust deep learning
via adversarially trained smoothed classifiers**
H. Salman et al. (NeurIPS 2019)

Randomized smoothing transforms a classifier f into

$$g(x) = \underset{y \in \mathcal{Y}}{\operatorname{Argmax}} \mathbb{P}_{\delta \sim N(0, \sigma^2 I)} [f(x + \delta) = y].$$

Look for adversarial examples for the smoothed classifier.

**Zero-shot knowledge transfer
via adversarial belief matching**
P. Micaelli and A. Storkey (NeurIPS 2019)

Model compression (pruning, quantization, distillation) usually requires training data, but one can use a generator instead. This works even though the generated samples do not look like actual samples – they suffice to describe the teacher’s decision boundaries.

Learning perceptual inference by contrasting
C. Zhang et al. (NeurIPS 2019)

Raven’s progressive matrices (RPM) are psychological tests for spatial-temporal reasoning (“thinking in pictures”, for humans). With computer-generated datasets (RAVEN, PGM), computers can have a go at it, modeling the attributes in the images and the rules they follow with a *Gumbel softmax*.

**Better transfer learning
with inferred successor maps**
T. Madarasz and T. Behrens (NeurIPS 2019)

Replace the Q -value function

$$Q_t^\pi(s, a) = \mathbb{E}[\sum \gamma^k r_{t+k} | s_t = s, a_t = a]$$

with the *successor representation* (SR)

$$M_t^\pi = \mathbb{E}[\sum \gamma^k \mathbf{1}_{s_{t+k+1}=s'} | s_t = s, a_t = a]$$

$$Q^\pi(s,) = \sum_{s'} M(s, a, s') w(s')$$

**Infra-slow brain dynamics
as a marker of cognitive function and decline**
S. Ajmera (NeurIPS 2019)

Gaussian process factor analysis (GPFA) can extract latent signals, at various time scales, from fMRI data.

y : high-dimensional signal (observed)
 x : low-dimensional signal (latent)
 $y = Ax + \text{noise}$
 $x_i \sim \text{GP}$

Understanding sparse JL for feature hashing
M. Jagadeesan (NeurIPS 2019)

Sparse Johnson-Lindenstrauss is a dimension reduction method trying to preserve distances, defined by a random transformation, with s nonzero entries in each column. Equivalently, it is the sum of s feature hashing dimension reductions.

$$h : \llbracket 1, n \rrbracket \rightarrow \llbracket 1, m \rrbracket \text{ hash function}$$

$$\sigma_i \in \{\pm 1\} \text{ random}$$

$$f(x) = \sum_{j \in h^{-1}(i)} \sigma_j x_j$$

There is a tradeoff between the number of hash functions s , the dimension m , and ℓ^2 distance preservation with 3 regimes:

- m small: poor performance, regardless of the number of hash functions;
- m large: performance proportional to \sqrt{s} ($s = 4$ is a good choice);
- m very large: good performance, regardless of the number of hash functions.

The performance is measured by looking at vectors with small ℓ_∞ -to- ℓ_1 norm ratio.

**A non-convex approach for exact and efficient
multichannel sparse blind deconvolution**
Q. Qu et al. (NeurIPS 2019)

Gradient descent, Huber loss and preconditioning efficiently solve the blind deconvolution problem.

Applications include superresolution (microscopy) and neuron spike identification.

**Efficiently learning
Fourier sparse set functions**
A. Amrollahi et al. (NeurIPS 2019)

The Walsh-Hadamard (or Fourier) transform of a *set function* $x : 2^V \rightarrow \mathbf{R}$, seen as a function $x : \mathbf{F}_2^n \rightarrow \mathbf{R}$, is

$$\hat{x} : \begin{cases} \mathbf{F}_2^n & \rightarrow \mathbf{R} \\ f & \mapsto \sum_{t \in \mathbf{F}_2^n} (-1)^{\langle f, t \rangle} x_t. \end{cases}$$

It is *sparse* if $\|\hat{x}\|_0 \leq k$, and low-frequency if $\forall f \in \operatorname{supp} \hat{x} \ |f| \leq d$, where $|f|$ is the Hamming weight of f , *i.e.*, the number of nonzero elements.

For instance, the *cut function* of a graph,

$$x(A) = \sum_{\substack{s \in A \\ t \in V \setminus A}} w(s, t)$$

is sparse ($k = |E|$) and low-frequency ($d = 2$).

Applications include hyperparameter tuning, where $x \in 2^V$ is a boolean vector describing the hyperparameters (SGD vs Adam, number of layers, layer size, etc.) and $F(x)$ the corresponding loss.

Surfing: iterative optimization over incrementally trained deep networks
G. Song et al. (NeurIPS 2019)

To invert a generator (e.g. a VAE), do not start with the fully trained model, but follow a local optimum through the training (“surfing”) – the loss landscape is much nicer at the beginning.

R2D2: repeatable and reliable detector and descriptor
J. Revaud (NeurIPS 2019)

To align two images, identify the “keypoints”, compute their “descriptors” (e.g., SIFT), and match the points if they are close. We want the keypoints to be, not only repeatable (still present on a slightly modified image), but also reliable (*i.e.*, useful for matching – this excludes repeated patterns),

Training image estimators without image ground truth
Z. Xia and A. Chakrabarti (NeurIPS 2019)

To learn how to restore image quality, e.g., for motion deblurring of face images, when (low-quality, high-quality) image pairs are not available, use pairs of low-quality images corresponding to the same high-quality image,

$$\begin{aligned} y_1 &= \theta_1 x + \varepsilon_1 \\ y_2 &= \theta_2 x + \varepsilon_2 \end{aligned}$$

with a *swap loss* $\|\hat{\theta}_1 \hat{x}_2 + \hat{\varepsilon}_1 - y_1\|$.

KernelGAN: blind SR kernel estimation using an internal GAN
S. Bell-Kligler (NeurIPS 2019)

Deep *linear* network (equivalent to a 1-layer network, but with more local minima) to infer the kernel to use for super-resolution (SR).

Differentiable ranking and sorting using optimal transport
M. Cuturi et al. (NeurIPS 2019)

The 1-dimensional optimal transport can be solved by sorting. Conversely, the entropic regularization of the OT problem provides a differentiable regularization of the sorting and ranking operations.

Nonparametric density estimation and convergence rates for GANs under Besov IPM losses
A. Uppal et al. (NeurIPS 2019)

Density estimation does not work well in high dimensions, but GANs solve a similar problem. GANs minimize an *integral probability metric* (IPM)

$$\begin{aligned} \hat{P} &= \operatorname{Argmin}_Q \sup_{f \in \mathcal{F}} \mathbb{E}_{X \sim Q} [f(X)] - \mathbb{E}_{X \sim \text{data}} [f(X)] \\ &= \operatorname{Argmin}_Q f_{\mathcal{F}}(Q, \text{data}) \\ d_{\mathcal{F}}(P, Q) &= \sup_{f \in \mathcal{F}} \left| \mathbb{E}_{X \sim P} [f(X)] - \mathbb{E}_{X \sim Q} [f(X)] \right| \end{aligned}$$

Besov spaces $B_p^s \approx \{f \in L^p : \|f^{(s)}\| \text{ bounded}\}$ are generalization of Sobolev spaces ($p = 2$); they are well-approximated with neural nets with ReLU activations.

Wasserstein Weisfeiler-Lehman graph kernels
M. Togninalli et al. (NeurIPS 2019)

Traditional graph kernels decompose the graphs into simple substructures, compute the similarities between those substructures and aggregate them in a simplistic way, by averaging. Use the Wasserstein distance instead (or, rather, $e^{-\lambda d_W}$).

Putting an end to end-to-end
S. Löwe et al. (NeurIPS 2019)

Greedy InfoMax (GIM) is a form of semi-supervised (or even unsupervised) learning which learns a neural network without using end-to-end back-propagation (the forward pass is still end-to-end, though, but can be done less often; learning can be asynchronous) by dividing it into “modules” (groups of layers), each with its own “self-supervised” loss, InfoNCE, the mutual information between nearby patches (for images or sound).

On the downstream performance of compressed word embeddings
A. May et al. (NeurIPS 2019)

The *eigenspace overlap score* (EOS) measures how much information is retained when compressing word embeddings $A_{\text{raw}} \mapsto A_{\text{compressed}}$, from the left singular vectors, $A = UDV'$,

$$\text{EOS} = \frac{1}{d} \|U'_{\text{compressed}} U\|_F^2.$$

Numerically accurate hyperbolic embeddings using tiling-based models
T. Yu and C. de Sa (NeurIPS 2019)

Euclidean models of hyperbolic space are numerically inaccurate far from the origin: instead of using Euclidean coordinates, consider a tiling of hyperbolic space and represent a point by a tile (an element of

the tiling group) and the Euclidean coordinates of the corresponding point in the central tile (close to the origin and therefore accurate).

XLNet for language pretraining **Z. Yang et al. (NeurIPS 2019)**

Autoregressive language models are usually unidirectional: XLNet changes this order of the words, so that it becomes bidirectional

$$P[x_{i_{k+1}} | x_{i_1}, \dots, x_{i_k}, x_{i_{k+1}}].$$

The new position i_{k+1} can be used as an attention key.

A step towards quantifying independently reproducible ML research **E. Raff (NeurIPS 2019)**

A paper is *independently reproducible* if it is reproducible without the author's code. They tried to reproduce 255 papers, succeeded for 60% of them, and identified the features of reproducible papers.

Average individual fairness **A. Roth (NeurIPS 2019)**

Fairness is often defined from the false negative rate for groups of interest. Instead of looking at the negative rate for a single problem for each group, look at the negative rate over several problems for a single subject.

Optimal transport methodology for lineage tracing **K. Yang (NeurIPS 2019)**

To use optimal transport for *lineage tracing* (to study cancer progression or embryogenesis):

- Use (unbalanced, relaxed) *Monge* optimal transport, *i.e.*, learn a transport map (instead of a coupling), parametrized by a neural net: it is faster and provides a mapping for new samples;
- Use optimal transport wrt the Euclidean distance in a latent space, learned by an autoencoder.

Estimation of Wasserstein distances in the spiked transport model **J. Niled-Weed (NeurIPS 2019)**

To estimate the Wasserstein distance $W_p(\mu, \nu)$ from samples $X_1, \dots, X_n \sim \mu$, $Y_1, \dots, Y_n \sim \nu$, one is tempted to use the plugin estimator $W_p(\hat{\mu}, \hat{\nu}_n)$, but the difference is of the order $n^{1/d}$: the empirical distribution $\hat{\mu}_n$ is a bad estimator of μ . In some cases (e.g., when μ has a density), better estimates are available.

While it may be possible to estimate $W_p(\mu, \nu)$ directly rather than through estimates $\hat{\mu}$ and $\hat{\nu}$ of μ and ν , the difference is still at least $(n \log n)^{-1/d}$.

The *spiked covariance model* is $X \sim N(0, \Sigma)$, $\Sigma = I + \beta vv'$, where I is high-dimensional noise and $\beta vv'$ a low-dimensional perturbation.

The *spiked transport model* assumes

$$\begin{aligned} \text{supp } X, \text{supp } Y &\subset \mathcal{U} \text{ (low-dimensional)} \\ \text{supp } Z &\subset \mathcal{U}^\perp \\ \mu &= \text{Law}(X + Z) \\ \nu &= \text{Law}(Y + Z) \end{aligned}$$

and looks for a coupling between X and Y . The difference is

$$n^{-1/k} + \sqrt{\frac{d \log n}{n}}$$

(the second term corresponds to the search for \mathcal{U} .)

Generalizing learning with optimal transport **S. Jegelka et al. (NeurIPS 2019)**

One can align word embeddings for different languages with optimal transport after adding some rotational invariance:

$$\text{Minimize}_{\Gamma \in \Pi(\mu, \nu)} \min_{P \in \mathcal{F}} \sum_{ij} \Gamma_{ij} d(x_i, Py_j)$$

with $\mathcal{F} = \{P \in \mathbf{R}^{d \times d} : \|P\|_p \leq k\}$, where $\|\cdot\|_p$ is the *Shatten norm* (the L^p norm of the singular values).

Use entropic regularization, normalization, and stabilized Sinkhorn.

Regularize the adversary: it should be close to an orthonormal transformation (no extreme distortion), $\beta \min_{P \in O_n} \|f_W(X) - XP'\|^2$, computed with *orthogonal Procrustes*, $P^* = UV'$, where $f_W(X')X = U\Sigma V'$.

Towards a mathematical theory of development **G. Schiebinger (NeurIPS 2019)**

Single-cell RNA sequencing (scRNA-seq) provides snapshots if the genes expressed at various stages of development. Optimal transport can link those snapshots: *unbalanced* optimal transport can account for cell proliferation and entropic regularization.

$$\begin{aligned} \text{Find} \quad & \pi \\ \text{To minimize} \quad & \iint c(x, y) \pi(x, y) dx dy - \varepsilon H(\pi) \\ \text{Such that} \quad & \pi(\cdot, y) = P_{t_2}(y) \\ & \pi(x, \cdot) = P_{t_1}(y) g(x)^{t_2 - t_1} \end{aligned}$$

Model the time dependence as $\dot{x} = f(x)$:

$$\underset{f}{\text{Minimize}} \|x_{t_2} - f(x_{t_1})\|^2 + \text{reg}(f).$$

***Unsupervised hierarchy matching
with optimal transport over hyperbolic space***
D. Alvarez-Melis et al. (NeurIPS 2019)

To match hierarchies using optimal transport, accounting for orthonormal transformations is not enough: the order of the branches can change. Use continuous non-linear mappings, parametrized by a neural net.

***Optimal transport mapping
input convex neural networks***
A.V. Makkuva (NeurIPS 2019)

The optimal transport can be defined as $T = \nabla f^*$,

$$f = \underset{f \in \text{CVX}}{\text{Argmin}} \mathbb{E}_{X \sim P}[f(X)] + \mathbb{E}_{Y \sim Q}[f^*(Y)]$$

and f can be parametrized as an *input convex neural network* (ICNN).

Wasserstein style transfer
Y. Mroueh (NeurIPS 2019)

To perform style transfer, from a style image I_s to a content image I_c , learn an encoder-decoder pair, $I \mapsto (F_j(I))_j \mapsto I$, where j is the position, in the image, of the features F , and a Monge map T between the empirical distributions $\sum \delta_{F_j(I_c)}$ and $\sum \delta_{F_j(I_s)}$.

That map is learned using a Gaussian approximation

$$W_2(\mu, \nu) \geq W_2(N(\mathbb{E} \mu, \text{Var} \mu), N(\mathbb{E} \nu, \text{Var} \nu)).$$

The Wasserstein distance and the Monge map for Gaussians are known in closed form.

To limit content loss, consider the McCann interpolates $(1-t)\text{Id} + tT$ instead. To interpolate between styles, use Wasserstein barycenters instead of linear interpolation.

***From entropy-regularized optimal transport
to Sinkhorn divergences***
A. Genevay (NeurIPS 2019)

There are three ways of computing “distances” between distributions:

- Csiszár ϕ -divergence, e.g., the Kullback-Leibler divergence;
- Maximum mean discrepancies,

$$\text{MMD}(\alpha, \beta) = \sup_{\|f\|_{\mathcal{H}} \leq 1} \left| \mathbb{E}_{x \sim \alpha}[f(X)] - \mathbb{E}_{y \sim \beta}[f(Y)] \right|$$

for some RKHS \mathcal{H} ;

- Optimal transport, which is slower to compute, but provides better gradients.

With an entropic regularization

$$H(\pi|\alpha \otimes \beta) = \int \log \frac{d\pi(x, y)}{d\alpha(x)d\beta(y)} d\pi(x, y),$$

the dual is an unconstrained optimization problem and the Sinkhorn algorithm solves it for discrete distributions. But this regularization assumes the data is observed with noise, and tries to remove it: you get

when you would prefer

The regularized Wasserstein distance is not a distance: $d_{W,\varepsilon}(\alpha, \alpha) \neq 0$. Instead, consider the *Sinkhorn divergence*,

$$\text{SD}_{\varepsilon}(\alpha, \beta) = d_{W,\varepsilon}(\alpha, \beta) - \frac{1}{2}d_{W,\varepsilon}(\alpha, \alpha) - \frac{1}{2}d_{W,\varepsilon}(\beta, \beta).$$

For $\varepsilon \rightarrow \infty$, it converges to a MMD.

***How does mini-batching
affect Curvature information
for second order deep learning optimization?***
D. Granziol et al. (NeurIPS 2019)

$\text{Spec}(A + \text{noise})$ is not an unbiased estimator of $\text{Spec} A$. In particular, the largest eigenvalue is perturbed upwards. Random matrix theory (RMT) can correct this bias.

Acceleration through spectral modeling
F. Pedregosa and S. Scieur (NeurIPS 2019)

Accelerated gradient methods only use the largest (and smallest) eigenvalue(s) of the Hessian, ignoring the rest of the spectrum: model the spectral distribution as a *Marcenko-Pastur* distribution (fitted using the largest eigenvalue and the trace) and use it to find the optimal first-order method. In special cases, this is equivalent to the *heavyball* method.

***The importance of better models
in stochastic optimization***
H. Asi and J Duchi (NeurIPS 2019)

SGD is very sensitive to step size and can diverge. **(Approximate) proximal optimization** (aProx) minimizes an approximation of the objective with a penalty to keep the new point close to the previous. Approximations include:

- The function itself (*i.e.*, no approximation, just a penalty);
- A linear approximation;
- A linear approximation floored at zero (it is often known that $f \geq 0$): this prevents divergence and can be implemented by replacing $x \leftarrow x - \alpha g$ with

$$x \leftarrow x = \text{Min}\left\{\alpha, \frac{f(x)}{\|g\|^2}\right\}g.$$

Beyond SGD: in search of a preconditioner
E. Hazan (NeurIPS 2019)

Preconditioning makes the loss surface more isotropic.

LiSSA (linear time second order stochastic optimization) writes the Hessian inverse as an infinite series (assuming the eigenvalues are below 1 in absolute value) and samples from it; to estimate the powers, use iid samples (one sample for each, *i.e.*, rank-1 matrices).

$$H^{-1} = \sum_{k \geq 0} (I - H)^k$$

$$H^{-1} \approx (I - H)^k p \cdot p_k^{-1}$$

$$(I - H)^k \approx \prod_{1 \leq i \leq k} (I - H_i)$$

For non-convex functions, use cubic regularization (FastCubic). For neural nets, there is no improvement on SGD.

Replace AdaGrad $x \leftarrow x - \text{diag}(\sum g_t g_t')^{-1/2} g$ (you can take the full matrix instead of the diagonal) with GGT , $x \leftarrow x - (G_t G_t')^{-1/2} g_t$, where $G_t = [g_t | \beta g_{t-1} | \beta^2 g_{t-2} | \dots]$. It can be efficiently implemented using $(GG')^{-1/2} x = G(G'G)^{-3/2} x$, since $G'G$ is smaller than GG' . Plot the eigenvalues of GG' against the epoch.

AdaGrad keeps two gradients, Adam three. To reduce memory usage, only keep a “low-rank approximation” of the gradients (first reshape them into matrices or tensors): *extreme tensoring*.

Symmetric and multi-secant quasi-Newton methods
D. Scieur et al. (NeurIPS 2019)

Quasi-Newton methods approximate the Hessian using the gradient and the secant equation $f''(x)^{-1}(f'y - f'x) \approx y - x$. Let Δx and ΔG be the matrices containing the first differences of successive estimates and gradients, and H be an estimator of $(f'')^{-1}$. The secant equation becomes $H\Delta G = \Delta X$. Quasi-Newton methods find a matrix H , close (for some norm), to some reference matrix H_0 , such that $H\Delta G = \Delta X$. For instance, LBFG uses $H_0 = H_k$, $N = 1$ seconds, $d(H, H_0) = \|H - H_0\|_{\nabla^2 f}$. For $N > 1$, the secant equation has no solution in general: use an approximation instead (it reduces to a Procrustes problem).

Stochastic Newton and cubic Newton methods with simple local linear quadratic rates
D. Koralev et al. (NeurIPS 2019)

Cubic regularization generalizes Newton’s method

$$\langle f'x_k, x - x_k \rangle + \frac{1}{2} \|x - x_k\|_{f''(x_k)}^2 + \frac{M}{6} \|x - x_k\|^3.$$

Subsampled methods estimate the gradient and the Hessian on different (independent) subsets; use a very large minibatch for the Hessian.

K-FAC: extensions, improvements and applications
J. Martens (NeurIPS 2019)

Second-order methods should be faster, but the curvature changes very quickly: the second-order approximation is only valid locally – use a *trust region*, either as a hard constraint or, equivalently, as an L^2 penalty.

One can replace the Hessian with GGN, Fisher information or (not recommended) empirical Fisher information.

The **generalized Gauss–Newton** method approximates the Hessian of

$$h(\theta) = \frac{1}{m} \sum_{i=0}^m L(y_i, f(x_i, \theta))$$

as $G = \frac{1}{m} \sum J_i' H_i J_i$ where $J_i = \nabla_{\theta} f$, $H_i = \nabla_{zz} L$. This is the Hessian of h with f replaced with its first-order approximation around θ . The square norm loss, $L(y, z) = \frac{1}{2} \|y - z\|^2$ gives $H = I$ and $G = \frac{1}{m} \sum J_i' J_i$ (Gauss–Newton). When z is the natural parameter of an exponential family, G is the Fisher information and $G^{-1} \nabla h$ the natural gradient. GGN works better than the Hessian in practice.

The Hessian is too large, but many approximations are available: diagonal (Adam), block-diagonal (TONGA), low-rank + diagonal (L-BFGS), Krylov (Newton-CG, HF).

The **Kronecker-factorized approximate curvature** (K-FAC) exploits the structure in layers of the neural net. For a single linear layer, $a \mapsto s = Wa$, and $L(y, f(x, \theta)) = -\log p(y|x, \theta)$, $\nabla_{\theta} L = ga'$, where $g = \nabla_s L$ and the Fisher information is $F = \text{Cov}(\text{vec } \nabla_w, \text{vec } \nabla_w) = \dots - E[aa'] \otimes E[gg'] = A \otimes G$. The Kronecker product allows efficient computations: $(B \otimes C)^{-1} = B^{-1} \otimes C^{-1}$, $(B \otimes C) \text{vec } X = \text{vec}(CXB')$.

Shared weights, in CNNs or RNNs, complicate things.

K-FAC works better than SGD for large batch sizes. TensorFlow implementation available.

HAWKV2: Hessian-aware trace-weighted quantization of neural networks
A. Gholami (NeurIPS 2019)

To choose how many bits to keep for each layer, use the trace of the Hessian, computed as

$$\text{tr } A = \mathbb{E}_{z \sim \text{Rademacher}} [z' A z].$$

Implementation: **PyHessian**.

New methods for regularization path optimization via differential optimization
P. Grigas and H. Liu (NeurIPS 2019)

The first order condition defining the regularization path, $\nabla_x F_\lambda(x(\lambda)) = 0$ leads to an ODE, which can be solved with the Euler scheme (or a better one); it involves the Hessian, but computations can be avoided using the conjugate gradient (CG).

Foundations of causal inference: challenges and opportunities of big data
N. Kiyavash (NeurIPS 2019)

Granger causality can be extended to point processes, using *directed information* as a loss function; the resulting *directed information graph* (DIG) is a Bayesian network; it can also, more easily, be estimated from a model of the point process, e.g., a *multivariate Hawkes process*. Applications include neural spike trains, twitter activity, econometric modeling of systemic risk, hyperlink creation between (one million) websites (showing clusters of merchant and review sites).

Insider threat detection via hierarchical neural temporal point processes
X. Wu (NeurIPS 2019)

Detect fraudulent sessions (from login time, email activity, web activity, device access, opening/copying/creating/deleting files) by combining RNNs (LSTM) and masked temporal point processes (MTPP), using encoder-decoders, predicting activity type and time (intra-session) and session time (inter-session).

Datasets: CERT insider threat, Wikipedia vandalism.

Temporal point processes: web, social media, and networking systems
N. Ganguly (NeurIPS 2019)

Hawkes-RNN models can be used to study:

- Temporal and information influence of social media users; latent opinion inference;
- Tweet-hashtag (reinforcement) and hashtag-hashtag interactions;
- Spikes in network traffic.

Temporal logic point processes
S. Li et al. (NeurIPS 2019)

Add prior knowledge (“event A happens before B”) to temporal point processes (TPP) using *temporal logic* soft constraints (with learned weights).

The graph Hawkes network for reasoning on temporal knowledge graphs
Z. Han et al. (NeurIPS 2019)

A *temporal knowledge graph* stores (S,V,O,timestamp) tuples. In a *neural Hawkes process*, the intensity of events of type k is $\lambda_k = f(w'_k h_t)$. However, there are

too many event types, and some are concurrent. Learn vector representations of entities and predicates; respond to queries of the form (S,V,?,t).

Data: political events, news.

Deep point process destructors
D. Inouye (NeurIPS 2019)

Destructive learning identifies patterns in the data, removes them in an invertible way, and starts again. For point processes, use time warping. A point process destructor is a time transformation that maps the point process studied to the unit process $\lambda \equiv 1$.

For deep point processes destructors, e.g. if $D = D_2 \circ D_1$,

$$\lambda(t) = \frac{dD}{dt} = \lambda_2(D_1(t))\lambda_1(t).$$

More generally, a *deep point process* replaces the mixture $\lambda_t = \sum_i \lambda_i(t)$ with $\lambda(t) = \prod_i \lambda_i(t^{(i-1)})$, $t^{(0)} = t$, $t^{(i)} = D_i(t^{(i-1)})$ (each D_i can be a weak model).

Bandits, estimation and hypothesis testing
S. Athey (NeurIPS 2019)

Bandits (aka *adaptive experiments* in statistics) are more data-efficient than traditional experiments. Bandits create unbalanced data (they are not iid); naively estimating the value of an arm is potentially biased and non-Gaussian. *Inverse propensity weighting* addresses those problems but increases variance; there are other weighting schemes.

Preserving causal constraints in counterfactual explanations for machine learning classifiers
(NeurIPS 2019)

Counterfactual explanations should be actionable (you cannot decrease your age or education level) and satisfy some constraints (you cannot be under 20 and have a PhD): use a structural causal model.

EconML: a machine learning library for estimating heterogeneous treatment effects
(NeurIPS 2019)

Includes: DeepIV, DoubleML, causal forests, etc.

Adaptive TRPO: convergence and faster rates for regularized MDPs
L. Shani et al. (NeurIPS 2019)

Mirror descent is the trust-region optimization algorithm

$$x_{k+1} \leftarrow \underset{x}{\operatorname{Argmin}} \langle \nabla f(x_k), x - x_k \rangle + \alpha_k B_\omega(x, x_k)$$

where the first term is a linear approximation of the objective and the second term is a *Bregman divergence*

$$B_\omega(x, y) = \omega(x) - \omega(y) - \langle \nabla \omega(y), x - y \rangle.$$

If ω is the Euclidean norm, B_ω is the Euclidean distance and mirror descent is projected gradient descent.

If ω is the negentropy, B_ω is the Kullback-Leibler divergence, and mirror descent is exponentiated gradient descent.

How metalearning could help us accomplish our grandest AI ambitions, and early, exotic steps in that direction (NeurIPS 2019)

Generative teaching networks (GTN) generate data to learn on. Backpropagate to train the generator, but use *weight normalization*. Use different model architectures.

In RNNs, do not only store information in the activations, but also in the weights, using *Hebbian learning*: “neurons that fire together wire together”.

$$w_{ij}^{t+1} = w_{ij}^t + \eta x_i^t x_j^t.$$

Train w and α (“differentiable plasticity”) with SGD:

$$y_i = \tanh \sum_j (w_{ij} + \alpha_{ij} H_{ij}^t) y_j$$

$$H_{ij}^{t+1} = \eta y_i y_j + (1 - \eta) H_{ij}^t.$$

In *modulated Hebbian learning*, the Hebbian trace H_{ij} is only updated if some neuron M fires:

$$H_{ij}^{t+1} = H_{ij}^t + M_t y_i^{t-1} y_j^t.$$

To prevent *catastrophic forgetting*, use a mask to select which part of the network to use for the current task.

One-ended algorithms (natural selection, human culture) generate their own problems and solve them. The “paired open-ended trailblazer” (POET) generates environments of varying difficulties (e.g., landscape, for a robot to navigate in); trains an agent on each of them in parallel; re-evaluate the agents on all models and copy them accordingly (this works better than linearly interpolating between easy and difficult environments – curriculum learning is hard, and a linear curriculum is rarely optimal).

Better model-based RL through meta-RL P. Abbeel (NeurIPS 2019)

Use *domain randomization*: simulated environments do not look like the real world, but they may be as different between them as they are different from the real world – instead of using just one simulated environment, use many, and measure the performance on unseen environments.

Overfitting plagues model-based RL much more than supervised learning: the agent would try to exploit regions of the state space where the model is imprecise but promising. Use domain randomization, e.g., with an ensemble of models.

Train asynchronously.

To speed up meta-RL: train separate RL agents for all the tasks, then train a global agent to match those local agents (imitation learning)

Abstraction and meta-RL D. Abel (NeurIPS 2019)

State abstraction tries to make reinforcement learning easier by replacing the state space with a smaller, discrete set, with no drop in the quality of the solution learned.

Action abstraction replaces the action space with a larger one, by adding *options*, i.e., long-term actions (defined by a start condition, an end condition, and a policy). Finding options that minimize planning time is NP-hard, and hard to approximate (at least in the worst case).

Scalable metalearning R. Hadsell (NeurIPS 2019)

WarpGrad learns to precondition the gradient – it learns the geometry of the space while optimizing the model.

Vanilla transformers do not work well in RL: add (GRU-like) gating.

Metalearning with warped gradient descent S. Flennerhag (NeurIPS 2019)

Learn how to warp the loss surface into something nice; this is equivalent to learning a gradient preconditioner.

Fairness assessment for AI in the finance industry (NeurIPS 2019)

AIF360 is a Python library for fairness measures and mitigation algorithms.

Forecasting firm material event sequences from SEC 8k reports (NeurIPS 2019)

Seq2seq transformer model to map past events to future events; the attention maps provide explanations.

Explainable small business credit scoring
(NeurIPS 2019)

Accounting software companies have access to detailed accounting data and can use it to decide whether to grant a loan (xgboost, monotonicity constraints, Shapley values).

***Adversarial learning of “deep fakes”
in accounting***
(NeurIPS 2019)

Adversarial autoencoders impose a structure on the latent representation, e.g., a mixture of clearly separated Gaussians, to disentangle.

Auditors use ERP data: a fraudulent company could use an adversarial attack to hide anomalous transactions.

Imperceptible attacks on tabular data
(NeurIPS 2019)

Tabular data is also susceptible to adversarial attacks. Since not all features are equally important (you can lie more about your number of pets than about your salary), define a notion of “perceptability” and minimize it to mount your attack (LowProFool, DeepFool, FGSM).

Understanding equilibria in multiagent systems
M. Woolridge (NeurIPS 2019)

While Siri does not (yet) talk to Siri, *multiagent systems* are already there, e.g., with algorithmic trading – but those systems are unstable and can lead to flash crashes.

1. To understand this instability, consider it as a bug, and use *model checking*: build the state transition graph of the system and use *temporal logic* (LTL, an extension of propositional logic with temporal operators)

$\Diamond\phi$	eventually
$\Box\phi$	always
$\phi\mathcal{U}\psi$	until
$\Box\Diamond\phi$	infinitely often
$\Diamond\Box\phi$	always after some point

to formulate and check the desired properties of the system, in particular reachability $\Diamond\phi$ and invariance $\Box\phi$.

2. This is too restrictive: an undesirable state could be reachable only through a sequence of irrational decisions. Use the *Reactive Modules* language to describe the agents and their goals, and check reachability under Nash equilibrium.

3. This approach only works on small systems: for large systems, use *agent-based models*, calibrated on real data, and simulations.

The flash crash prevention measures (stop trading if the prices drop too much) seem ineffective and even

counterproductive: if investors need to sell ad cannot, they will find something else to sell – the flash crash is contagious.

Putting ethical AI to the vote
A. Procaccia (NeurIPS 2019)

When there are several stakeholders for a given problem (e.g., food donations allocation), if the problem is recurring, build a model for each stakeholder and aggregate their preferences (*social choice*). Since the output of the model is noisy, the aggregation mechanism, should be robust to noise: Borda count is robust, pairwise-majority consistent (PMC) methods are not. [This is currently used as a decision-support tool; it is more efficient than humans in terms of diversity and cost.]

Other applications of this *virtual democracy* (the models vote, or the humans) include ethical decisions for self-driving cars (aggregating the ethical choices of one million Americans in a fraction of a second), or ESG investment (when several people, e.g., a family, want to invest together, but do not have the same views on ESG).

***Gaussian process behaviour
in wide deep neural networks***
A.G.G. Matthews (NeurIPS 2019)

As the width of a 1-layer neural net tends to infinity, it converges to a Gaussian process (natural tangent kernel). This is still the case for k -layer neural nets, if deeper layers grow faster.

The natural tangent kernel
T.G.J. Rudner et al. (NeurIPS 2019)

In continuous time, gradient descent is just an ODE, $\dot{\theta} = -\eta\nabla_{\theta}\mathcal{L}(\theta)$; it also gives us the dynamics of the output of the neural net during gradient descent: a diffusion, for the *neural tangent kernel*

$$\Theta(x, y) = \nabla_{\theta}f(\theta)\nabla_{\theta}f(\theta)'.$$

For natural gradient descent, this becomes

$$\Theta^{\text{nat}}(x, y) = \nabla_{\theta}f(\theta)F(\theta)^{-1}\nabla_{\theta}f(\theta)',$$

where $F(\theta)$ is the Fisher information matrix. Linearize those dynamics and solve the resulting ODE, instead of SGD to train the network.

Deep ensembles: a loss landscape perspective
S. Fort et al. (NeurIPS 2019)

Ensembles work better than Bayesian neural nets: ensemble can cover several modes; Bayesian approaches struggle to (since the modes are connected, they should be able to).

Average the weights around each mode, and the predictions across modes.

MIM Mutual information machine
M. Livne et al. (NeurIPS 2019)

Replace the VAE loss

$$\ell(\theta) = \text{KL}(q_\theta(z|x)p(x) || p_\theta(x|z)p(z))$$

where x is the observed variable and z the latent representation, with the more symmetric Jensen-Shannon divergence, and add a regularizer

$$H(q_\theta(z|x)p(x)) + H(p_\theta(x|z)p(z))$$

(entropy of the two joint distributions on (x, z)) to help maximize the mutual information between x and z

$$H(x, z) = H(x) + H(z) - I(x; z).$$

Pitfalls of in-domain uncertainty estimation and ensembling in deep learning
(NeurIPS 2019)

Metrics used for uncertainty estimation (log-likelihood, Brier score, calibration error, AUC) have pitfalls, but can be fixed.

Neural tangents: fast and easy infinite neural networks in Python
R. Novak et al. (NeurIPS 2019)

Infinite-width neural nets (Gaussian processes) in JAX/stax.

Using loss surface geometry for practical Bayesian deep learning
A.G. Wilson (NeurIPS 2019)

<http://losslandscape.com/>

A simple baseline for Bayesian uncertainty in deep learning
W. Maddox et al. (NeurIPS 2019)

SWAG fits SGD iterates with a low-rank + diagonal Gaussian distribution.

Can you trust your model's uncertainty?
J. Snoek et al. (NeurIPS 2019)

Measures of uncertainty include the expected calibration error (ECE), which can be gamed, and *proper scoring rules* such as the negative log-likelihood, which emphasizes tails too much, or the Brier score.

Methods include:

- Post hoc calibration, with temperature scaling;
- Ensembling;
- Monte Carlo dropout;
- Stochastic variational inference;
- Bayesian only in the last layer.

Under distribution shift, post hoc calibration is the worst, ensembling (with small ensembles: 5) is the best.

Dropout as a Bayesian approximation: representing model uncertainty in deep learning
Y. Gal and Z. Gharhamani (2015)

Dropout performs approximate Bayesian inference.

High-dimensional Bayesian optimization using low-dimensional feature spaces
R. Moriconi et al. (NeurIPS 2019)

Bayesian optimization in high dimension ($d \geq 20$) can use a random projection, an additive decomposition of the objective function, or a nonlinear embedding, learned with a VAE, progressively, during optimization.

Function space prior in Bayesian deep learning
R. Grosse (NeurIPS 2019)

The *automatic statistician* searches for compositional GP kernels describing the data (and can output an English text describing the model): having a better prior makes it better at extrapolation.

The *neural kernel network* (NKN) is a neural network computing $(x, y) \mapsto k(x, y)$; each layer combines primitive kernels (or kernels from previous layers), using additions and multiplications (good for extrapolation and exploration).

Functional variational BNNs specify a prior on the stochastic process, not on the weights; variational inference can be done on function (not weight) space. [GPs are currently still preferable.]

Try depth instead of weight correlation
S. Farquhar et al. (NeurIPS 2019)

The widespread belief that the approximate posterior for Bayesian neural nets needs correlations between weights only holds for shallow networks. Even for linear networks, $n \geq 3$ layers gives a full correlation matrix for the outputs.

Deep generative models for genetic variation and drug design
D. Marks (NeurIPS 2019)

The alignment and evolution of biological sequences (mutation, insertion, deletion) can be modeled with Bayesian VAEs or Bayesian seq2seq models, and be used to sample from possible future flu viruses to make vaccines.

**Measure-valued derivatives
for approximate Bayesian inference**
M. Rosca et al. (NeurIPS 2019)

Besides the REINFORCE (score function) and reparametrization estimators of the gradient of an expectation

$$\begin{aligned}\frac{d}{d\theta} \mathbb{E}_{x \sim p_\theta} f(x) &= \frac{d}{d\theta} \int f(x) p_\theta(x) dx \\ &= \int f(x) \frac{dp_\theta}{d\theta} dx \\ &= \int f(x) \frac{dp_\theta}{d\theta} \frac{p_\theta(x)}{p_\theta(x)} dx \\ &= \int f(x) \frac{d \log p_\theta}{d\theta} p_\theta(x) dx \\ &= \mathbb{E}_{x \sim p_\theta} [f(x) \nabla_\theta \log p_\theta(x)] \\ \frac{d}{d\theta} \mathbb{E}_{x \sim p_\theta} f(x) &= \frac{d}{d\theta} \mathbb{E}_{x \sim p} f(g_\theta(x)) \\ &\text{if } z \sim p \implies g_\theta(z) \sim p_\theta\end{aligned}$$

the *measure-valued derivative* is less known

$$\begin{aligned}\frac{d}{d\theta} \mathbb{E}_{x \sim p_\theta} f(x) &= \int f(x) \frac{dp_\theta}{d\theta} dx \\ &= c_\theta \left(\mathbb{E}_{x \sim p_\theta^+} f(x) - \mathbb{E}_{x \sim p_\theta^-} f(x) \right)\end{aligned}$$

[when sampling from p_θ^+ and p_θ^- , use the same random numbers, to lower variance] where $dp_\theta/d\theta = c_\theta(p_\theta^+ - p_\theta^-)$ is the decomposition of the signed measure $dp_\theta/d\theta$ into difference of probability measures, up to a multiplicative factor (e.g., *Hahn-Jordan decomposition*) [the authors provide a table of such decompositions]. For instance, for the Gaussian distribution,

$$\frac{d}{d\mu} \phi_{\mu,1}(x) = \frac{1}{\sqrt{2\pi}} (W_{2,.5}(x - \mu) - W_{2,.5}(\mu - x))$$

where W is the Weibul distribution.

This requires no strong assumptions (it works with discrete distributions and discontinuous f), has low variance, but requires $2|\theta|$ evaluations of f (in terms of clock time, the score function with baseline is faster for $|\theta| \geq 100$).

**Monte Carlo gradient estimation
in machine learning**
S. Mohamed et al. (2019)

Survey article: why we need the gradient

$$\nabla_\theta \mathbb{E}_{x \sim p_\theta} [f_\theta(X)]$$

and three ways of computing it: score function (REINFORCE), reparametrization (“pathwise”) and measure-valued.

**Information in the weights and emergent
properties of deep neural networks**
S. Soatto and A. Achille (NeurIPS 2019)

Supervised learning looks for a representation z , as small as possible, *i.e.*, minimizing $I(x; z)$, containing as much information on the task as the input, *i.e.*, $I(z; y) = I(x; y)$. The Lagrangian of the constrained optimization problem is

$$\mathcal{L}(p(z|x)) = \underbrace{H(y|z)}_{\text{crossentropy}} + \beta \cdot \underbrace{I(z; x)}_{\text{regularizer}}.$$

Troublingly, setting z to the index of the image in the training set is close to optimal (16 bits on CIFAR): the Lagrangian should be minimized, not on the training data, but on the data we do not have yet.

Information is also stored in the weights. However, since the weights are real, the information is infinite, and most if it is irrelevant: the relevant information can be measured by how much noise can be added to the weights without changing the result (or the drop in accuracy as a function of noise). More precisely,

$$\begin{aligned}\text{Minimize} & \quad \text{KL}(q(w|\text{data})||p(w)) \\ \text{Such that} & \quad \mathbb{E}_{w \sim q(w|\text{data})} [\mathcal{L}_{\text{data}}(w)] \leq t\end{aligned}$$

with Lagrangian

$$\mathcal{L} = \underbrace{\mathbb{E}_{w \sim q(w|\text{data})} [\mathcal{L}_{\text{data}}(w)]}_{\text{expected loss}} + \beta \cdot \underbrace{\text{KL}(q(w|\text{data})||p(w))}_{\text{information in the weights}}$$

SGD minimizes the Fisher information of the weights. The distance between two tasks (for transfer learning) can be defined as

$$d(\mathcal{D}_1 \rightarrow \mathcal{D}_2) = \underbrace{I(\mathcal{D}_1 \mathcal{D}_2; w)}_{\text{complexity of learning together}} - \underbrace{I(\mathcal{D}_1; w)}_{\text{complexity of learning one}}$$

Alternatively, one can represent a task with the diagonal of its Fisher information matrix (task2vec),

$$d(\mathcal{D}_1, \mathcal{D}_2) = \cos(F_1, F_2).$$

**Understanding
thermodynamic variational inference**
R. Brekelmans et al. (NeurIPS 2019)

The *thermodynamic variational objective* gives a tighter alternative to the ELBO.

**GAIT:
a geometric approach to information theory**
J. Gallego et al. (NeurIPS 2019)

Shannon entropy considers that all symbols are different in the same way. Information theory can be extended to account for the geometry of the space – like the Wasserstein distance, but in closed form. Consider a *similarity space* (\mathcal{X}, κ) ,

$$\begin{aligned} \forall x, y \quad 0 &\leq \kappa(x, y) \leq 1 \\ \forall x \quad \kappa(x, x) &= 1 \end{aligned}$$

and a probability distribution P on \mathcal{X} .

$$\begin{aligned} KP(x) &= \mathbb{E}_{y \sim p} [\kappa(x, y)] && \text{ordinariness of } x \\ 1/KP(x) &&& \text{rarity of } x \\ H_1^k[p] &= \mathbb{E}_{x \sim p} [-\log KP(x)]. \end{aligned}$$

It is conjectured that H_1^k is concave (under reasonable conditions): we can use $-H_1^k$ to define a similarity-sensitive Bregman divergence.

$$D^k(P\|Q) = 1 + \mathbb{E}_{x \sim P} \left[\log \frac{KP(x)}{KQ(x)} \right] - \mathbb{E}_{x \sim Q} \left[\log \frac{KP(x)}{KQ(x)} \right]$$

Contrastive predictive coding
A. van den Oord (NeurIPS 2019)

Contrastive predictive coding (InfoNCE, noise contrasting encoding) learns to distinguish pairs with the same label, e.g., $(\text{dog}_1, \text{dog}_2)$ from pairs with different labels, e.g., $(\text{dog}_1, \text{cat}_2)$. Labels are not strictly necessary to learn a useful representation: just assume that nearby patches (of the sound signal, etc.) are from the same class (phoneme, speaker, etc.) while other matches from the dataset are unrelated.

**Perception as generative reasoning:
structure, causality probability**
(NeurIPS 2019)

$$\begin{aligned} \text{Discriminative model} & \quad p(\text{label}|\text{image}) \\ \text{Generative model} & \quad p(\text{image}|\text{label}) \times p(\text{label}) \end{aligned}$$

In the generative model, the first factor can include physics engines and renderers, the second can add structure, e.g., $p(\text{label}) = p(\text{label}|z)p(z)$.

**Perception and action
from generative models of physics**
K. Smith (NeurIPS 2019)

Perception is inverse optics informed by dynamics.

It can be used to keep track of 3D objects under occlusion.

CvxNet: learnable convex decomposition
B. Deng et al. (NeurIPS 2019)

Vision is inverse graphics: a complex shape can be described using simple primitives, e.g., boxes, ellipsoids or, more generally, convex shapes, defined implicitly as intersections of half-spaces

$$\Phi(x) = \text{LogSumExp}(\delta(Nx + d)) \quad (\text{softmax}).$$

A (union) of convex shapes can be learnt with a (multi-headed) auto-encoder.

To convert the implicit representation into an explicit one (extreme points), compute the convex hull in the dual (cf. F-Rep, *function representation*)

Variational graph convolutional networks E.V. Borilla (NeurIPS 2019)

Graph convolutional networks (GCN) are not robust to noise in the graph structure:

- Add a prior on the graph structure;
- Use a *low rank* parametrixation of the variational posterior

$$q(A) = \prod_{ij} q(A_{ij})$$

$$q_{ij} = \text{Bernoulli}(A_{ij}, \rho_{ij})$$

ρ : low rank

- Relax the discrete Bernoulli distribution into a “binary concrete” distribution.

Representation and generation of molecular graphs W. Jin (NeurIPS 2019)

(Permutation-invariant) graph neural nets (GNN) are not expressive enough: they cannot predict girth, circumference, diameter, total number of cycles, etc. In practice, we add cycle-related features, e.g., whether an atom is in an aromatic ring.

View molecules at multiple levels, using a dictionary of structures,

which define a coarser graph, and use message passing, e.g., to forecast molecule properties (data from the ZINC database).

For *de novo molecule optimization*, modify an existing molecule into a new one, usable as a drug, using an encoder-decoder network, and incrementally construct the hierarchical graph of the output. Use the EM algorithm to satisfy the specifications: the E step generates candidates and reweights them, the M step maximizes the weighted log probability.

Proposal for an open graph benchmark J. Leskovec (NeurIPS 2019)

PyTorch code available (dgl, pytorch_geometric): <http://ogb.stanford.edu/>.

Graph representation learning for optimization on graphs B. Dilkina (NeurIPS 2019)

1. Machine learning components can be used inside optimization algorithms, in particular when we have to

repeatedly solve the same problem with new data. For instance, one can use reinforcement learning to learn the scoring function (Q -value function) of a greedy algorithm to solve combinatorial optimization problems on graphs such as minimal cover (the degree is often used as a score, but one can do better), maximum cut or TSP, from the features of the graph – the graph representation (features) is learnt by structure2vec.

2. Two-stage processes are often suboptimal:

A pure end-to-end approach is possible, but combinatorial optimization complicates things. A simpler approach is to find a related problem, easier to solve, and learn a mapping from the original problem to the simpler one.

(For the backward pass, only unroll one of the k -means iterations.)

Deep graph library Z. Zhang (NeurIPS 2019)

PyTorch library for (message-passing) neural nets. Also check `pytorch_geometric`.

Graph networks for learning physics P. Battaglia (NeurIPS 2019)

Graph networks are a formalism for graph neural networks based on *learned message passing*.

$$v_i, v_j : \text{node features}$$

$$e_{ij} : \text{edge features}$$

$$\phi : \text{neural networks}$$

$$e'_{ij} = \phi(e_{ij}, v_i, v_j) \quad \text{edge function}$$

$$e_i = \sum_j e_{ji} \quad \text{aggregation}$$

$$v'_i = \phi(e_i, v_i) \quad \text{node function}$$

They can learn physical systems from observations, e.g., n -body problems, balls bouncing in a box, springs; the learned model generalizes to larger systems.

Once they have learned the physical laws, one can replace the Euler integrator (computing the state of the system at the next time) with a better one.

Code: `graph_net`; also check `dgl`, `pytorch_geometric`.

Learning DAGs and trees with box embeddings and hyperbolic embeddings

A. McCallum (NeurIPS 2019)

Knowledge can be represented as raw (indexed) text, a trained deep learning model (BERT – type 1 reasoning) or a knowledge base (KB – type 2 reasoning).

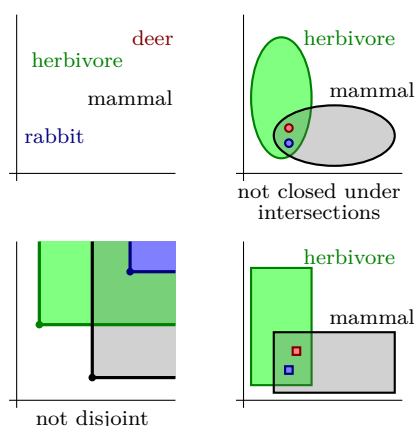

From text, extract entities and relations; put them in an entity pair \times relation matrix, and use classical matrix completion, or “multi-hop reasoning” to infer the missing relations.

Instead of using actual entity pairs and relations as rows and columns, use a latent representation: it will accommodate entities and relations not seen during training.

Add types to those entities, with a hierarchical structure (e.g., president \Rightarrow human), learned with a *bilinear model* ($c_1^T A c_2 > 0$ iff $1 \Rightarrow 2$, i.e., 1 is_a 2, i.e., $1 \subset 2$).

To add probabilities to those hierarchical relations (e.g., $P[\text{president} \Rightarrow \text{writer}] = .8$), do not represent concepts as points in a vector embedding, but as Gaussian densities, cones or boxes.

Those boxes can be transformed with a neural net once you define addition and multiplication of boxes.

To learn those hierarchies from scratch, embed concepts in *Poincaré space*: this gives a continuous representation of trees.

Representation learning and fairness

S. Koyejo (NeurIPS 2019)

Fairness can be ensured by

- Pre-processing: representation learning, feature adjustment, metric learning;
- In-processing: learning with fairness penalties;
- Post-processing: adjustments.

For the preprocessing approach, clearly separate the roles:

- The *data regulator* defines the fairness criteria and audits the sanitized data and the final model;
- The *data producer* turns the raw data into a fair representation;
- The *data user* uses the sanitized data to fit a model.

There are many, often incompatible, fairness criteria. *Individual fairness* requires that “similar” individuals be treated “similarly” – this requires a metric. *Group fairness* asks that some statistics be equalized across predefined groups, e.g., *statistical parity* (TP+FP), *equalized odds* (TP, FP), *equality of opportunity* (TP). To choose the statistics to equalize, present the end user with several confusion matrices and ask her which ones she prefers (metric elicitation). Group fairness does not imply individual fairness; fairness for attributes A and B does not imply joint fairness for (A, B) .

For individual fairness, the regulator can provide sets of examples which should be treated in the same way, and the data producer trains a model using

$$x_1 \sim x_2, x_1 \not\sim x_3 \implies \|x_1 - x_2\| \leq \|x_1 - x_3\|.$$

For group fairness one can replace the observations with prototypes ensuring statistical parity.

Disentanglement trains a VAE which separates the sensitive attributes from the non-sensitive ones.

There is a trade-off between accuracy and fairness.

Pay attention to inappropriate data, e.g., feedback effects.

Synthetic control

A. Abadie et al. (NeurIPS 2019)

To estimate the effects of an intervention from *observational* data, in particular when the intervention is applied to large units (cities, countries) – this is sometimes needed because of fairness considerations or possible interactions – match each treated unit, not with a single control, but with a weighted average of controls. The synthetic control is computed by constrained optimization, matching the features of the unit and the pre-intervention values.

It may be useful to denoise the time series first, e.g., with a low-rank approximation, minimizing $\|\hat{Y} - Y\|_{2,\infty}^2$ rather than $\|\hat{Y} - Y\|_F^2$. This can be generalized to multiple interventions (“what if unit i had received intervention j instead of i ?”), with a low-rank tensor decomposition.

Examples include: German GDP after reunification, smoking regulations in California, UK GDP after Brexit, cricket results if it had not rained.

**Machine learning
for computational biology and health**
A. Goldenberg and B. Engelhardt (2019)

**Imitation learning
and natural language generation**
K. Cho and H. Daumé (NeurIPS 2019)

One can generate text in a non-monotonic order.

Deep learning with Bayesian principles
M.E. Khan (NeurIPS 2019)

Deep learning scales well with data and model complexity; Bayesian learning estimates uncertainty and can be incrementally updated. Bayesian updates are global; deep learning updates are local.

Consider an exponential family,

$$q(\theta) = \exp[\lambda' T(\theta)] \quad \mu = E[T(\theta)]$$

where λ are the natural parameters, T the sufficient statistic, and μ the expectation parameters. Deep learning

$$\text{Minimize}_{\theta} \ell(\theta)$$

$$\theta \leftarrow \theta - \rho H_{\theta}^{-1} \nabla_{\theta} \ell(\theta)$$

and Bayesian learning are eerily similar.

$$\text{Minimize}_q E_{\theta \sim q} [\ell(\theta)] - H(q)$$

$$\lambda \leftarrow \lambda - \rho \nabla_{\mu} \left(E_{\theta \sim q} [\ell(\theta)] - H(q) \right)$$

For instance, Bayesian learning with $q(\theta) = N(m, 1)$ and a “global-to-local” approximation $E[\ell(\theta)] \approx \ell(\theta)$, gives gradient descent; $q(\theta) = N(m, S^{-1})$ gives Newton’s method.

**Interpretable comparison
of distributions and models**
A. Gretton et al. (NeurIPS 2019)

1. Integral probability metrics (IPM) compare measures p, q by looking at their difference

$$\text{IPM}(p, q) = \sup_{g \in H} \left| E_{x \sim p} g(x) - E_{y \sim q} g(y) \right|$$

while ϕ -divergences look at their ratio

$$D(p, q) = \int q(x) \phi \left(\frac{p(x)}{q(x)} \right) dx.$$

If H is the unit ball in a RKHS, the IPM is a maximum mean discrepancy (MMD)

$$\begin{aligned} f(x) &= \langle f, \phi(x) \rangle = \sum f_k \phi_k(x) \\ E_{x \sim p} [f(x)] &= \left\langle f, E_{x \sim p} [\phi(x)] \right\rangle = \langle f, \mu_p \rangle \\ \text{MMD}(p, q) &= \sup_{\|f\| \leq 1} E_{x \sim p} f(x) - E_{x \sim q} f(x) \\ &= \sup_{\|f\| \leq 1} \langle f, \mu_p - \mu_q \rangle \\ &= \|\mu_p - \mu_q\| \end{aligned}$$

2. To test if two datasets (e.g., CIFAR-10 and CIFAR-10.1) come from the same distribution, compute their MMD.

$$\begin{aligned} \text{MMD}(p, q) &= \|\mu_p - \mu_q\|^2 \\ &= \langle \mu_p, \mu_p \rangle - 2\langle \mu_p, \mu_q \rangle + \langle \mu_q, \mu_q \rangle \\ &= E[\langle \phi X, \phi X' \rangle - 2\langle \phi X, \phi Y \rangle + \langle \phi Y, \phi Y' \rangle] \\ &= E[k(X, X') - 2k(X, Y) + k(Y, Y')]. \end{aligned}$$

When $p \neq q$, the distribution of $\widehat{\text{MMD}}(p, q)$ is asymptotically Gaussian, but when $p = q$, it depends on the kernel and the distribution of the data. Use *permutation testing* to select the test threshold; for the kernel, use a relevant representation $\varphi : \mathcal{X} \rightarrow \mathbf{R}^d$, e.g., a late hidden layer of a pretrained related classifier,

$$k(x, y) = k_{\text{top}}(\varphi(x), \varphi(y));$$

train the kernel to maximize the power $\text{MMD}^2(p, q) / \sigma_{H_1}(p, q)$.

A classifier to predict if a sample comes from p or q is a special case.

$$\begin{aligned} k(x, y) &= \frac{1}{4} \mathbf{1}_{f(x) > 0} \mathbf{1}_{f(y) > 0} \\ f : \mathcal{X} &\rightarrow \{\pm 1\} \text{ classifier} \\ \text{MMD}(p, q) &= |\text{accuracy} - \frac{1}{2}| \end{aligned}$$

3. The *witness function* (difference between kernel density estimates of the two distributions) defines the *un-normalized mean embedding*

$$\begin{aligned}\mu_p(v) &= E_{x \sim q}[k(x, v)] \\ \mu_q(v) &= E_{y \sim q}[k(y, v)] \\ \text{witness}(v) &= \mu_q(v) - \mu_p(v) \\ \text{UME}(p, q)^2 &= \frac{1}{J} \sum (\mu_q(v_j) - \mu_p(v_j))^2.\end{aligned}$$

Choose the v_j 's to maximize the (normalized) mean embedding.

4. The *Stein operator*

$$\begin{aligned}[T_p f](x) &= \frac{1}{p(x)} \frac{d}{dx} [f(x)p(x)] \\ E_p[T_p f] &= 0\end{aligned}$$

defines the *kernel Stein discrepancy*

$$\begin{aligned}\text{KSD}_p(q) &= \sup_{\|f\| \leq 1} \left| E_q[T_p f] - E_p[T_p f] \right| \\ &= \sup_{\|f\| \leq 1} E_q[T_p f],\end{aligned}$$

which can be computed as the norm of the *Stein witness function*

$$g(v) = E_{x \sim q} \left[\frac{1}{p(x)} \frac{d}{dx} [k(x, v)p(x)] \right]$$

which gives a goodness-of-fit test between a model p , known up to a normalization factor, and samples from a distribution q .

$$\begin{aligned}\text{KSD}_p^2(q) &= \|g\|^2 = E_{q \sim q} E_{y' \sim q} h_p(y, y') \\ h_p(x, y) &= s_p(x)' s_p(y) k(x, y) \\ &\quad + s_p(x)' \nabla_y k(x, y) + s_p(y)' \nabla_x k(x, y) \\ &\quad + \text{tr} \nabla_{xy} k(x, y) \\ s_p(x) &= \nabla_x \log p(x) \text{ score function}\end{aligned}$$

To select the test threshold, use the *wild bootstrap*

$$\frac{1}{n^2} \sum_{ij} w_i w_j h_p(y_i, y_j)$$

where $w_i = \pm 1$ is Bernoulli($\frac{1}{2}$).

5. The *finite set Stein discrepancy* test evaluates the Stein witness function at several points.

$$\text{FSSD}^2 = \frac{1}{d} \frac{1}{J} \sum \|g(v_j)\|^2$$

Geometric algebra E. Chisolm (2012)

Vector algebra, *i.e.*, vector manipulations in \mathbf{R}^3 , with scalar and cross products, looks unsatisfactory: it seems limited to dimension 3 (what about space-time?) and some operations look unnatural (the cross-product

needs a “handedness” convention and is not associative). Geometric algebra (Clifford algebras) can replace and generalize it.

A **geometric algebra** is a graded k -vector space $G = G_0 \oplus G_1 \oplus \dots$ with a (non-graded, non-commutative) k -algebra structure satisfying properties (i) to (iv) below. A **scalar** is an element of G_0 . A **vector** is an element of G_1 . An **r -blade** is a product of r anti-commuting vectors. An **r -vector** is a sum of r -blades. An **r -versor** is a product of r vectors. A **rotor** is a product of two invertible vectors.

- (i) $G_0 = k$.
- (ii) The square of every vector is a scalar.
- (iii) The symmetrized product of two vectors $(u, v) \mapsto \frac{1}{2}(uv + vu) = \frac{1}{2}((u+v)^2 - u^2 - v^2)$ is a non-degenerate bilinear form.
- (iv) $G_r = \text{span}\{r\text{-blades}\}$, *i.e.*, the r -vectors are the homogeneous elements of degree r .

Let $\langle \cdot \rangle_r : G \rightarrow G_r$ denote the projection. The product of $A_r \in G_r$ and $B_s \in G_s$ is a sum of terms of degrees $|r-s|, |r-s|+2, \dots, r+s$. One can define inner and outer products as the first and last terms:

$$\begin{aligned}A_r \lrcorner B_s &= \langle A_r B_s \rangle_{s-r} \\ A_r \llcorner B_s &= \langle A_r B_s \rangle_{r-s} \\ A_r \wedge B_s &= \langle A_r B_s \rangle_{r+s}\end{aligned}$$

Those operations have a simpler form for vectors, or vectors and versors.

$$\begin{aligned}a \lrcorner b &= b \llcorner a = \frac{1}{2}(ab + ba) \\ a_1 \wedge \dots \wedge a_r &= \frac{1}{r!} \sum_{\sigma} \text{sign}(\sigma) a_{\sigma(1)} \dots a_{\sigma(r)} \\ a A_r &= \langle a A_r \rangle_{r-1} + \langle a A_r \rangle_{r+1} = a \lrcorner A_r + a \wedge A_r \\ a \lrcorner A_r &= \frac{1}{2}(a A_r - (-1)^r A_r a) \\ a \wedge A_r &= \frac{1}{2}(a A_r + (-1)^r A_r a) \\ A_r \llcorner a &= (-1)^{r-1} a \lrcorner A_r \\ A_r \wedge a &= (-1)^r a \wedge A_r\end{aligned}$$

Those operations have geometric interpretations:

- $a_1 \wedge \dots \wedge a_r \neq 0$ iff a_1, \dots, a_r are linearly independent;
- $a \in \text{Span}\{a_1, \dots, a_r\}$ iff $a \wedge a_1 \wedge \dots \wedge a_r = 0$;
- $a \perp \text{Span}\{a_1, \dots, a_r\}$ iff $a \lrcorner (a_1 \wedge \dots \wedge a_r) = 0$;
- $\text{Span}\{a_1, \dots, a_r\} = \text{Span}\{b_1, \dots, b_r\}$ iff $\exists \lambda \ a_1 \wedge \dots \wedge a_r = \lambda b_1 \wedge \dots \wedge b_r$;
- $\text{Span}\{a_1, \dots, a_r\} \subset \text{Span}\{b_1, \dots, b_r\}$ iff $\exists c \ c \wedge a_1 \wedge \dots \wedge a_r = b_1 \wedge \dots \wedge b_r$.

Blades correspond to subspaces:

- $A \lrcorner B = 0$ iff $\exists a \in A \ a \neq 0, \ a \perp B$;
- $A \lrcorner B$ is the orthogonal complement of A in B ;
- $A^2 \in k$;
- $A^{-1} = A/A^2$;
- $A \subset B$ iff $AB = A \lrcorner B$;
- $A \perp B$ iff $AB = A \wedge B$.

One can define many more operations (I is the volume element).

Grade involution	$a^* = -a$ $A_r^* = (-1)^r A_r$
Reversion	$a^\dagger = a$ $(AB)^\dagger = BA$
Clifford conjugation	$A^\ddagger = A^*\dagger$
Scalar product	$A * B = \langle A^\dagger B \rangle$
Norm	$\ A\ ^2 = A * A$ (can be negative)
Dual	$A^\perp = A \lrcorner I^{-1} = AI^{-1}$
Commutator	$A \times B = \frac{1}{2}(AB - BA)$

Geometric algebra for computer science L. Dorst et al. (2009)

Geometric algebra represents geometric objects (points, lines, planes, circles spheres) and their transformations (translations, rotations, symmetries, Euclidean transformations, and even conformal transformations) as elements of a single set endowed with a dizzying array of products corresponding to geometric operation. There are three flavours, based on \mathbf{R}^3 , for linear geometry, on \mathbf{R}^4 , for affine geometry, on $\mathbf{R}^{4,1}$, for conformal geometry.

The book refuses to give clear, concise definitions of the operations and sets it uses and only provides verbose lists of special cases from which you are expected to get the general picture.

The **geometric product** is defined on $\bigwedge \mathbf{R}^n$ by

$$\begin{aligned} x^2 &= G(x, x) && \text{if } x \text{ is a vector} \\ \alpha\beta &&& \text{if } \alpha, \beta \text{ are scalars} \\ \alpha x &&& \text{if } \alpha \text{ is a scalar and } x \text{ a vector} \end{aligned}$$

and extended by distributivity, linearity and associativity (it is not commutative). For vectors, one can recover the scalar and external products as the symmetric and anti-symmetric parts of the geometric product,

$$xy = x \cdot y + x \wedge y.$$

Contrary to the outer product, the geometric product produces elements of mixed grade.

A **k -vector** is an element of $\bigwedge^k \mathbf{R}^n$. A **k -blade** is an outer product of k vectors (a k -vector is a linear combination of k -blades). A **versor** is a product of invertible vectors. A **rotor** is the product of an even number of unit vectors (*i.e.*, reflexions); in $\mathbf{R}^{n,0}$ and $\mathbf{R}^{n,1}$, it is the exponential of a bivector. Reflexions are $x \mapsto \hat{a}x\hat{a}^{-1}$; rotations are $x \mapsto RxR^{-1}$, where R is a rotor, e.g., $R = b/a$.

For *affine geometry*, let e_0, e_1, \dots, e_n be a basis of \mathbf{R}^{n+1} and use the embedding

$$\left\{ \begin{array}{ll} \mathbf{R}^n & \longrightarrow \mathbf{R}^{n+1} \\ \sum_{i \geq 1} a_i e_i & \longmapsto e_0 + \sum_{i \geq 1} a_i e_i. \end{array} \right.$$

For *conformal geometry*, let $e, e_1, \dots, e_n, \bar{e}$ be a basis of $\mathbf{R}^{n+1,1}$, set $o = \frac{1}{2}(e + \bar{e})$, $\infty = e - \bar{e}$ and use the embedding

$$\left\{ \begin{array}{ll} \mathbf{R}^n & \longrightarrow \mathbf{R}^{n+1,1} \\ p = \sum_{i \geq 1} a_i e_i & \longmapsto o + p + p^2 \infty. \end{array} \right.$$

Points in \mathbf{R}^n are represented by null vectors in $\mathbf{R}^{n+1,1}$ (*i.e.*, $p \cdot p = 0$; o and ∞ are also null vectors), and their product corresponds to the Euclidean distance

$$\frac{p}{-\infty \cdot p} \cdot \frac{q}{-\infty \cdot q} = -\frac{1}{2}(p - q)^2.$$

A vector $v \in \mathbf{R}^{n+1,1}$ can be interpreted in a dual way, $\{x : v \cdot x = 0\}$: null vectors are points; vectors with no o component are (dual) planes; in general, they are (dual) spheres.

Euclidean transformations are versors preserving ∞ . Lines are elements of the form point \wedge point $\wedge \infty$ or point \wedge direction $\wedge \infty$. Planes are of the form point \wedge point \wedge point $\wedge \infty$; replacing ∞ with a finite point gives circles and spheres.

A primer on reproducing kernel Hilbert spaces A.H. Manton and P.O. Amblard (2015)

A **finite-dimensional RKHS** is a subspace $V \subset \mathbf{R}^n$ endowed with an inner product. Its **kernel** is the unique matrix $k = (k_1, \dots, k_n) \in \mathbf{R}^{n \times n}$ satisfying the following three equivalent properties.

- (i) The k_i are in V and $\forall v \in V \quad \langle v, k_i \rangle = e'_i v$, *i.e.*, $\langle v, k_i \rangle$ is the i th coordinate of v ;
- (ii) $k = u_1 u'_1 + \dots + u_r u'_r$ where u_1, \dots, u_r is an orthonormal basis of V ;
- (iii) The k_i 's span V and $k_{ij} = \langle k_i, k_j \rangle$.

[Note that we do not need the scalar product of \mathbf{R}^n , only the coordinates.]

Graphically, a RKHS can be represented as the ellipsoid $\{v \in V : \langle v, v \rangle = 1\}$.

The columns of the kernel can be recovered as follows:

- Let $H_i = \{z \in \mathbf{R}^n : e'_i z = 1\} = \{z \in \mathbf{R}^n : z_i = 1\}$;
- If $V \cap H_i = \emptyset$, let $k_i = 0$;
- Otherwise, let $\tilde{k}_i = \text{Argmin}_{z \in V \cap H_i}$ and $k_i = \langle \tilde{k}_i, \tilde{k}_i \rangle^{-1} \tilde{k}_i$.

A **RKHS** is a subspace $V \subset \mathbf{R}^X$, with an inner product making it complete (a Hilbert space), such that the evaluation functionals

$$\text{ev}_x : \left\{ \begin{array}{ll} V & \longrightarrow \mathbf{R} \\ f & \longmapsto f(x), \end{array} \right.$$

for $x \in X$, be bounded (*i.e.*, continuous). Since $f \mapsto f(y)$ is continuous, from the Riesz representation theorem, there exists $k(\cdot, y) \in V$ such that $f(y) = \langle f, k(\cdot, y) \rangle$. The **kernel** $k : X \times X \rightarrow \mathbf{R}$ is positive semidefinite (often, when V is large enough, it is positive definite). Conversely, a positive semidefinite function $k : X \times X \rightarrow \mathbf{R}$ defines a RKHS $V = \text{Span}\{k(\cdot, y), y \in X\} \subset \mathbf{R}^X$.

Here are a few examples.

- The **Paley-Wiener space** is the space of band-limited functions $\mathbf{R} \rightarrow \mathbf{R}$,

$$f(t) = \frac{1}{2\pi} \int_{-a}^a F(\omega) e^{i\omega t} d\omega,$$

$F \in L^2$, for the scalar product $\langle f, g \rangle = \int_{-\infty}^{\infty} f g$; the kernel is

$$k(s, t) = \frac{\sin(a(s - t))}{\pi(s - t)}.$$

- The space of absolutely continuous functions $f : [0, 1] \rightarrow \mathbf{R}$, with $f(0) = 0$, whose derivative is square integrable, with the inner product $\langle f, g \rangle = \int_0^1 f' g'$; the kernel is $k(s, t) = \text{Min}(s, t)$;
- The **Bregman space** is the space of analytic and square-integrable functions on a domain $\Omega \subset \mathbf{C}$ with the inner product $\langle f, g \rangle = \int_{\Omega} f \bar{g}$; if Ω is the unit disk, the kernel is

$$k(z, w) = \frac{1}{\pi} \frac{1}{(1 - z\bar{w})^2}.$$

**The Ramanujan machine:
automatically generated conjectures
on fundamental constants
G. Raayoni et al. (2019)**

Given a fundamental constant (e.g., π , e , etc.), find 4 polynomials $\alpha, \beta, \gamma, \delta$ such that

$$\frac{\gamma(c)}{\delta(c)} = \text{GCF}(\alpha, \beta),$$

where the generalized continued fraction is

$$\text{GCF}(\alpha, \beta) = \alpha + \frac{\beta_1}{\alpha_1 + \frac{\beta_1}{\alpha_2 + \dots}}.$$

The meet-in-the-middle algorithm estimates the RHS at low precision, puts the result in a hash table, and check which LHS match; the precision is progressively increased.

Surprisingly, gradient descent to minimize

$$\left\| \frac{\gamma(c)}{\delta(c)} - \text{GCF}(\alpha, \beta) \right\|$$

can also lead to a solution:

- The minima are not isolated points but $(d - 1)$ -dimensional manifolds;
- All the minima seem to be global, and their error is zero;
- Start with a large number of point (500);
- Alternate gradient descent steps and “Coulomb repulsion” steps [?]
- To arrive at grid points, use gradient descent for the function $\sin^2(\pi x)$.

One can also allow α and β to be interlaced polynomials (e.g., different polynomials for even and odd terms) or transform the continued fraction with a simple function (e.g., $x \mapsto 1/x$).

Algorithms for reinforcement learning C. Szepesvári (2009)

2. Known MDP. A Markov decision process (MDP) (X, A, P_0) is the datum of a state space X , a set of actions A , and a mapping $P_0 : X \times A \rightarrow \mathcal{P}(X \times \mathbf{R})$ from state-action pairs to probability distributions on the next state and the reward. If $(X_{n+1}, R_{n+1}) \sim P_0(\cdot | X_n, A_n)$, the discounted reward is $R = \sum_{t \geq 0} \gamma^t R_{t+1}$.

An *episodic* MDP has a terminal (absorbing) state.

A *bandit* is an 1-state MDP.

A deterministic (resp. stochastic) *policy* is the choice of an action for each state, $A_t = \pi(X_t)$, resp. $A_t \sim \pi(\cdot | X_t)$.

A **Markov reward process** (MRP) is an MDP without actions – or, equivalently, with a stationary policy.

The value function of a MRP

$$V^\pi(x) = E\left[\sum \gamma^t R_{t+1} \mid X_0 = x\right]$$

$$Q^\pi(x, a) = E\left[\sum \gamma^t R_{t+1} \mid X_0 = x, A_0 = a\right]$$

satisfies the Bellman equation

$$\begin{aligned} V^\pi(x) &= r(x, \pi(x)) + \gamma \sum_{y \in X} P(x, \pi(x), y) V^\pi(y) \\ &= (T^\pi V^\pi)(x). \end{aligned}$$

Likewise, the optimal value function V^* (or Q^*) of an MDP satisfies

$$\begin{aligned} V^*(x) &= \sup_{a \in A} r(x, a) + \gamma \sum_{y \in X} P(x, a, y) V^*(y) \\ &= (T^* V^*)(x). \end{aligned}$$

It can be obtained by **value iteration**, $V_{k+1} = T^* V_k$, or $Q_{k+1} = Q^* V_k$.

Policy iteration uses the state-action value function Q instead of the state value function V and iterates the following two steps:

- Compute the value Q^{π_k} of the policy π_k ;
- Compute the greedy policy π_{k+1} for this value function Q^{π_k} .

3. Unknown MDP. The value of a state can be of independent interest: probability of reaching a state, or expected time until we reach a state.

TD(0) moves the estimation of the value of the current state X_t towards a target.

$$\text{target} = R_{t+1} + \gamma V_t(X_{t+1})$$

$$\delta_{t+1} = \text{target} + \gamma V_t(X_{t+1})$$

$$V_{t+1}(x) = \begin{cases} V_t(X_t) + \alpha \delta_{t+1} & \text{if } x = X_t \\ \text{unchanged} & \text{otherwise} \end{cases}$$

The step size α_t should satisfy the Robbins-Monroe condition, e.g., $\alpha_t \propto t^{-\eta}$, $\frac{1}{2} < \eta \leq 1$, with $\eta = 1$ for good asymptotic behaviour, and η close to $\frac{1}{2}$ for good small sample properties – and $\eta = 0$ in practice.

TD(0) can be used for off-policy learning.

Every-visit-Monte-Carlo is similar, but the target is the discounted reward until the end of the episode. TD(0) converges faster, but struggles with delayed rewards.

It is actually not necessary to wait until the end of the episode: one can keep track of the eligibility of each state for the next rewards; the eligibility is increased by 1 each time the state is reached and then exponentially decays. TD(λ) lets it decay faster than the discounting faster; TD(1) is every-visit MC.

$$\begin{aligned}\delta_{t+1} &= R_{t+1} + \gamma V_t(X_{t+1}) - V_t(X_t) \\ z_{t+1}(x) &= \mathbf{1}_{x=X_t} + \gamma \lambda z_t(x) \\ V_{t+1}(x) &= V_t(x) + \alpha \delta_{t+1} z_{t+1}(x) \\ z_0(x) &= 0\end{aligned}$$

Variants of the eligibility traces include $z_{t+1}(x) = \text{Max}(\mathbf{1}_{x=X_t}, \gamma \lambda z_t(x))$, corresponding to *first-visit Monte Carlo* – it may perform better. The optimal value of λ is determined by trial and error.

For large state spaces, the value function can be approximated from state features, $\phi(x)$, e.g., $V_\theta(x) = \theta' \phi(x)$, with

- $\phi_i(x) = \exp(-\eta \|x - x^{(i)}\|^2)$ for manually-chosen points $x^{(i)}$ (if these points are model parameters, this is an **RBF network**);
- ϕ_i 's rescaled so that $\sum \phi_i \equiv 1$ (*averager*);
- Kernel smoothing, spline smoothing, Gaussian process (GP) regression, regression tree.

With function approximation, the eligibility traces are for the coordinates of θ instead of the states, and they use the gradient $\nabla_\theta V_\theta$ instead of the indicator function $\mathbf{1}_{X_t=x}$.

$$\begin{aligned}\delta_{t+1} &= R_{t+1} + \gamma V_{\theta_t}(X_{t+1}) - V_{\theta_t} \\ z_{t+1} &= \nabla_\theta V_\theta(X_t)|_{\theta=\theta_t} + \gamma \lambda z_t \\ \theta_{t+1} &= \theta_t + \alpha_t \delta_{t+1} z_{t+1}\end{aligned}$$

There is no convergence guarantee for TD(λ) with function approximation if the model is not linear or for off-policy learning.

Gradient TD learning directly minimizes the loss function

$$J(\theta) = \|V_\theta - \Pi T V_\theta\|_2^2$$

where T is the Bellman operator and Π the best approximation of its argument in the set of functions considered. The gradient of J is complicated: write it using θ and some other quantity $w(\theta)$; successively update θ (assuming w fixed) and w . There are several ways of choosing such a decomposition (GTD2, TDC, LS, etc.).

4. There are several types of reinforcement learning problems:

- No interaction: the data has already been collected;

- *Active*: we can explore freely – the system is running, but not live yet;
- *Online*: we already want good rewards – the system is already live – we can explore, but not as freely as we want.

For online learning of bandits, ε -greedy (with decreasing ε) or *Boltzman exploration* $\pi(a) \propto \exp \beta Q(a)$ are popular.

UCB₁ takes the action with the best upper confidence bound.

$$\begin{aligned}U(a) &= r(a) + R \sqrt{\frac{2 \log t}{n(a)}} \\ r(a) &= \text{average reward for action } a \\ n(a) &= \text{number of times action } a \text{ was chosen} \\ R &= \text{variance or range of the rewards for } a\end{aligned}$$

For Bernoulli rewards, we can explicitly compute the policy maximizing the expected reward (Gittins index).

$$\begin{aligned}R(a) &\sim \text{Bernoulli}(p_a) \\ p_a &\sim \text{Beta}(\alpha_a, \beta_a) \\ \alpha_a, \beta_a &\sim \text{some prior}\end{aligned}$$

For active learning of bandits, compute upper and lower bounds for each action and discard an action a if

$$U_t(a) < \text{Max}_{\substack{a' \in \mathcal{A} \\ a' \neq a}} L_t(a').$$

While it is possible to recover a deterministic MDP (find the closest state with an unexplored action), there is no known (reasonable) algorithm to recover a stochastic MDP.

The UCRL2 algorithm, for online learning of MDPs, constructs confidence intervals for the transition probabilities and the reward function, defining a set C_t of plausible MDPs, and updates the policy when those estimates are precise enough, to maximize the discounted reward.

$$\pi^*, M^* = \underset{\substack{\pi \text{ policy} \\ M \in C_t}}{\text{Argmax}} \rho^\pi(M)$$

4.3 Q-learning is TD(0) for Q instead of V , for off-policy learning (TD(λ) is on-policy), for ε -greedy or Boltzman exploration. The MDP can sometimes be simplified by separating the deterministic effects of an action from its stochastic effect (“after-effect”).

Q-learning with function approximation is not guaranteed to converge for non-linear approximation or off-policy learning.

4.4 Actor-critic methods generalize policy iteration (the actor is the policy, the critic the value function): they update the policy before it has been completely evaluated; they may oscillate: they keep track of the best performing policy. **SARSA** is an extension of

TD(0) to Q instead of V .

$$\text{target} = R_{t+1} + \gamma \max_{a' \in \mathcal{A}} Q(y_{t+1}, a') \quad \text{Q-learning}$$

$$\text{target} = R_{t+1} + \gamma Q(y_{t+1}, A'_{t+1}) \quad \text{SARSA}$$

The other value estimation algorithms for V can be extended to Q : TD(λ), LSTD(λ), etc.

The actor is updated less often, either as a greedy policy (which can be computed on the fly) or, for parametrized stochastic policies, e.g., Boltzman

$$\pi_\omega(a|x) \propto \exp w' \xi(x, a),$$

where ξ are features, or Gaussian,

$$\pi_\omega(a, x) \sim N(g_\omega(x, a), \beta_\omega(x, a)^2 I),$$

with gradient ascent

$$\nabla_\omega \rho = E[G(\omega)]$$

$$G(\omega) = (Q^{\pi_\omega}(X, A) - h(X))\psi_\omega(X, A)$$

$$\psi_\omega = \nabla_\omega \log \pi_\omega \quad \text{score function}$$

$$h(X) = V(X) \quad \text{or an arbitrary function,} \\ \text{for variance reduction}$$

REINFORCE updates the parameters at the end of the episodes.

The score function can be used as features,

$$Q_\theta(x, a) = \theta' \psi_\omega(x, a).$$

The natural actor-critic uses the natural gradient but has simpler updates.

Distral:
robust multitask reinforcement learning
Y.W. Teh et al.

For multitask learning, learn the tasks separately, with a penalty to make them closer to an average task, computed by distillation.

Large-scale optimal transport
and mapping estimation
V. Seguy et al.

The dual of the regularized Kantorovich relaxation

$$\underset{\substack{\text{pr}_{1*} \pi = \mu \\ \text{pr}_{2*} \pi = \nu}}{\text{Minimize}} \quad E_{(X,Y) \sim \pi} c(X, Y) + \varepsilon R(\pi)$$

$$\text{with } R(\pi) = \int \left(\log \frac{p\pi}{d(\mu \times \nu)} - 1 \right) d\pi$$

$$\text{or } R(\pi) = \int \left(\frac{p\pi}{d(\mu \times \nu)} \right)^2 d\mu d\nu$$

is an unconstrained optimization problem

$$\underset{u, v}{\text{Maximize}} \quad E_{\substack{X \sim \mu \\ Y \sim \nu}} u(X) + v(Y) - F_\varepsilon(u(X), v(Y))$$

which can be solved by stochastic gradient descent, if u and v are modeled by neural nets (the Sinkhorn algorithm is quadratic and only works with discrete distributions); the coupling π can then be turned into a map f (modeled with a neural net and estimated by SGD) by *barycentric projection*

$$f(x) = \underset{y \in \mathcal{Y}}{\text{Argmin}} \quad E_{Y \sim \pi(X, \cdot)} [d(z, Y)].$$

Machine learning applications include *domain adaptation* (transfer learning: aligning different datasets), shape matching, colour transfer, data assimilation (aligning biased model(s) and data).

Sliced Gromov-Wasserstein
T. Vayer et al.

The **sliced Wasserstein distance** is the average of the Wasserstein distance of projections on random 1-dimensional subspaces.

The **Gromov-Wasserstein distance** between $\mu = \sum a_i \delta_{x_i} \in \mathcal{P}(\mathbf{R}^p)$ and $\nu = \sum b_j \delta_{y_j} \in \mathcal{P}(\mathbf{R}^q)$ for the dissimilarity measures

$$c_X : \mathbf{R}^p \times \mathbf{R}^p \longrightarrow \mathbf{R}_+$$

$$c_Y : \mathbf{R}^q \times \mathbf{R}^q \longrightarrow \mathbf{R}_+$$

is

$$\text{GW}_2 = \underset{\pi \in \Pi(a, b)}{\text{Min}} \sum_{ijkl} |c_X(x_i, x_k) - c_Y(y_j, y_\ell)|^2 \pi_{ij} \pi_{kl}.$$

The 1-dimensional uniform case, with squared Euclidean distances, is easy: sort the x_i 's and y_j 's (in increasing or decreasing order, whichever is better).

Pushing the right boundaries matters!
Wasserstein adversarial training
for label noise
B.B. Damodaran et al.

For an observation (y, x) , **virtual adversarial training** adds a regularization term $D(p_\theta(x) \| p_\theta(x + r))$ where p_θ are the predicted class probabilities (when computing the gradient wrt θ , fix the first argument and only differentiate the second) and r , with $\|r\| \leq \varepsilon$, is the direction in which the divergence increases the most (the dominant eigenvector of the Hessian, $D(p(x) \| p(x + r)) \sim \frac{1}{2} r' H r$, obtained by power iteration – one step is enough).

Replace the KL divergence with the Wasserstein distance (with entropic regularization), with a cost reflecting similarities between classes (e.g., from word2vec).

The regularization is then more important for classes that should not be confused, that are less likely to be affected by noise.

Other ways of dealing with noisy labels include robust methods, data cleaning (with another network), adding a noise layer on top of the softmax, and learning the *noise transition matrix*.

The Wasserstein transform
F. Mémoli et al (2019)

A point cloud $X \subset \mathbf{R}^n$ can be seen as a uniform distribution α on the metric space (X, d) . The local ε -truncation of α is the probability measure

$$m_\alpha^\varepsilon(x) \propto \alpha|_{B_\varepsilon(x)}.$$

The **Wasserstein transform** is a new distance on X

$$d_\alpha^\varepsilon(x, y) = d_{W,1}(m_\alpha^\varepsilon(x), m_\alpha^\varepsilon(y))$$

where $d_{W,1}$ is the ℓ^1 Wasserstein distance. The iterated Wasserstein transform generalizes the mean-shift algorithm and has a denoising effect.

An introduction to topological data analysis: fundamental and practical aspects for data scientists
F. Chazal and B. Michel (2017)

To turn persistence diagrams into features, use persistence landscapes, or build a persistence diagram *kernel*.

Information-geometric optimization algorithms: a unifying picture via invariance principles
Y. Ollivier et al. (2017)

Gradient descent on $F(\theta) = \mathbb{E}_{X \sim p_\theta} [f(\theta)]$ (where the p_θ are, e.g., Gaussians) converges to a Dirac mass at the minimum of f :

- Rewrite f using quantiles, to make the algorithm invariant to monotonic transformations;
- Use the natural gradient;
- Approximate the expectation using quantiles (as CMA-ES or CEM).

Riemann manifold Langevin and Hamiltonian Monte Carlo
M. Girolami et al.

The Metropolis-adjusted Langevin algorithm is a Metropolis-Hastings Markov chain with a drift term (the Langevin diffusion is unbiased when the step size tends to zero – for finite step sizes, a MH accept-reject step is needed – HMC has the same problem).

One-step HMC updates are Langevin updates.

On a Riemannian manifold, one can leverage the metric:

$$\begin{aligned} d\theta &= \frac{1}{2} \nabla_\theta \ell(\theta) dt + db && \text{flat} \\ d\theta &= \frac{1}{2} \tilde{\nabla} \ell dt + \tilde{db} && \text{Riemann} \\ \tilde{\nabla} \ell &= G^{-1} \nabla \ell && \text{Natural gradient} \\ \tilde{db} &= \dots dt + G^{-1/2} db. \end{aligned}$$

In the Riemannian Brownian motion, the second term accounts for the curvature, and the first for the change in curvature.

The Hamiltonian is simpler,

$$\begin{aligned} H(\theta, p) &= -\ell(\theta) + \frac{1}{2} \log(2\pi)^D |G| + \frac{1}{2} p' G^{-1} p \\ \frac{d\theta_i}{d\tau} &= \frac{\partial H}{\partial p_i} \\ \frac{dp_i}{d\tau} &= -\frac{\partial H}{\partial \theta_i} \end{aligned}$$

but the naive discrete integrator is not volume-preserving: use an implicit integrator instead.

Topological denoising: strengthening the topological signal
J. Kloeke and G. Carlsson (2018)

A few steps of the **mean-shift** algorithm have a denoising effect on a point cloud X . If there is more noise, take a subset $S_0 \subset X$ (e.g., 10%) and progressively move them in the direction of the gradient of

$$F_n(x) = f_D(x) + \omega f_{S_n}(x)$$

where f_D and f_{S_n} are density estimators (Gaussian, with the same bandwidth σ) of D and S_n and $\omega \in [.1, .5]$. The first term is from the mean-shift algorithm; the second keeps the points of S_n away from each other.

A topological regularizer for classifiers via persistent homology
C. Chen et al. (2019)

The **topological complexity** of the decision boundary $f^{-1}(0)$ of a classifier $f : X \rightarrow \mathbf{R}$ is $\sum_c \rho(c)^2$ where the **robustness** $\rho(c)$ of connected component c of $f^{-1}(0)$ is

$$\text{Min}\{|f(p_c)|, |f(q_c)|\},$$

where p_c and q_c are the critical points corresponding to the birth and death of the component (0th dimensional persistent homology – the *persistence* is $f(q_c) - f(p_c)$). It can be used as a regularizer (TDA usually yields features); to compute its gradient, use a piecewise approximation of the classifier function.

Connectivity-optimized representation learning via persistent homology
C.D. Hofer et al. (2019)

Use connectivity-optimized representation learning via persistent homology.

On characterizing the capacity of neural networks using algebraic topology
W.H. Gus and R. Salakhutdinov

The minimum number of neurons depends on the “geometric complexity” of the dataset. Conversely, the “topological capacity” of a neural net can be estimated with topological data analysis (TDA).

Neural persistence: a complexity measure for deep neural networks using algebraic topology
B. Rieck et al. (2019)

The *neural persistence* of a layer is the L^p norm of the 0th homology persistence diagram of the corresponding bipartite graph for the filtration induced by the weights. Regularized networks (batchnorm, dropout) have a higher (normalized) persistence.

Weisfeiler-Lehman graph kernels
N. Shervashidze et al. (2011)

The **Weisfeiler-Lehman test** for graph isomorphism between G and G'

- Augments the node labels with the (sorted) labels of the neighbours;
- Compresses the label multisets into shorter labels (e.g., with a hash function, or with a bijection with $\llbracket 1, k \rrbracket$);
- Repeats until the label sets of G and G' differ or a timeout is reached.

Those new labeled graphs $G_0, G_1, G_2, \dots, G'_0, G'_1, \dots$ can be used to define graph kernels as

$$\sum_{i=0}^h k(G_i, G'_i) \quad \text{or} \quad k(G_h, G'_h),$$

where k is an easy-to-compute kernel, e.g., the number of matching node labels, or the number of edge pairs whose extremities have matching labels.

A persistent Weisfeiler-Lehman procedure for graph classification
B. Rieck et al. (2019)

Label propagation (Weisfeiler test) defines a distance between adjacent vertices

$$d^h(u, v) = \mathbf{1}_{\ell_u^{h-1} \neq \ell_v^{h-1}} + d(\ell_u^h, \ell_v^h) + 1$$

where ℓ_u^h is the label multiset of node u after h steps and the distance between multisets is the L^p distance between their count vectors. The distance d^h defines a filtration on the graph, for which we can compute the persistence diagram, which can be added (at each step) to the WL features (to define a graph kernel).

A tutorial on variational Bayesian inference
C. Fox and S. Roberts

We want to approximate a probability distribution $P(x)$, e.g., from a graphical model, $P(x) = \prod_I \Phi(x_I)$,

with a **mean-field approximation**, i.e., $Q(x, \theta) = \prod_i Q_i(x_i, \theta)$, by minimizing $\text{KL}(Q\|P)$.

$$\begin{aligned} \text{KL}(Q\|P) &= \int Q \log \frac{Q}{P} \\ &= \int Q(x) \log \frac{Q(x)}{P(x|\text{data})} dx \\ &= \int Q(x) \log \frac{Q(x)P(\text{data})}{P(x, \text{data})} dx \\ &= \int Q(x) \log Q(x) dx - \int Q(x) \log P(x, \text{data}) dx + \\ &\quad \int Q(x) dx P(\text{data}) \\ &= -H(Q) - \int E(x, \text{data}) Q(x) dx + P(\text{data}) \end{aligned}$$

$$H(Q) = - \int Q(x) \log Q(x) dx \quad \text{Shannon entropy}$$

$$E(x, \text{data}) = \log P(x, \text{data}) \quad \text{Energy}$$

$$L = \langle E \rangle + H \quad \text{Lower bound on } P(\text{data})$$

Since $Q(x) = \prod_i Q_i(x_i)$, we have $H(Q) = \sum_i H(Q_i)$ and

$$\begin{aligned} \langle E \rangle &= \int Q(x_i) \int Q(\bar{x}_i) E(x, \text{data}) d\bar{x}_i dx_i \\ &= \int Q(x_i) \log Z Q^*(x_i) dx_i \\ &= \int Q(x_i) \log Q_i^*(x_i) dx_i + \log Z \end{aligned}$$

where

$$Q_i^* = \frac{1}{Z} \exp \int Q(\bar{x}_i) E(x, \text{data}) d\bar{x}_i.$$

Therefore,

$$\begin{aligned} L &= \langle E \rangle + H \\ &= \int Q(x_i) \log Q_i^*(x_i) dx_i + \log Z - \sum_j \int Q(x_j) \log Q(x_j) dx_j \\ &= \int Q(x_i) \log \frac{Q_i^*(x_i)}{Q_i(x_i)} + \log Z - \sum_{j \neq i} H(Q_j) \\ &= -\text{KL}(Q_i\|Q_i^*) + \log Z - \sum_{j \neq i} H(Q_j). \end{aligned}$$

The lower bound L is maximal when $\text{KL}(Q_i\|Q_i^*) = 0$, i.e., when $Q_i = Q_i^*$. This gives an EM-like algorithm

$$Q_i(x_i) \leftarrow \frac{1}{Z} \exp \langle \log P(x_i, \bar{x}_i | \text{data}) \rangle_{Q(\bar{x}_i)}$$

where $\bar{x}_i = x_{I \setminus \{i\}}$ or $\bar{x}_i = \text{MarkovBlanket}(x_i)$.

Automatic differentiation variational inference A. Kucukelbir et al.

Variational inference (VI) requires model-specific derivations and implementations, but the gradient of the VI objective can be written as an expectation (involving $\nabla_{\theta} p_{\theta}(x)$, which can be computed by automatic differentiation (AD)) over the variational distribution q_{ϕ} and approximated with Monte Carlo methods (ADVI). ADVI is not limited to mean-field approximations: full-rank approximations do not underestimate the posterior variance as much.

Examples include nonnegative matrix factorization, e.g., Gamma-Poisson

$$\begin{aligned}\theta_{uk} &\sim \text{Gamma}(a, b) \\ \beta_{ik} &\sim \text{Gamma}(c, d) \\ y_{ui} &\sim \text{Poisson}(\theta'_u \beta_i)\end{aligned}$$

or Dirichlet-exponential-Poisson

$$\begin{aligned}\theta_u &\sim \text{Dir}(\alpha) \\ \beta_{ik} &\sim \text{Exp}(\lambda) \\ y_{ui} &\sim \text{Poisson}(\theta'_u \beta_i)\end{aligned}$$

and models with a sparsifying *automatic relevance determination* (ARD) prior, e.g., a linear model

$$\begin{aligned}\sigma &\sim \text{InvGamma}(a, b) \\ \alpha_i &\sim \Gamma(c, d) \\ w_i &\sim N(0, \sigma^2 / \alpha_i) \\ \varepsilon &\sim N(0, \sigma^2) \\ y &= w'x + \varepsilon\end{aligned}$$

or probabilistic PCA (PPCA), or supervised PPCA.

Deep set prediction networks Y. Zhang et al.

To provide sets as input to a neural network, use an invariant function $\{x_i\}_i \mapsto \sum_i g(x_i)$, where g is a neural net.

To compare sets, use an optimal alignment

$$\ell(\hat{y}, y) = \min_{\sigma \in \mathfrak{S}_n} \|\hat{y} - \sigma \cdot y\|^2.$$

To output sets, decode the latent representation into the set whose encoding is closest to the desired latent representation (this requires an optimization). For variable-sized sets, pad the sets to a fixed size and add a mask feature.

This can also be used for an autoencoder.

$$\begin{aligned}\{x_i\}_i &\mapsto z = \sum_i g(x_i) \mapsto \text{Argmin}_{\{y_i\}} \|x - \sum g(y_i)\|^2 \\ x = \sum_i g(y_i) &\longleftarrow \{y_i\}_i\end{aligned}$$

Provably robust deep learning via adversarially trained smoothed classifiers H. Salman

Randomized smoothing transforms a classifier to retain the most likely class in a neighbourhood of the query

$$g(x) = \text{Argmax}_c \mathbb{P}_{\varepsilon \sim N(0, \sigma^2 I)} [f(x + \varepsilon) = c];$$

it makes the classifier robust to random (non-adversarial) perturbations.

It can be generalized to *soft classifiers*, which output a probability distribution on classes rather than a single class.

Adversarial training uses the gradient at adversarial perturbations instead of the actual observations; It can be applied to smoothed (soft) classifiers.

Kervolutional neural networks C. Wang et al.

The convolution $f(x) = x * w = (\langle x_{(i)}, w \rangle)_i$, where $x_{(i)}$ is the circular shift of x by i elements, can be kernalized

$$g(x) = x \circledast w = (\langle \phi(x_{(i)}), \phi(w) \rangle)_i = (\kappa(x_{(i)}, w))_i$$

where κ is a fixed kernel (polynomial or RBF).

DeepRED: deep image prior powerd by RED G. Mataev et al. (2019)

The **deep image prior** (DIP) addresses inverse imaging problems (denoising, deblurring, inpainting, super-resolution, tomographic reconstruction) with a neural net T_{θ} :

$$\begin{aligned}\text{Find} & \quad x \text{ reconstructed image} \\ & \quad \theta \text{ model parameters} \\ \text{To minimize} & \quad \|Hx - y\|_2^2 \\ \text{Such that} & \quad x = T_{\theta}(z)\end{aligned}$$

where H is the (known) corruption (the identity for denoising, a convolution for deblurring, etc.), y is the corrupted image and z a fixed random vector.

While this already provides an implicit regularization, one can add an explicit regularization and minimize

$$\|Hx - y\|_2^2 + \lambda x'(x - f(x))$$

where f is a fixed denoiser (for a reasonable choice of f , the gradient of the regularizer has a simple form, $x - f(x)$).

Visualizing and measuring the geometry of BERT A. Coenen et al.

BERT provides contextual word embeddings whose (squared) distance matches the distance on the parse

tree; the attention matrices contain similar information. Any tree has a power-2 embedding (*i.e.*, $\|f(x) - f(y)\|^2 = d(x, y)$) in \mathbf{R}^{n-1} :

$$\begin{aligned} f(t_0) &= 0 \\ f(t_i) &= e_i + f(\text{parent}(t_i)) \end{aligned}$$

where the e_i 's form an orthonormal basis (or are random unit vectors in a high-dimensional space). The semantic information of the embeddings and the polysemy of the words can be visualized by selecting a word, picking 1000 Wikipedia sentences containing it, computing the embeddings, and plotting them with UMAP.

***MixMatch: a holistic approach
to semi-supervised learning***
D. Berthelot et al.

To leverage unlabeled data, semi-supervised learning can use

- **Consistency regularization**, to ensure the output of the classifier remains the same after data augmentation (image patches, orientation, deformations, noise, etc.),
- **Entropy minimization**, to prevent the decision boundary from going through high-density regions, by minimizing the entropy $p_{\text{model}}(y|x)$ for unlabeled data,

in addition to the traditional (supervised) regularizations:

- L^2 regularization, often implemented as a **weight decay**, to prevent the model from memorizing the training data;
- **MixUp**, which trains the model on convex combinations of inputs and labels.

MixMatch combines those ideas:

- Data augmentation on both labeled and unlabeled data;
- Label distribution guess for unlabeled observations by averaging the predicted distributions after data augmentation;
- Distribution sharpening, $q_i \propto p_i^{1/T}$, $T < 1$;
- Train the model on convex combinations of labeled and/or unlabeled observations, but with a different loss function depending on whether the labeled or unlabeled observation is closer.

***Phase transitions of spectral initialization
for high-dimensional nonconvex estimation***
Y.M. Lu and G. Li

Phase retrieval is the problem of estimating ξ given noisy measurements $y_i = (a'_i \xi)^2 + \varepsilon_i$; more generally, one may want to estimate ξ from measurements $y_i \sim f(\cdot | a'_i \xi)$.

Spectral initialization suggests to initialize ξ to the first eigenvector of the variance matrix of the a_i 's [*i.e.*, where the information is the “densest”: that is not

where the solution is, but that is where you will see the most clearly where to go – provided there is enough data].

Stochastic bouncy particle sampler
A. Pakman et al.

The **Bouncy particle sampler** (BPS) samples from $p(w) \propto e^{-U(w)}$, $w \in \mathbf{R}^f$, by adding a random velocity vector $v \in \mathbf{S}^{d-1}$

- w follows the direction v (straight lines);
- v is relected along ∇U^\perp , following an inhomogeneous Poisson process of intensity $\lambda = (v \cdot \nabla U)_+$:

$$v \leftarrow v - 2 \frac{v \cdot \nabla U}{\|\nabla U\|^2} \nabla U;$$

- Occasionally resample v to ensure ergodicity.

With noisy gradients, the Poisson intensity becomes stochastic (doubly stochastic process, aka Cox process) – the bounces are more frequent and mixing is slower. To sample from it, find an upper bound on λ , e.g., using a local regression $\lambda \sim t$.

(**Zig-zag Monte Carlo** is similar, with $v \in \{\pm 1\}^d$, and only changes one coordinate at a time.)

***The bouncy particle sampler:
a nonreversible rejection-free
Markov chain Monte Carlo method***
A. Bouchard-Côté et al. (2018)

***Adaptive hard thresholding
for near optimal consistent robust regression***
A.S. Suggala et al. (2019)

Robust linear regression by discarding observations with “large” residual:

- Iteratively estimate the regression coefficients on the set of uncorrupted observations;
- Use an adaptive threshold to detect outliers;
- Add some noise when deciding whether to include an observations.

The (slower) Huber loss also works well.

The cult of statistical significance
S.T. Ziliak and D.N. McCloskey (2009)

The p -value is easy to compute, but it is not the *loss function* you want – prefer something involving the effect size. For instance, $X_1 \sim N(\mu = 5, \sigma = 0.5)$ has a better p -value than $X_2 \sim N(\mu = 20, \sigma = 10)$, 10^{-23} versus 10^{-1} (for $H_0 : X > 0$), but $P(X_1 > X_2) = 0.07\dots$

***Uncertainty propagation
with functionally correlated quantities***
M. Giordano (2016)

The **Mesurements.jl uncertainty propagation** package handles *functional correlations*, *i.e.*, deterministic relations $y = f(x)$; for instance, given $x = x_0 \pm \sigma$, it estimates $x - x = 0 \pm 0$, not $x - x = 0 \pm 2\sigma$.

**On cross-validation
for sparse reduced-rank regression
Y. She and H. Tran (2018)**

Consider a jointly sparse and low-rank linear model

$$\begin{matrix} m \\ \boxed{Y} \end{matrix} = \begin{matrix} p \\ \boxed{X} \end{matrix} \times \begin{matrix} m \\ \boxed{B} \end{matrix} + \varepsilon$$

where B is both low-rank and row-sparse (some of the rows are zero).

To choose the regularization parameters, e.g., λ for the lasso, one can use cross-validation

- On λ , the scale of the penalty $\lambda \|\beta\|_1$, but a different number of variable may be selected in different folds;
- Or on c , the corresponding constraint $\|\beta\|_1 \leq c$, but this is difficult to solve.

Instead, use cross-validation on both

- Which variables are retained by the model;
- The (low-rank) subspace spanned by the coefficient matrix

(each can be encoded as a matrix, S and U , which can be recovered from their product SU).

[I am not sure how to use that in practice: with λ , we can just try a few values, on a grid, but here, we have a combinatorial choice ($p!$ subsets of predictors) and a subspace.]

The optimal rank and sparsity can be estimated using

- Some information criterion (AIC, BIC, etc. – but it is not clear which one to use);
- Or cross-validation.

**Natural analysts in adaptive data analysis
T. Zrnic and M. Hardt**

Data analysis is no longer limited to 1- or 2-step procedures (statistical tests, post-selection inference): by progressively interrogating the data, the analyst's knowledge evolves – it is a discrete dynamical system. *Differential privacy* can help limit overfitting.

**Minimax optimal rates
for Mondrian trees and forests
J. Mourtada et al. (2018)**

A *Mondrian process* is a distribution on infinite nested trees (partitions of $[0, 1]^d$) defined from iid sequences of random variables $e \sim \text{Exp}(1)$ used to select the dimension to split, by comparing it with the side lengths of the box to split

$$\tau_i = \frac{e_i}{\text{length}_i} \quad i = \underset{i}{\text{Argmin}} \tau_i \quad \tau = \underset{i}{\text{Min}} \tau_i,$$

and $u \sim U(0, 1)$ used to choose the threshold to split. A *Mondrian forest* is a *purely random forest* whose trees are sampled from a Mondrian process.

**Implicit generation and modeling
with energy-based models
Y. Du and I. Mordatch**

Energy-based models, $p(x) \propto e^{-E(x)}$, E unknown, can be estimated by MCMC

$$\begin{aligned} \ell(\theta) &= \underset{x \sim \text{data}}{\text{E}} [-\log p_\theta(x)] \\ &= \underset{x \sim \text{data}}{\text{E}} [E_\theta(x) - \log Z(\theta)] \\ \nabla \ell(\theta) &= \underset{x^+ \sim \text{data}}{\text{E}} [\nabla_\theta E_\theta(x^+)] - \underset{x^- \sim p_\theta}{\text{E}} [\nabla_\theta E_\theta(x^-)] \end{aligned}$$

**Meta-learning how to forecast time series
T.S. Talagala et al. (2018)**

Train a random forest to forecast the best time series forecasting algorithm (SARIMA, exponential smoothing, random walk) using time series features (length, trend, seasonality, linearity, curvature, spikiness, autocorrelation, stability, lumpiness, spectral entropy, Hurst exponent, nonlinearity test, ETS model parameters, unit root tests). Implementation: **seer**.

**On fast convergence of proximal algorithms
for SQRT-lasso optimization:
don't worry about its nonsmooth loss function
X. Li et al.**

The optimal regularization parameter for the lasso regression depends on the noise variance

$$\underset{\theta}{\text{Argmin}} \frac{1}{n} \|y - X\theta\|_2^2 + \lambda \|\theta\|_1 \quad \lambda \approx \sigma \sqrt{\frac{\log d}{n}}$$

while that for the *SQRT-lasso* (whose loss function is the *unsquared* ℓ^2 norm) does not

$$\underset{\theta}{\text{Argmin}} \frac{1}{\sqrt{n}} \|y - X\theta\|_2 + \lambda \|\theta\|_1 \quad \lambda \approx \sqrt{\frac{\log d}{n}}.$$

The **proximal Newton** algorithm solves this problem by using a second order expansion of the loss function (leaving the penalty intact)

$$\begin{aligned} \ell(\theta) &= \frac{1}{\sqrt{n}} \|y - X\theta\|_2 + \lambda \|\theta\|_1 \\ Q(\theta, \theta_t) &= \ell(\theta_t) + \nabla \ell(\theta_t)'(\theta - \theta_t) + \frac{1}{2}(\theta - \theta_t)' \nabla^2 \ell(\theta_t)(\theta - \theta_t) \\ \theta_{t+0.5} &= \underset{\theta}{\text{Argmin}} Q(\theta, \theta_t) \text{ (coordinate descent)} \\ \theta_{t+1} &= \theta_t + \eta_t(\theta_{t+0.5} - \theta_t) \text{ (line search)} \end{aligned}$$

where the line search halves η_t until $\ell(\theta_{t+1}) \leq \ell(\theta_t)$.

The **proximal gradient** algorithm uses a coarser quadratic approximation

$$\ell(\theta) = \ell(\theta_t) + \nabla \ell(\theta_t)'(\theta - \theta_t) + \frac{1}{2} L \|\theta - \theta_t\|_2^2 + \lambda \|\theta\|_1$$

where L is obtained by line search.

Pathwise optimization, *i.e.*, a decreasing sequence of regularization parameters ending at the desired one, helps yield sparse solutions.

Two-player games for efficient non-convex constrained optimization
A. Cotter et al. (2018)

To solve a constrained, non-convex optimization problem, with non-differentiable (step function) constraints (e.g., in fair machine learning)

$$\begin{array}{ll} \text{Find} & \theta \\ \text{To minimize} & f(\theta) \\ \text{Such that} & \forall i \ g_i(\theta) \leq 0, \end{array}$$

consider the Lagrangian

$$\mathcal{L}(\theta, \lambda) = f(\theta) + \sum_i \lambda_i g_i(\theta) \quad (\lambda_i \geq 0)$$

and a differentiable proxy

$$\tilde{\mathcal{L}}(\theta, \lambda) = f(\theta) + \sum_i \lambda_i \tilde{g}_i(\theta)$$

and alternate

$$\begin{array}{l} \theta \leftarrow \underset{\theta}{\text{Argmin}} \ \tilde{\mathcal{L}}(\theta, \lambda) \\ \lambda \leftarrow \underset{\lambda \geq 0, \|\lambda\| \leq R}{\text{Argmin}} \ \mathcal{L}(\theta, \lambda) \end{array}$$

(we can compute the partial gradient $\partial \mathcal{L} / \partial \lambda$ of the original Lagrangian, even if the g_i 's are not differentiable: only $\partial \mathcal{L} / \partial \theta$ is problematic).

Keep the whole optimization history:

$$\mathbb{E}_{\theta \sim \text{Unif}(\{\theta_1, \dots, \theta_T\})} [g(\theta)]$$

is close to the minimum of g (there is no *pure* Nash equilibrium: all we can hope for is an approximation of a mixed Nash equilibrium).

(It is possible to reduce the number of points to $m+1$, where m is the number of constraints, with a simple linear program.)

Implementation in Tensorflow

Accelerated extra-gradient descent: a novel accelerated first-order method
J. Diakonikolas and L. Orecchia

Nesterov accelerated gradient descent can be interpreted as an explicit Euler discretization followed by a correction of the discretization error; instead, one can use an *implicit* Euler discretization.

Learned primal-dual reconstruction
J. Adler and O. Öktem

In the primal-dual optimization used to solve ill-posed problems (such as tomography) with a regularizing prior (total variation, TV), replace the proximal operator with a learned reconstruction operator, thereby combining deep-learning and model-based reconstruction.

Bridging the gap between constant step size stochastic gradient descent and Markov chains
A. Dieuleveut et al.

Averaged (Cesàro) constant-step-size stochastic gradient descent (SGD, Robins-Monro) benefits from Richardson-Romberg extrapolation.

Provable certificates for adversarial examples: fitting a ball in the union of polytopes
M. Jordan et al.

The *pointwise robustness* of a classifier is the radius of the largest ℓ^p ball centered at an input point x_0 for which the model output remains unchanged.

The *Chebyshev center* of a polytope is the center of the largest ℓ^p ball fitting inside it.

Spectral normalization for generative adversarial networks
T. Miyato et al. (2018)

Ensure the gradient of the discriminator remains bounded by normalizing each layer: divide each weight matrix W by its largest singular value (spectral norm, $\sigma(W)$); the Lipschitz constant of the nonlinearities is often 1.

Face aging with conditional generative adversarial networks
G. Antipov et al.

- Train a conditional GAN,
 - (age category, noise) \mapsto image
 - (they use 6 age categories);
- Train an auto-encoder to learn the inverse mapping
 - (age, latent) \mapsto image \mapsto (age, latent)
 - minimizing the Euclidean distance between the latent representations;
- Improve the latent representation by minimizing the distance between the embedding of the original and reconstructed image for a face recognition net (FaceNet);
- Change the age and re-generate the image.

Boosted generative models
A. Grover and S. Ermon

Boosting (multiplicative rather than additive) applied to the generator and/or the discriminator of a GAN.

GANSynth: adversarial neural audio synthesis
J. Engel et al. (2019)

Divide time into frames and generate, for each of them, a spectrogram, with log-amplitudes and (unwrapped) phases (the phase is needed to ensure a continuous signal; the unwrapped phase is smooth); train on the NSynth dataset (musical notes).

***Harmonizing maximum likelihood with GANs
for multimodal conditional generation***
S. Lee et al. (2019)

Conditional GANs are often trained with a loss combining minimax

$$\min_G \max_D \mathbb{E}_{x,y \sim \text{data}} \log D(x,y) + \mathbb{E}_{\substack{x \sim \text{label} \\ y \sim \text{noise}}} \log(1 - D(x, G(x,z)))$$

and reconstruction

$$\mathbb{E}_{\substack{x,y \sim \text{data} \\ z \sim \text{noise}}} \|y - G(x,z)\|_p^p$$

which worsens mode collapse.

Replace the reconstruction loss with a **moment reconstruction loss**: have the generator generate a *set* of samples, compute its moments μ, σ , and use a Gaussian (or Laplace) MLE loss

$$\mathbb{E} \left[\frac{(y - \mu)^2}{\sigma^2} + \frac{1}{2} \log \sigma^2 \right].$$

***Adversarial examples are not bugs,
they are features***
A. Ilyas et al.

The *usefulness* and *robustness* of a features f are

$$\begin{aligned} \rho(f) &= \mathbb{E}_{x,y} \text{Cor}(y, f(x)) \\ \gamma(f) &= \mathbb{E}_{x,y} \text{Cor}(y, f(x + \delta_x)) \end{aligned}$$

where $\delta)x$ is an adversarially chosen perturbation,

$$\delta_x = \underset{\delta \in \Delta}{\text{Argmin}} y \cdot f(x + \delta)$$

and $y \in \{0, 1\}$.

A robust model can be trained by minimizing the dver-sarial loss

$$\mathbb{E}_{x,y} \max_{\delta \in \Delta} \text{Loss}(x + \delta, y)$$

instead of $\mathbb{E}_{x,y} \text{Loss}(x, y)$.

Build a dataset of similar images using only useful robust features

$$x \mapsto x_r \in \underset{\delta \in \Delta}{\text{Argmin}} \|g(x_r) - g(x)\|$$

where g is the penultimate layer f a robust model and the optimization starts with noise.

Build a dataset of similar images using only useful non-robust features

$$x \mapsto x_a = \underset{x' : \|x' - x\| \leq \varepsilon}{\text{Argmin}} \text{Loss}(x', y')$$

where the loss is non-robust and the new class y' is chosen at random.

Non-robust models trained on those datasets have good performance: the existence of adversarial examples is a property of the dataset, not of the model – adversarial examples often transfer to other, independently-trained models.

***The Riemannian geometry
of deep generative models***
H. Shao et al.

Stochastic gradient descent can compute (discretized) geodesics (and parallel transport) of the data manifold of variational autoencoders (VAE) (the gradient of the decoder is expensive to compute, but that of the encoder suffices): it appears flat.

***Optimizing the latent space
of generative networks***
P. Bojanowski et al.

Learn a GAN without a discriminator (or an autoencoder with an unconstrained encoder):

$$\underset{\theta}{\text{Argmin}} \text{Mean}_{x \in \text{Data}} \min_{z \in \text{Ball}} \text{Loss}(g_\theta(z), x).$$

To avoid blurry images, use the *Laplacian pyramid* Lap₁ loss.

***Good semi-supervised learning
that requires a bad GAN***
Z. Dai et al. (2017)

GANs can be used for semi-supervised learning: the discriminator tries to forecast the class the sample comes from for labeled or unlabeled data, and a $(k + 1)$ st class for generated samples – the objective function has three terms, labeled, unlabeled and generated.

$$\begin{aligned} &\mathbb{E}_{(x,y) \sim \text{labeled}} \log P_D[y|x, y \leq k] + \\ &\mathbb{E}_{x \sim \text{unlabeled}} \log P_D[y \leq k|x] + \\ &\mathbb{E}_{x \sim P_G} \log P_D[y = k + 1|x] \end{aligned}$$

With a perfect generator, the GAN performs no better than supervised learning. Instead, use a discriminator of the form $P_D(k|X) \propto \exp(w_k f(x))$ for some features f , with support in $\{z : \forall k p_k(z) \leq \varepsilon_k\}$ where p_k is the distribution, on feature space, of class k .

***Approximation and convergence properties
of generative adversarial learning***
S. Liu et al. (2017)

GAN-style algorithms are of the form

$$\inf_{\nu} \sup_{f \in \mathcal{F}} \mathbb{E}_{\substack{x \sim \mu \\ y \sim \nu}} [f(x, y)],$$

i.e., $\inf_{\nu} \tau(\mu \| \nu)$ for an *adversarial divergence* on X

$$\tau(\mu \| \nu) = \sup_{f \in \mathcal{F}} \mathbb{E}_{\mu \otimes \nu} [f],$$

for some $\mathcal{F} \subset \mathcal{C}_b(X^2)$.

For limited-capacity discriminators, the set of distributions μ^* minimizing $\tau(\mu \| \mu^*)$ is the set of distributions with generalized moments (depending on τ) matching those of μ .

***Learning to discover cross-domain relations
with generative adversarial networks***
T. Kim et al.

To convert images from one domain to another (e.g., bags to shoes), without paired data:

The measure of intelligence
F. Chollet

Intelligence is not “skill”, but “skill-acquisition efficiency”: the ability to turn prior knowledge and training data into skill.

For humans, priors (*Core Knowledge*) include objectness (elementary physics: the world is made of objects), agentness (goal-directedness), numbers and geometry.

Intelligence could be defined, for a fixed level of skill, as

$$\text{Intelligence} = \frac{\text{Skill} \times \text{Generalization Difficulty}}{\text{Prior} \times \text{Experience}},$$

averaged over training datasets (curriculum) and tasks. The factors can be defined from information theory (Kolmogorov complexity).

$$\text{Difficulty} = \frac{H(\text{Solution} | \text{Optimal solution})}{H(\text{Solution})}$$

$$\text{Prior} = 1 - \frac{H(\text{Solution})}{H(\text{Solution} | \text{Initial State})}$$

$$\text{Experience} = H(\text{Solution} | \text{IS}) - H(\text{Solution} | \text{Data}).$$

The abstraction and reasoning corpus (ARC) contains 1000 tasks, each with 3 or 4 examples, one test, and allows for 3 trials. The task is to complete a grid, using geometric principles not explicitly stated, from a few examples. Humans can solve the problems without any training – the geometric prior suffices.

Alternatives include video games (train on a level and test on others, train on a game and test on other similar games) or data science competitions (train on a few Kaggle dataset, test on others).

***Universal intelligence:
a definition of machine intelligence***
S. Legg and M. Hutter (2007)

Define the intelligence of a reinforcement learning algorithm π as its expected value,

$$\Upsilon(\pi) = \sum_{\mu \in E} 2^{-K(\mu)} V_{\mu}^{\pi},$$

where E is the set of environments to test and $K(\mu)$ the Kolmogorov complexity (approximated by the minimum description length and the running time) of environment μ (simple environments are more probable)

***Deep lattice networks
and partial monotonic functions***
S. You et al (2017)

Lattices (interpolated lookup tables, which can easily enforce monotonicity constraints) and calibrators (1-dimensional lattices) can be used as layers and activation functions.

***Scaling limits of wide neural networks
with weight sharing: Gaussian process
behaviour, gradient independence
and neural tangent kernel derivation***
G. Yang

Infinitely large, 1-layer neural nets with random weights are Gaussian processes.

***Identity crisis:
memorization and generalization
under extreme overparametrization***
C. Zhang

When asked to reconstruct a *single* example,

- Some networks (FC) learn the constant function (memorization);
- Some (shallow CNN) learn the identity function (generalization).

***Spectrally-normalized margin bounds
for neural networks***
P.L. Bartlett et al.

The *spectral complexity* of a network is

$$R = \left(\prod \rho_i \|A_i\|_{\sigma} \right) \left(\sum \frac{\|A'_i - M'_i\|_{2,1}^{2/3}}{\|A_i\|_{\sigma}^{2/3}} \right)^{3/2}$$

where ρ_i is the Lipschitz constant of the nonlinearity of layer i , $\|A_i\|_{\sigma}$ is the spectral norm of the weight matrix A_i , M_i is a reference matrix (e.g., $M_i = 0$, or $M_i = I$ for ResNets), $\|A\|_{p,q}$ is the (p, q) matrix norm

$$\left\| (\|A_{\cdot 1}\|_p, \dots, \|A_{\cdot m}\|_p) \right\|_q.$$

It is lower for networks that generalize better. For multiclass classification, we expect the normalized margin

$$\frac{f(x)_y - \max_{i \neq y} f(x)_i}{R \cdot \|x\|_2 / n}$$

to increase as generalization improves.

***Not all samples are created equal:
deep learning with importance sampling***
A. Katharopoulos and F. Fleuret

When training a neural net, *importance sampling* helps focus the computations on informative examples, but the importance, the per-sample gradient, is expensive to compute – try $\|\nabla_{x_i^L} \text{Loss}\|$ instead, where i is the sample and x^L the activation of the last layer.

***Deep, skinny neural networks
are not universal approximators***
J. Johnson (2019)

Skinny networks (the dimension of the hidden layers never exceeds that of the input) cannot approximate functions with a level set containing a bounded connected component.

***PaperRobot:
incremental draft generation of scientific ideas***
Q. Wang et al.

Extract entities (gene, disease, chemical) and relations (marker, therapeutic, increased expression, etc.) from research papers to build a knowledge graph (KG); use both graph structure and contextual (text) embeddings of the nodes to forecast missing links; use them to automatically write papers: entities+relations \rightarrow title \rightarrow abstract \rightarrow conclusion and future work \rightarrow next article \rightarrow etc.

Attention is not explanation
S. Jain and B.C. Wallace

Attention weights need not be correlated with importance measures: it is possible to change them to meaningless ones without impacting performance.

Are sixteen heads really better than one?
P. Michel et al.

Multiple attention heads (in transformer networks, e.g., BERT) are useful during training but most layers can be pruned to a single head without a significant drop in performance.

***Fair is better than sensational:
man is to doctor as woman is to doctor***
M. Nissim et al. (2019)

The code used to compute analogies of the form “doctor + woman – man = nurse” excludes one of the inputs (“doctor”) and even similar items (“gynecologist”, etc.).

***A kernel for time series
based on global alignments***
M. Cuturi et al. (2006)

Dynamic time-warp (DTW), Smith-Waterman local alignments and edit distance do not readily lead to a positive definite kernel.

Gaussian and polynomial kernels are not satisfactory either: they cannot deal with time series of different lengths and ignore the time series structure.

Taking the best alignment (with no gaps but possible repetitions: gaps make more sense for biological sequences, repetitions for time series, e.g., speech) does not give a positive definite kernel, but combining them all often does:

$$\begin{aligned} S(\pi) &= \text{score of alignment } \pi \\ \kappa(x, y) &= \sum_{\pi} e^{S(\pi)} \\ &= \sum_{\pi} \exp \sum_i \phi(x_{\pi_1(i)}, y_{\pi_2(i)}) \\ &= \sum_{\pi} \prod_i \exp \phi(x_{\pi_1(i)}, y_{\pi_2(i)}). \end{aligned}$$

The kernel can be computed in $|x| \cdot |y|$ iterations by dynamic programming (as for DTW).

Natural language understanding
C. Potts et al. (2019)

Vector space models require several choices:

- Design matrix: word \times document, word \times word, word \times context, etc.;
- Reweighting, to “de-emphasize the mundane and the quirky”: probabilities, length normalization, TF-IDF, PMI, PPMI, T-test (prefer PMI);

$$\text{PMI} = \log \frac{\text{observed}}{\text{expected}} = \log \frac{X_{ij}}{X_{i.} X_{.j} / X_{..}}$$

- Dimension reduction: PCA, LSA, PLSA, LDA, NMF, etc.
- Vector comparison: Euclidean, cosine, Dice, Jaccard, KL, etc. (prefer cosine).

Large, flat windows capture semantic information, small, scaled windows syntactic (collocational) information.

GloVe learns word vectors such that

$$\langle u | v \rangle \propto P(u, v);$$

more precisely, they minimize

$$\sum_{ij} f(X_{ij})(w'_i \tilde{w}_k + b_i + \tilde{b}_k - \log X_{ik})$$

where $f(x) = \text{Min}\{(x/x_{\max})^\alpha, 1\}$, $x_{\max} = 100$, $\alpha = .75$.

Word2Vec learns word embeddings such that

$$P(b|a) \propto \exp(w_a w_b).$$

Maximizing the likelihood is problematic because of the denominator,

$$\text{Argmax}_{x,w} \sum_{a \sim b} \log \frac{\exp(x_a w_b)}{\sum_c \exp(x_a w_c)}.$$

Instead, use *noise contrastive estimation*

$$\sum_{a \sim b} -\log \sigma(x_a w_b) + \sum_{a, b} \log \sigma(x_a w_b).$$

Retrofitting modifies the word vectors to incorporate information (e.g., sentiment, WordNet) from a *knowledge graph*.

$$\text{Minimize} \sum_q \|q_i - \hat{q}_i\|^2 + \sum_{(i,j) \in E} \beta_{ij} \|q_i - q_j\|^2$$

To compare models, use the Wilcoxon signed rank test, if you run several experiments, or the *McNemar*, to compare confusion matrices, if you cannot.

Features for sentiment analysis could include: bag of subparts (subtrees with at most k leaves), negation (add `_NEG` to all the tokens until the end of the subtree – idem for other modifiers: *might*, etc.), lexicon-derived features, modal adverbs (totally, quite possibly, etc.), non-literal language, character n -grams, tf-idf, part-of-speech, sentence length, GloVe, etc. Use BERT (pretrained and fine-tuned) or a BiLSTM with subtree labels, or manual features

Distant supervision builds training data for the relation extraction problem from a knowledge base (database of known relations), assuming that, for each known relation, any sentence mentioning both entities expresses that relation.

For natural language inference (entailment), try the following features: words that appear in both clauses, words that appear in either clause, wordnet features (pairs of words, in the first and second clause, with $w_1 \succ w_2$ or $w_1 \preceq w_2$, edit distance, negation, models, quantifiers (every, some), named entities.

Given the hidden states for the words in the first, resp. second, clause, h_1, h_2, h_3 , resp. h_A, h_B, h_C , the **attention mechanism** is

Scores	$\tilde{\alpha} = [h'_C h_1; h'_C h_2; h'_C h_3]$
Attention	$\alpha = \text{softmax } \tilde{\alpha}$
Context	$\kappa = \text{mean}(\alpha_1 h_1, \alpha_2 h_2, \alpha_3 h_3)$
Combination	$\tilde{h} = \tanh([\kappa; h_C]W)$
Classifier	$y = \text{softmax}(\tilde{h}W + b).$

Other score functions are possible: $h'_C h_i$, $h'_C W h_i$ or $W[h_C; h_i]$.

Language understanding requires *grounding*: many utterances depend on the context (“there aren’t any”), so do answers (“Where are you from?”) and even modals (is “The door must be open” a rule or a deduction?).

In the **rational speech act** (RSA) model, the listener has a model of how the speaker thinks, and conversely.

$$\begin{aligned} \ell_0(\text{world}|\text{text}) &\propto \text{language}(\text{text}, \text{world}) \cdot P(\text{world}) \\ s_1(\text{text}|\text{world}) &\propto \left(\frac{\ell_0}{C(\text{word})} \right)^\lambda \\ \ell_1(\text{world}|\text{text}) &\propto s_1(\text{text}|\text{world}) P(\text{world}) \end{aligned}$$

literal listener = lexicon \times prior

pragmatic speaker = literal speaker – message costs

pragmatic listener = pragmatic speaker \times prior

Semantic parsing transforms text into a formal language, suitable for constraint satisfaction solvers.

The F_β evaluation metric is a weighted harmonic average of recall (weight β^2) and precision (weight 1); use $\beta = 1$ or 0.5; for multiclass classification, the *macro* F_β is the (unweighted) average of the F_β ’s for each class.

Check if your model performs well in an adversarial setting:

- Add a misleading sentence to the input;
- Replace a word with synonym, a more general word, a comparable word (co-hyponym);
- Swap subject and object;
- Move an adjective to another noun phrase;
- Add negations; add a negation and swap subject and object (contrapositive).

Easy data augmentation uses simple changes:

- Synonym replacement;
- Random insertion: take a word in the sentence and put another copy of it somewhere else;
- Random swap;
- Random deletion.

Back-translation also provides data augmentation.

Language models provide *contextual embeddings*:

- ELMo, a biLSTM with highway layers to forecast the next word
- Transformers use multi-headed self-attention, position embedding, dropout, residual connections and layer normalization
- BERT is a masked language model, with a small vocabulary (subwords), position embedding, using CNNs with several perceptive fields and max pooling.

To probe black-box models, take the word or sentence representation and check if you can predict, with a shallow network: sentence length, which word is present, tense, POS, named entities, semantic information (anything from WordNet, sentiment, entailment, etc.), tense. Alternatively, change something in the sentence (tense, word order by swapping two consecutive words) and see how the representation changes.

Linear algebraic structure of word senses, with applications to polysemy S. Arora et al.

Use *sparse coding* (and alternating minimization) to decompose a given word embedding $w \mapsto v_w$ into disambiguated embeddings, $\alpha_{w,i} A_i$,

$$v_w = \sum_i \alpha_{w,i} A_i + \text{noise}$$

where the $\alpha_{w,\cdot}$ are sparse; the A_i ’s are the contexts (“atoms of discourse”).

**Contextual string embeddings
for sequence labelings**
A. Akbik et al.

A character-level (BiLSTM) language model provides *contextualized* word embeddings (somehow aggregate the hidden states corresponding to the word letters), which can be fed to another BiLSTM for named entity recognition (NER) or some other labeling task.

**Machine translation
with weakly paired bilingual documents**
(2019)

Use weakly-aligned documents (e.g., matching Wikipedia articles) to train a machine translation model: find matching sentences from the cosine similarity of their bag-of-word embeddings, from a multilingual word embedding (MUSE).

**A syntactic neural model
for general-purpose code generation**
P. Yin and G. Neubig

When translating natural language into code, do not directly use a sequence-to-sequence model: translate into an AST (abstract syntax tree) instead, to ensure the code is syntactically correct.

Data from manually-annotated Django code, a card game, and an automation app.

**Neural machine translation
and sequence-to-sequence models: a tutorial**
G. Neubig (2017)

Tutorial, with exercises, covering count-based n -gram language models

$$P[e_{1:n}] = \prod_i P[e_i | e_{1:i-1}]$$

$$\approx \prod_i P[e_i | e_{i-k:i-1}],$$

with modified Kneser-Ney smoothing, log-linear models (with features ϕ and a softmax)

$$P[e_{1:n}] \approx \prod_i P[e_i | \phi(e_{i-k:i-1})],$$

neural networks (idem, but non-linear), RNNs, Seq2seq and attention.

**A regularized framework for sparse
and structured neural attention**
V. Niculae and M. Blondel

The maximum

$$\text{Max}^* y = \begin{cases} 0 & \text{if } y \in \Delta \\ \infty & \text{otherwise} \end{cases}$$

$$\text{Max } x = \text{Max}^{**} x = \sup_{y \in \Delta} y'x$$

can be regularized

$$\text{Max}_\Omega^* y = \begin{cases} \gamma \Omega(y) & \text{if } y \in \Delta \\ \infty & \text{otherwise} \end{cases}$$

$$\text{Max}_\Omega x = \text{Max}_\Omega^{**} x = \sup_{y \in \Delta} y'x - \gamma \Omega(y).$$

The softmax can be generalized to

$$\Pi_\Omega(x) = \underset{y \in \Delta}{\text{Argmax}} y'x - \gamma \Omega(y) = \nabla \text{Max}_\Omega(x).$$

The softmax attention mechanism yields dense weights: sparsemax gives sparse weights, fusedmax sparse continuous weights, oscarmax clustered weights regardless of position.

$$\Omega(y) = \sum y_i \log y_i \quad \text{negentropy}$$

$$\Pi_\Omega(x) = \frac{\exp(x/\gamma)}{\sum \exp(x_i/\gamma)} \quad \text{softmax}$$

$$\Omega(y) = \frac{1}{2} \|y\|_2^2$$

$$\Pi_\Omega(x) = \underset{y \in \Delta}{\text{Argmin}} \|y - x/\gamma\|^2 \quad \text{spacemax}$$

$$\Omega(y) = \frac{1}{2} \|y\|_2^2 + \lambda \sum \|y_{i+1} - y_i\| \quad \text{fused lasso}$$

$$\Pi_\Omega(x) = \underset{y \in \Delta}{\text{Argmin}} \|y - x/\gamma\|^2 + \lambda \sum \|y_{i+1} - y_i\|$$

$$\Omega(y) = \frac{1}{2} \|y\|_2^2 + \lambda \sum_{i < j} \text{Max}\{\|y_i\|, \|y_j\|\}$$

$$\Pi_\Omega(x) = \underset{y \in \Delta}{\text{Argmin}} \|y - x/\gamma\|^2 + \lambda \sum_{i < j} \text{Max}\{\|y_i\|, \|y_j\|\}$$

Searching for activation functions
P. Ramachandran et al.

Automated search for new activation functions, by combining 30+ common unary and binary functions, using an RNN trained with RL to explore the search space, suggests $\text{swish}(x) = x \cdot \text{sigmoid}(x)$.

Learning explanatory rules from noisy data
R. Evans and E. Grefenstette (2017)

Inductive logic programming (ILP) turns a set of positive and negative examples, e.g.,

$$P = \{0, 2, 4, 6, 8, \dots\}$$

$$N = \{1, 3, 5, 7, 9, \dots\}$$

into rules, e.g.,

$$\begin{aligned}\text{even}(X) &\leftarrow \text{zero}(X) \\ \text{even}(X) &\leftarrow \text{even}(Y) \wedge \text{succ2}(Y, X) \\ \text{succ2}(X, Y) &\leftarrow \text{succ}(X, Z) \wedge \text{succ}(Z, Y).\end{aligned}$$

The consequences of a set of rules can be obtained by breadth-first search (*forward chaining*).

The top-down approach to ILP, which generates programs and tests them on the positive and negative examples, can be turned into a satisfiability problem, and relaxed into a continuous one (replace boolean values with number in $[0, 1]$), amenable to gradient descent (forward chaining is differentiable: only perform T steps of it).

***Image search using multilingual texts:
a cross-modal learning approach
between image and text***
M. Portaz et al.

Embed text (MUSE, a multilingual FastText extension) and images in the same latent space.

***Deep learning for image super-resolution:
a survey***
Z. Wang et al.

The different approaches include pre-upsampling ($\text{up} \cdot \text{conv}^k$), post-upsampling ($\text{conv}^k \cdot \text{up}$), progressive upsampling ($((\text{conv}^k \cdot \text{up})^n)$), iterative up-and-down-sampling ($((\text{conv} \cdot \text{up} \cdot \text{down})^n \cdot \text{up})$).

The upsampling can be nearest-neighbour, linear, bilinear, or a fractionally-strided convolution (“deconvolution”).

The network can have residual connections, dense connections, and parallel paths (as in inception modules).

Loss functions include pixel loss, content loss (hidden layer of some classifier), texture loss (Gram matrix of such a layer, as in style transfer), adversarial loss, cycle-consistency loss.

***EfficientNet: rethinking model scaling
for convolutional neural networks***
M. Tan and Q.V. Le (2019)

Scale your network as

$$\begin{array}{ll}\text{depth} & d = \alpha^\phi \\ \text{width} & w = \beta^\phi \\ \text{resolution} & r = \gamma^\phi\end{array}$$

where α, β, γ are determined by grid search and satisfy $\alpha^2 \beta^2 \gamma^2 = 2$, $\alpha, \beta, \gamma \geq 1$.

***Interactive sketch & fill: multiclass
sketch-to-image translation***
A. Ghosh et al. (2019)

GAN to convert partial sketches to complete sketches, and then complete sketches to images. The desired object class is enforced using channel-wise gates – conditional GANs tend to forget the input class. The data comes from occluded contours, automatically extracted from images.

***Measuring the tendency of CNNs to learn
surface statistical regularities***
J. Jo and Y. Bengio

CNNs to not recognize high-level features, but focus on statistical regularities: for instance, they are not robust to Fourier filtering.

***Deep normal estimation for automatic shading
of hand-drawn characters***
M. Hudon et al.

Use a CNN (U-net) to infer normals from (and automatically shade) hand-drawn 2D characters; training data from Blender’s *FeeStyle* (an edge- and line-based non-photorealistic (NPR) rendering engine).

Deformable convolutional networks
J. Dai et al.

Deformable convolution networks use deformed grids as filters (like *active convolution*), whose offsets are position-dependent, computed from the features of the previous layer.

When a neural net generates both a list of regions of interest (ROI) and (localized) features, *ROI pooling* pools the features in each ROI (the pooling regions do not have a fixed size), usually dividing the ROI into a regular grid. It can be deformed: deformable ROI pooling.

***In defence of the triplet loss
for person re-identification***
A. Hermans et al.

Person re-identification often uses the triplet loss

$$\sum_{\substack{i,j,k \\ y_i=y_j \\ y_i \neq y_k}} (m + d_{ij} - d_{ik})_+,$$

but since the number of triplets grows quadratically, *hard triplet mining* is necessary. Instead,

- Build a batch of P classes, with K images in each, and compute the loss for all resulting triplets, or only for the hardest positive and hardest negative for each anchor;
- Use the (non-squared) Euclidean distance;
- Use a soft margin (softplus).

***Variational image compression
with a scale hyperprior***
J. Ballé et al. (2018)

Variational autoencoders (VAE)

can be used for image compression

and trained by replacing the quantization with uniform additive noise

Have the variational distribution $p(\tilde{y})$ depend on the image x (or on the latent representation y).

SegNet: a deep convolutional encoder-decoder architecture for image segmentation
V. Badrinarayanan et al. (2016)

SegNet performs pixel-wise image segmentation by using

- An encoder (VGG16);
- Followed by a decoder, which upsamples the features using the *pooling indices* from the encoder’s pooling layers;
- Followed by a pixelwise classification layer.

ENet: a deep neural network architecture for real-time semantic segmentation
A. Paszke et al. (2016)

The EfficientNet (ENet) combines the following ideas to reduce the number of floating point operations when compared with VGG16: SegNet (pooling indices), early downsampling, decoder smaller than the encoder, *PReLU* instead of ReLU, pooling and convolution in parallel, *factorizing filters* (5×1 and 1×5 instead of 5×5), dilated convolutions, *spatial dropout*

(dropout all channels at random locations).

ShuffleNet: an extremely efficient convolutional neural network for mobile devices
X. Zhang et al. (2017)

The 1×1 convolutions are dense matrix multiplications: they are costly and can be replaced with block-diagonal matrices (“pointwise group convolutions”) and (random) permutation matrices (“channel shuffle”).

ShuffleSeg: real-time semantic segmentation network
M. Gamal et al. (2018)

RepPoint point set representation for object detection
Z. Yang et al. (2019)

Rectangular bounding boxes do not account for an object’s shape and pose. Instead, use a set of (9) points, inside the object, computed with a feature pyramidal network (FPN) with deformable convolutions, trained with a localization loss (it should give the same bounding box) and a recognition loss.

Complex-YOLO: an Euler-region-proposal for real-time 3d object detection on point clouds
M. Simon et al. (2019)

To feed Lidar data to a YOLO network to find 3D bounding boxes, discretize the cloud of points into a top-view image, with 3 channels: maximum height, maximum intensity, number of points. For the orientation of the boxes, output a complex number of modulus 2 instead of an angle to avoid singularities.

Oriented response networks
Y. Zhou et al.

To detect rotation-invariant patterns, and keep track of their orientation, consider N rotations of a given filter (sharing the same parameters).

**Limitations
of the empirical Fisher approximation**
F. Kunstner et al.

The *empirical Fisher*

$$\sum_n \nabla_{\theta} \log p_{\theta}(y_n|x_n) \nabla_{\theta} \log p_{\theta}(y_n|x_n)'$$

is not a good approximation of the Fisher information matrix

$$\sum_n \mathbb{E}_{y \sim p_{\theta}(\cdot|x_n)} [\nabla_{\theta} \log p_{\theta}(y_n|x_n) \nabla_{\theta} \log p_{\theta}(y_n|x_n)']$$

Do not use it for natural gradient descent [but it is still better than plain gradient descent].

**Model compression
by entropy penalized reparametrization**
D. Oktay et al.

To compress the weights of a neural net, **scalar quantization** discretizes each coordinate independently, while **vector quantization** uses some clustering algorithm (e.g., *k*-means).

Learn another network to generate weights from a low-dimensional, discrete (scalar quantization) latent representation (hypernetwork) with a penalty for the length of the Shannon-encoded latent representation (entropy).

**Learning relational representations
with auto-encodding logic programs**
S. Dumančić et al.

An auto-encoder, with (Prolog) facts as input and latent representation, and (inverse) logical (Prolog) programs as encoder and decoder can be learnt using constraint satisfaction tools (large neighbourhood search: BUSL learner for Markov logic networks (MLN)), minimizing the reconstruction error with constraints on

- The average number of facts per predicate;
- Redundancy (if $c_1 \models c_2$, include at most one);
- Coverage (reconstruct at least one of each predicate).

**Joint semantic analysis and
morphological analysis of the derived word**
R. Cotterell and H. Schütze

Estimate word embeddings by modeling the derivation of words, e.g.,

questionably = question:stem + able:suffix + ly:suffix.

Relational knowledge distillation
W. Park et al.

To distill a (teacher) model (into a student model), do not just try to reproduce the individual outputs, but also the distances and angles.

**Interacting conceptual spaces I:
grammatical composition of concepts**
J. Bolt (2016)

Many grammars can be modeled as a monoidal category \mathfrak{G} , with reduction rules (e.g., noun \otimes verb \otimes noun \rightarrow sentence) as morphisms. To model the meaning of sentences from that of words, learn:

- A word embedding Words $\rightarrow V$;
- A monoidal functor $\mathfrak{G} \rightarrow \mathfrak{Vect}$.

The category of vector spaces can be replaced by that of convex sets and relations (more generally: convex algebras and convex relations).

Byzantine-tolerant machine learning
P. Blanchard et al.

Distributed stochastic gradient descent is not tolerant to Byzantine failure: use the vector closest to the average of its $n - k$ neighbours.

**Solving ill-posed inverse problems
using iterative deep neural networks**
J. Adler and O. Öktem (2017)

Use deep neural networks to find an approximate inverse of $T : X \rightarrow Y$, minimizing

$$\mathbb{E}_{\substack{x \sim \text{data} \\ y = Tx}} [\text{Loss}(TT_{\theta}^{-1}y, y) + \text{Penalty}(T_{\theta}^{-1}y)].$$

Snapshot ensembles: train 1, get M for free
G. Hunag et al. (2017)

Use a cyclic learning rate and ensemble the local minima found during the optimization.

Personalized re-ranking for recommendation
C. Pei et al. (2019)

Reranking models, to transform a list of search results, sorted by their closeness to a query (or the estimated probability that the user will click on it), should be reranked to account for interaction (e.g., to ensure diversity and avoid redundant results). The reranking model takes, as input, features of the items, their positions, possibly user-specific item features (a learned user-specific linear transformation of the item features). It is often an RNN generating a sequence of scores, along which to sort the items, but it can be replaced with a transformer with attention.

**FreezeOut: accelerate training
by progressively freezing layers**
A. Brock et al.

Freeze the first layers of the network after a while: they converge faster, to simple configurations (e.g., edge detectors).

Stochastic depth, in a resnet, drops whole layers at a time.

On connected sublevel sets in deep learning
Q. Nguyen (2019)

If there are enough hidden neurons (half as many in the first hidden layer as training samples), then the sublevel sets of the loss function are connected – in particular, the set of global minima is connected.

**A constructive approach
for one-shot training of neural networks
using hypercube-based topological coverings**
W.B. Daniel and E. Yeung

Decision trees are special cases of neural nets (and can be used to initialize them or choose their topology): decision boundaries are ReLU operations.

**Anchors:
high-precision model-agnostic explanations**
M.T. Ribeiro et al. (2018)

To explain a model forecast, find a single rule of the form $a_1 \wedge \dots \wedge a_k$, with beam search, which applies to the observation of interest (local), but with high (global) precision and decent coverage.

Contrary to purely local explanations (LIME), anchors give correct forecasts with high probability whenever they apply.

Axiomatic attribution for deep neural networks
M. Sundararajan et al. (2017)

Attribution of the output of a neural net to input features should be

- Sensitive: if x_1 and x_2 only differ by one feature and $f(x_1) \neq f(x_2)$, then this feature's contribution should be non-zero;
- Implementation-invariant: two different neural nets computing the same function should have the same contributions.

Integrated gradients (along a rectilinear path, between a baseline input, e.g., a black image, and the image of interest) satisfy those conditions.

**BOHB: robust and efficient
hyperparameter optimization at scale**
S. Falkner et al. (2018)

Hyperband uses *successive halving* for hyperparameter tuning:

- Pick N configurations at random;
- Train them for a while;
- Discard the worst half;
- Train the remaining models for a while;
- Continue until only one is left.

BOHB uses Bayesian optimization to replace the configurations at the beginning of each HB iteration.

**Fixup initialization:
residual learning without normalization**
H. Zhang et al. (2019)

Initialize the classification layer, the last layer of the residual branches, and the biases to zero; rescale the other residual layers by \sqrt{L} , where L is the number of layers (or $L^{1/2(m-1)}$, if there are m layers in the residual blocks).

**Geometric matrix completion
with recurrent multi-graph networks**
F. Monti et al. (2017)

Matrix completion is often done with a low-rank approximation, or its relaxation with the nuclear norm (sum of the singular values)

$$\begin{aligned} & \underset{X}{\text{Minimize}} \text{rank}(X) + \lambda \|\Omega \odot (X - Y)\|_F^2 \\ & \underset{X}{\text{Minimize}} \|X\|_* + \lambda \|\Omega \odot (X - Y)\|_F^2. \end{aligned}$$

Given a user-item matrix, consider the corresponding row (user) and column (item) similarity graphs, and their Laplacians

$$\begin{aligned} \Delta_r &= \Phi_r \Lambda_r \Phi_r' \\ \Delta_c &= \Phi_c \Lambda_c \Phi_c'. \end{aligned}$$

The *geometric completion* problem is

$$\underset{X}{\text{Minimize}} \|X\|_{\Delta_r}^2 + \|X\|_{\Delta_c}^2 + \lambda \|\Omega \odot (X - Y)\|_F^2$$

where the **Dirichlet norm** is $\|X\|_{\Delta} = \text{trace}(X' \Delta X)$. Define the Fourier transform and the convolution as

$$\begin{aligned} \hat{X} &= \Phi_r' X \Phi_c \\ X * Y &= \Phi_r (\hat{X} \odot \hat{Y}) \Phi_c' \end{aligned}$$

and approximate the filter Y with Chebychev polynomials

$$\tilde{X} = \sum_{0 \leq i, j \leq p} \theta_{ij} T_i(\tilde{\Delta}_r) X T_j(\tilde{\Delta}_c)$$

where $\tilde{\Delta} = 2\lambda_n^{-1} \Delta - I$ are the rescaled Laplacians, with eigenvalues in $[-1, 1]$.

Train such a *multi-graph CNN* (MGCNN) for geometric matrix completion, and feed its features to an RNN.

***Probabilistic matrix factorization
for automated machine learning***
N. Fusi et al.

AutoML can be framed as a recommendation problem, matching datasets (users) to ML pipelines (items), with matrix factorization to recommend pipelines, or with *probabilistic matrix factorization* to optimize an acquisition function (as in Bayesian optimization).

Probabilistic matrix factorization
R. Salakhutdinov and A. Mnih

Matrix factorization $R \approx U'V$ can be made Bayesian

$$\underset{U,V,\sigma}{\text{Argmax}} \prod_{\substack{i \text{ user} \\ j \text{ item} \\ i \text{ rated } j}} \phi(R_{ij}, \mu = U'_i V_j, \sigma^2)$$

***Graph2Seq: graph to sequence learning
with attention-based neural networks***
K. Xu et al.

Estimate a node embedding by

- Aggregating neighbour features (with mean, LSTM on random permutations of the neighbours, separating inbound and outbound neighbours, or element-wise max of a 1-layer neural net);
- Concatenate with the node features;
- Feed to a 1-layer neural net to get new node features;
- Iterate 3 to 5 times (with different aggregators and neural nets).

Convert it to a graph embedding with an elementwise max/min/mean, and feed this graph representation to a sequence generator with attention.

***CayleyNets: graph convolutional neural
networks with complex rational spectral filters***
R. Levie et al. (2017)

In the (spectral) graph convolution $f \mapsto \Phi g(\Lambda) \Phi' f$, where $\Delta = \Phi \Lambda \Phi'$ is the eigen decomposition of the Laplacian Δ and $f \mapsto \hat{f} = \Phi' f$ the Fourier transform, do not model g with Chebychev polynomials (a high degree is needed to produce narrow-band filters – in presence of communities, eigenvalues tend to cluster) but with Cayley “polynomials” $\lambda \mapsto \text{Re } C(h\lambda)^k$ where the Cayley transform is

$$\begin{cases} \mathbf{R} & \longrightarrow e^{i\mathbf{R}} \setminus \{1\} \\ \lambda & \longmapsto \frac{\lambda - i}{\lambda + i} \end{cases}$$

and h a zoom parameter.

***Amplifiers and suppressors of selection
for the Moran process in undirected graphs***
G. Giakkoupis (2018)

The **Moran process** models the spread of genetic mutations on a graph:

- Start with a single mutant node;
- Pick a node at random, with probability proportional to its fitness (1 for non-mutants, $r > 1$ for mutants);
- The node copies itself to one of its neighbours.

There exist families of (directed or undirected) graphs for which

- The probability of fixation tends to 1 (strong amplifier);
- The probability of extinction tends to 0 (strong suppressor).

***A unified framework
for structured graph learning
via spectral constraints***
S. Kumar et al.

Using the Laplacian, add constraints to the graphical lasso (for graph reconstruction from a covariance matrix) to make the graph bipartite, regular, or to specify the number of connected components.

***Multi-dimensional count sketch:
dimension reduction
that retains efficient tensor operations***
Y. Shi and A. Anandkumar

The **count sketch**

$$\text{CS}(x) = \left(\sum_{h(i)=j} s_i x_j \right)_j = (s \odot x)' H$$

can be generalized to tensors

$$\text{MS}(T) = ((s_1 \otimes \cdots \otimes s_p) \circ T)(H_1, \dots, H_p)$$

where $T \in \mathbf{R}^{n_1 \times \cdots \times n_p}$, $s_i \in \{\pm 1\}^{n_i}$, $H_i \in \{0, 1\}^{n_i \times m_i}$ with exactly one 1 in each row.

***Gorilla: a fast, scalable, in-memory
time series database***
T. Pelkonen et al. (2015)

In 2013, Facebook moved from an HBase-backed OpenTSDB-like time series database to an in-memory one (for the last 26 hours, HBase for the rest), using

- Delta of delta (variable length encoding) compression for timestamps: observations are almost equally spaced;
- XOR encoding (and VLE compression) for numeric values: nearby values are often close, and share the beginning of the mantissa, the exponent, and sometimes the precision.

Also check InfluxDB (no Hadoop required, distributed, metadata), OpenTSDB (HBase, metadata), Whisper (aka Graphite, regularly-spaced data, RDD, on-disk), M3DB (from Uber).

Towards understanding generalizations of deep learning: perspective of loss landscapes
L. Wu et al.

Minima whose bassins of attraction have a larger volume generalize better (and are more likely to be reached after random initialization).

Loss landscapes of regularized linear autoencoders
D. Kunin et al. (2019)

Linear autoencoders are GL_k -invariant: they learn the subspace spanned by the first k principal directions, but not the separate directions. L^2 -regularized linear encoders do.

A PCA-like autoencoder
S. Ladjal et al. (2019)

To make the coordinates of the latent space of an autoencoder more interpretable and independent:

- Iteratively increase the dimension of the latent space, keeping the already learned dimensions fixed (discard and learn the decoder anew each time);
- Add a penalty for the (off-diagonal) covariances.

Fader networks: manipulating images by sliding attributes
G. Lample et al. (2018)

To train an autoencoder some of whose latent space coordinates have a pre-specified interpretation (e.g., presence of glasses, beard, etc.), add the interpretable feature to the latent space, and ensure it is not present in the rest of the latent representation with a discriminator $D : z \mapsto y$ and an adversarial loss.

Early visual concept learning with unsupervised deep learning
I. Higgins et al.

In the latent factor model

$$\text{Maximize}_{\phi, \theta} \mathbb{E}_{z \sim q_{\phi}(z|x)} [\log p_{\theta}(x|z)]$$

the β -VAE adds a constraint or penalty to make the latent representation q_{ϕ} close to a prior, e.g., $p \sim N(0, 1)$, to “disentangle” it.

$$\text{Maximize}_{\phi, \theta} \mathbb{E}_{z \sim q_{\phi}(z|x)} [\log p_{\theta}(x|z)] - \beta \cdot \text{KL}(q_{\phi}(z|x) \| p(z))$$

The original VAE corresponds to $\beta = 1$.

CorrGAN: sampling realistic financial correlation matrices using generative adversarial networks
G. Marti (2019)

GAN to generate *reordered* (with hierarchical clustering) correlation matrices.

Estimation of theory-implied correlation matrices
M. López de Prado (2019)

A hierarchical classification (e.g., GICS) can improve the estimation of the correlation matrix:

- Compute the sample correlation matrix;
- Represent the hierarchy as a tree and use the correlations to define distances between nodes, using $d = \sqrt{\frac{1}{2}(1 - \rho)}$;
- Compute the distances between all pairs of leaves, and convert them back to “correlations”, using $\rho = 1 - 2d^2$;
- Clean the resulting matrix (it may not even be positive definite) using random matrix theory (RMT).

DeepTraX: embedding graphs of financial transactions
C.B. Bruss et al. (2019)

Project the credit card (bipartite) transaction graph to only keep merchants and compute a random-walk based vector embedding (DeepWalk, Node2vec); use as additional features in fraud detection systems.

Testing for multiple bubbles 1: historical episodes of exuberance and collapse in the S&P 500
P.C.B. Phillips et al. (2013)

The SADF test,

$$\text{SADF} = \sup_{0 < t_0 \leq t \leq 1} \text{ADF}_{[t_0, 1]},$$

to detect bubbles (explosive behaviour: bubble-less log-prices should be $I(1)$, not more) can be generalized to account for multiple bubbles by using a moving window (reset after each bubble) instead of an expanding one.

Decomposing value
J. Gerakos and J.T. Linnainmaa (2016)

Decompose the B/P into a component explained by past (5-year) size changes, and a residual – only the former leads to excess returns.

Time-dependent Black-Litterman
M. van der Schans and H. Stehouwer (2016)

Black-Litterman and Kalman filter can be combined: both are (linear, Gaussian) Bayesian updates.

***Listening to chaotic whispers:
a deep learning framework
for news-oriented stock trend prediction***
Z. Hu et al (2017)

Attention-based RNN, not for sequences of words, but for sequences of news (bags of (vector embeddings of words), to forecast trends.

Practical volume computation of structured convex bodies, and an application to modeling portfolio dependencies and financial crises
L. Calès et al. (2018)

The *cross-sectional score* of a portfolio is the probability that a random (uniform in Δ^d) portfolio has worse returns (or is worse for some other portfolio metric). It can be computed with a quasi Monte Carlo method. [This is a special case of P. Burns's random portfolios, which also account for portfolio constraints; the uniform distribution does not give insightful results if there are too many assets.]

Notes on Fano ratio and portfolio optimization
Z. Kakushadze and W. Yu

Daily and monthly Sharpe ratios are not comparable (because of the square root of time rule), but the mean-to-variance ratios (Fano ratios) are comparable across investment horizons. Fano-optimal portfolios are more diversified.

Nonlinearity in stock networks
D. Hartman and J. Hlinka (2018)

Differences between stock networks computed from correlation matrices and mutual information (which requires joint density estimation) may not come from nonlinearities but from non-stationarity and non-Gaussian margins.

Conic CPPI
I. Marquet and W. Schoutens (2017)

A 1-asset investment strategy can be seen as a reinforcement learning problem in which the state is described by the VIX and the current wealth. Instead of maximizing the expected future reward, for the real or the risk-free measure, one can maximize

$$\inf_{Q \in \mathcal{M}} E^Q[\text{future rewards}]$$

which can be computed as the expectation under a concave *distortion function*

$$\psi : [0, 1] \rightarrow [0, 1], \quad \psi(0) = 0, \quad \psi(1)$$

(*Choquet expectation*, expectation under a *non-additive probability*, to emphasize tail loss events and de-emphasize tail gain events)

$$E^\psi[Y] = - \int_{-\infty}^0 \psi(F_Y(y)) dy + \int_0^\infty (1 - \psi(F_Y(y))) dy.$$

The *min-max-var* family of distortion functions is

$$\psi(u) = 1 - (1 - u^{1/(1+\lambda)})^{1+\lambda}.$$

***Equity portfolio risk (volatility) estimation
using market information and sentiment***
L. Mitra et al. (2008)

Implied volatility and change in news sentiment (Ravenpack) have a predictive power in future volatility, and can be used as part of a factor risk model.

Indirect influences in international trade
R. Díaz and L. Gómez

To compute the influence of a country on the trade network, use

- PageRank
- The incidence matrix D (direct influence);
- MicMac: D^k ;
- The heat kernel: $\exp \lambda(D - I)$;
- PWP: $\expm1(\lambda D) / \expm1(\lambda)$

with the trade network

$$D_{A \rightarrow A} = \frac{\text{Exports}_{A \rightarrow B} + \text{Imports}_{B \rightarrow A}}{\text{Exports}_A + \text{Imports}_A}$$

or the offer network

$$D_{A \rightarrow A} = \frac{\text{Exports}_{A \rightarrow B} + \text{Imports}_{B \rightarrow A}}{\text{GDP}_A + \text{Imports}_A}.$$

Dissecting characteristics nonparametrically
J. Freyberger et al. (2017)

Spline regression, with a group lasso penalty, performs better than a linear model (with a lasso penalty) on uniformized variables. [I use GAM boosting to the same effect.]

Taming the factor zoo
G. Feng et al. (2017)

To check if a new factor adds value, to forecast returns, to an already large set of factors $(f_j)_j$, use the *double-selection lasso*:

- Select a small set of factors using the lasso, $(g_i)_i$;
- For each selected factor g_i , select factors f whose covariance with the returns r is correlated with $\text{Cov}(g_i, r)$, using the lasso: $\text{Cov}(g_i, r) \sim \text{Cov}(f, r)$;
- Use all those factors to test the new candidate.

The cross-section of risk and return
K. Daniel et al. (2018)

Separate the priced from the unpriced components of the Fama-French portfolios – removing the industry is sufficient.

***A review of portfolio choice
based on stochastic dominance***
T. Post (2017)

The integrated cdf, used to define stochastic dominance, is the expected shortfall (seen as a function of the threshold): a portfolio λ dominates a portfolio τ if its expected shortfall is better, for all thresholds – equivalently, if it is better for all (increasing, concave) utility functions.

***The dynamic factor model
with an application to global credit risk***
F. Bräuning and S.J. Koopman (2016)

Model the financial network (Granger causality tests for CDSs of US and European banks) as

$$\begin{aligned} f_t &: \text{factors (global, not observed)} \\ z_{ij} &: \text{factor loadings (constant)} \\ \theta_{ijt} &= z'_{ij} f_t \\ \phi_{ijt} &= \text{logistic}(\theta_{ijt}) \\ y_{ijt} &\sim \text{Bernoulli}(\phi_{ijt}) \text{ incidence matrices} \\ \gamma_i &\sim N(\mu, \Sigma) \\ \pi_i &\propto \exp(\gamma_i) \quad k\text{-dimensional} \\ \delta_{ij} &= \pi_i \otimes \pi_j \quad k^2\text{-dimensional} \\ z_{ij} &\sim \text{Multinomial}(\delta_{ij}) \\ f_{t+1} &= \Phi f_t + \xi_t \\ \xi_t &\sim N(0, \Sigma) \\ f_1 &\sim N(0, V) \\ V &= \Phi V \Phi' + \Sigma \end{aligned}$$

***Using dynamic model averaging in state space
representation with dynamic Occam's window
and applications to the stock and gold market***
M. Risse and L. Ohl (2016)

A time-varying regression can be modeled with a state space model and estimated with a Kalman filter; one can make some empirical changes to the variance matrix updates to simplify the computations (scalar variance matrix) or account for stochastic volatility.

Dynamic model averaging (DMA) estimates those models for subsets of the variables, whose forecasts can then be averaged (as in Bayesian model averaging, BMA), with weights depending on the previous weights (shrunk towards uniform weights) and the predictive density of each model.

The *dynamic Occam window* (DOW) does not consider all 2^K models but only a subset, updated at each time step, obtained by adding/removing variables to/from the current model and by keeping only the best ones (as with particle filters).

***Multiperiod portfolio selection
and Bayesian dynamic models***
P. Kolm and G. Ritter (2014)

Assume the transaction-cost-aware portfolio x_t and the ideal portfolio (TC=0) y_t are the hidden and observed states of a hidden Markov chain (HMM) with transition and emission probabilities

$$\begin{aligned} -\log p(x_t | x_{t-1}) &= c_t(x_{t-1}, x_t) \\ -\log p(y_t | x_t) &= \frac{1}{2} \lambda (y_t - x_t)' \Sigma (y_t - x_t). \end{aligned}$$

Treat one asset at a time, in a Gibbs fashion, until convergence (blockwise coordinate descent).

For time, either treat the periods one at a time, or use a particle filter.

Volatility trading
E. Sinclair (2013)

2. There are many measures of volatility (standard deviation of the Brownian motion (with drift and jumps) modeling log-prices): standard deviation of the log-returns (the sample variance gives a biased estimator of volatility: $E[\sqrt{s^2}] < \sqrt{E[s^2]}$, but it can be corrected if we assume Gaussian log-returns), from the absolute returns $\sigma = \sqrt{\frac{\pi}{2}} E[|r|]$, from OHLC data (they can account for drift and jumps, but the true high and low are not observed: these estimators under-estimate volatility), or from high-frequency data (by looking at the time τ needed to achieve a fixed change in price Δ – it is biased, but the bias can be corrected).

There is microstructure noise if the frequency is too high.

Volatility varies through the day.

3. Stylized facts include: volatility clustering, mean reversion ($\sigma_{\text{daily}} > \sigma_{\text{weekly}}$), leverage ($\text{Cor}(\sigma, r) < 0$, with an even lower value if $r < 0$), $\text{Cor}(\sigma, \text{volume}) > 0$, $\sigma \sim \text{LogGaussian}$.

4. Volatility can be forecasted with a GARCH(1,1) model, or its many variants. It can also be compared with the *volatility cone*, the quantiles of the realized volatility as a function of the window size. Overlapping windows give biased estimators, but the bias can be corrected (Hodges-Tompkins).

Fundamental data has some predictive power on volatility: R&D, cash flow volatility, accruals, size, ROA, leverage.

Implied volatility is usually above the volatility forecasts (by 30%): this *variance premium* can sometimes be explained by higher moments.

$$\left(\frac{\text{IV}}{\text{RV}} \right)^2 \approx 1 - \gamma \sigma \text{skew} + \frac{1}{2} \gamma^2 \sigma^2 (\kappa - 3), \quad \gamma = \text{risk aversion}$$

5. PCA suggests that 60% to 80% of the changes in the volatility surface are due to parallel shifts: it suffices to look at ATM IV (but it is tricky to compute: there

is no ATM strike, there is no exact 1-month maturity, there are calls and puts, there are bid and ask prices – interpolate or use the VIX).

volatility surface : $IV \sim \text{strike} + \text{expiry}$
 volatility smile (skew) : $IV \sim \text{strike} |, \text{expiry}$
 volatility term structure : $\text{ATM } IV \sim \text{expiry}$

The VIX is mean reverting (if it were tradable, we could make a profit).

Implied volatility rises before earnings announcements and falls afterwards: buy a front-month straddle 10 days before, sell 1 day before; this is more profitable if analyst dispersion is high (but also look at other firm characteristics). More generally, regardless of the underlying, volatility rises before (planned) news. The expected jump size can be estimated by comparing the IV of the front and second months,

The movement of the IV smile is often described heuristically, as a *sticky strike* (fixed skew: the IV, as a function of the strike, does not change) or a *sticky delta* (floating skew, swimming skew: the IV, as a function of delta, does not change). Each gives rise to an arbitrage: delta-neutral call spread, and delta-neutral OTM call minus put.

The smile, which can be rescaled as $IV/IV_{\text{ATM}} \sim \Delta$, can be explained by differences in supply and demand, presence or absence of hedging (market makers vs other actors), correlation (for indices), skewness, Kurtosis.

The Corrado-Su formula extends the Black-Scholes model to include skewness and kurtosis and explain the smile; it can be used to compute implied skewness and kurtosis.

Back-month IV often over-reacts (Stein effect).

6. Continuous hedging, to ensure $\Delta = 0$, is too costly (the transaction costs are non-zero) and impossible (because of the bid-ask spread). Heuristics include: hedging at regular intervals, hedging to a delta band, hedging when the spot changes.

The trade-off between cost and risk can be measured with a utility function, e.g., $U(w) = -e^{-\gamma w}$, which has a constant risk aversion $\gamma = U''/U'$.

The *Hodges-Neuberger* model does not price the option, but the replication strategy, and includes transaction costs; it only hedges so that the trader be indifferent between the risk of the mis-hedged position and the hedging cost – it re-hedges when Δ leaves a band around/near the Black-Scholes delta. There is no closed-form solution, but an asymptotic, incorrect (centered, symmetric) formula (Whalley-Wilmott) if the transaction costs are small. Zakamouline provides a heuristic (fitted) approximation of the HN bands.

Market impact is

$$F(n) = \text{volatility} \times \sqrt{\text{proportion of the ADV}}.$$

To reduce costs, try to hedge a position on a stock with an index, using β , after aggregating all positions.

To account for jumps, consider static hedging (with other options) rather than dynamic hedging,

7. The P&L is path-dependent.

$$\text{P\&L} = \frac{1}{2}(IV^2 - RV^2) \int e^{-rt} S_t^2 \Gamma dt$$

We do not know the volatility, but prefer it to be biased upward or downward, depending on the market and Γ .

	$\Gamma < 0$	$\Gamma > 0$
trend	low	high
no trend	high	low

We do not hedge continuously.

$$E[\text{P\&L}] = \text{Vega} \times (\sigma_{\text{implied}} - \sigma_{\text{realized}})$$

$$\text{Sd}[\text{P\&L}] \approx \sqrt{\frac{\pi}{4}} \text{Vega} \frac{\sigma}{\text{number of hedges}}$$

8. Trade sizing is often done heuristically (fixed trade size, fixed fraction size).

The **Kelly criterion** can help: take successive iid bets on a fraction of your wealth, win (resp. lose) with returns w (resp. ℓ) with probability p ; after n wins and m losses, your wealth is $w_0(1+fw)^n(1-f\ell)^m$; maximize the expected utility, assuming logarithmic utility:

$$f = \frac{pw + (1-p)\ell}{w\ell}.$$

This can be generalized to continuous outcomes: $f \approx r/\sigma^2$.

While optimal in the long term, trading at the Kelly rate is a very volatile strategy, which can take centuries or millennia to beat other strategies – many suggest trading a fraction of the Kelly rate (never more: both returns and volatility would be worse).

There are many progressive betting systems: positive (increase your bet after you win, e.g., Kelly), negative (increase your bet after you lose) or mixed (Oscar: bet one unit; if you lose, bet the same amount; when you win, increase the amount by 1; stop when you have won one unit).

Browne dynamic sizing maximizes the probability of reaching a target wealth within a specified time (Kelly sizing is constant).

Optimal sizing for an OU process is $-w\sigma/2$, where w is the wealth and σ the distance (in standard deviations) to the long-term mean.

9. The variance of the Sharpe ratio is high.

$$\text{Var}[\text{IR}] = \frac{1}{\sqrt{T}}(1 + \frac{1}{2}\text{IR}^2)$$

Also consider other performance ratios: Sortino, Omega.

Measure the persistence of the performance, e.g., by comparing different periods, or with the Hurst exponent.

11. To profit from the variance premium ($IV > RV$), short *index* volatility, by selling 20- Δ straddles or strangles on QQQ, second month, Δ -hedged, rebalanced monthly, when $VIX < 35$.

To profit from the correlation premium (short correlation, dispersion trading): sell index vol, buy component vol.

To profit from the skewness premium, sell 30- Δ risk reversals (sell the put, buy the call, Δ -hedge), or sell skew swaps (the payoff is the difference between realized and implied skew).

12. A model-free implied variance can be computed from all the calls and puts,

$$\text{Var}_{[T_1, T_2]} = \frac{2}{T_2 - T_1} \int_0^\infty \frac{C_{T_2}(Xe^{rT_2}) - C_{T_1}(Xe^{rT_1})}{X^2} dX$$

$$\text{Var}_{[0, T]} = \frac{2}{T} e^{rT} \left[\int_0^F \frac{P_T(X)}{X^2} dX + \int_F^\infty \frac{C_T(X)}{X^2} dX \right]$$

where F is the forward price.

The (cash) VIX is a finite sum approximation of those integrals; it is not tradable, but there are VIX futures; the cash VIX is a good predictor of VIX futures.

There are short- and long-term volatility ETNs (VXX, VXZ). The implied volatility term structure is

$$\text{IVTS} = \frac{\text{VIX}}{\text{VXV}},$$

where VIX and VXV are estimating the 1- and 3-month IV. A calendar strategy uses the IVTS to combine VXX and VXZ.

A calendar put spread, in contango, buys the front month ATM put and sells the second month put with the same strike.

13. *Leveraged ETFs* are computed using daily returns, compounded (if you expect to get λ times the monthly performance, you will be disappointed): they exhibit *volatility drag* (a rise of 10% and a drop of 10% and the effect is amplified as the leverage increases. To use it, buy one dollar of L and sell λ dollars of S .

$$L = L_0 \left(\frac{S}{S_0} \right)^\lambda \exp \left[-\frac{1}{2} \lambda (\lambda - 1) \sigma^2 t \right]$$

Deep analytics

B. Huge and A. Savine (2019)

Pricing options often requires lengthy Monte Carlo simulations: this is not scalable. Replace those computations with a trained deep learning model. The Longstaff-Schwartz model is an early example, but uses a linear model. Use *differential regularization*: two loss terms, one for the value of the option, the other for its gradient (sensitivities, Greeks); this has the added advantage of improving extrapolation. With code examples.

Modern Computational Finance: AAD and Parallel Simulations with professional implementation in C++

A. Savine (2019)

C++ book on parallel processing, with applications to automatic differentiation (with xVA computations in mind).

Edgeworth trading on networks

D. Cassese and P. Pin

Pure exchange model (no production and consumption), with n goods, in which each agent has a utility function determining how he trades.

Kernels and regularization on graphs

A.J. Smola and R. Kondor (2003)

The **graph Laplacian** $L = D - W$ is defined by

$$f' L f = \frac{1}{2} \sum_{i-j} (f_i - f_j)^2 \quad \text{for } f \in \mathbf{R}^n.$$

The pseudo-norm $\|f\|_L = \langle f, Lf \rangle$ is a discrete analogue of

$$\|f\|_\Delta = \langle f, \Delta f \rangle = \langle \nabla f, \nabla f \rangle = \int \|\nabla f\|^2.$$

Up to row/column/sum operations, the graph Laplacian (or the **normalized graph Laplacian**, $\tilde{L} = I - D^{-1/2} W D^{-1/2}$, whose spectrum is in $[0, 2]$) is the only permutation-invariant linear operator.

By analogy with radial basis function regularization

$$\Omega(f) = \langle f, r(\Delta) f \rangle = \int |\hat{f}(\omega)| r(\|\omega\|^2) d\omega$$

$$k(x, y) = \langle k(x, \cdot), r(\Delta) k(y, \cdot) \rangle$$

one can define regularization for functions on a graph, $f : V \rightarrow \mathbf{R}$, i.e., $f \in \mathbf{R}^{|V|}$,

$$\Omega(f) = \langle f, r(\tilde{L}) f \rangle \quad \text{regularizer}$$

$$K = r(\tilde{L})^{-1} \quad \text{kernel.}$$

For instance,

$r(\lambda) = 1 + \sigma^2 \lambda$	regularized Laplacian
$r(\lambda) = \exp(\sigma^2 / 2 \lambda)$	diffusion
$r(\lambda) = (a - \lambda)^{-1}$	1-step random walk, $a \geq 2$
$r(\lambda) = (a - \lambda)^{-p}$	p -step random walk
$r(\lambda) = \cos(\lambda \pi / 4)^{-1}$	inverse cosine.

To compute Ω or K , use a low-degree polynomial approximation of $r(\lambda)$ or $r(\lambda)^{-1}$: Taylor expansion around zero, $\exp(B) \approx (I + B/n)^n$, Chebychev polynomials on $[0, 2]$, etc. (more simplifications are available for product graphs).

The Eikonal equation

$$\begin{aligned} |\nabla\phi| &= 1 \\ \phi|_\gamma &= 0 \end{aligned}$$

computes the distance to a subset $\gamma \subset M$ of a Riemannian manifold but, being nonlinear and hyperbolic, it is difficult to solve (*fast marching algorithm*).

Varadhan's formula gives the distance from the heat kernel,

$$\phi(x, y) = \lim_{t \rightarrow 0} \sqrt{-4t \log k_{t,x}(y)}$$

(interpreting the heat equation with random walks: after a small time t , a walk reaching y from x has not had time to deviate much from the geodesics), but it is very sensitive to errors in the kernel (especially if t is small).

The heat method

- Integrates the heat flow $\dot{u} = \Delta u$ for some fixed time t ;
- Evaluates the vector field $X = -\nabla u / |\nabla u|$ – we only keep the direction: the amplitude is imprecise and, for geodesics, is known to be one;
- Find the corresponding distance by solving $\nabla\phi = X$, *i.e.*, $\text{Argmin}_\phi \int |\nabla\phi - X|$, *i.e.*, $\Delta\phi = \nabla \cdot X$ (Poisson).

The emergence of spectral universality in deep networks

F. Pennington et al.

To study the spectrum of the Jacobian *doutput/dinput* of a neural net (if all the singular values are close to 1, learning is faster), use **free probability theory**.

$$\rho_X(\lambda) = \left\langle \frac{1}{N} \sum_{i=1}^n \delta(\lambda - \lambda_i) \right\rangle_X \quad \text{Limiting spectral density}$$

$$G_X(z) = \int_{\mathbf{R}} \frac{\rho_X(t)}{z - t} dt \quad \text{Stieltjes transform } (z \notin \mathbf{R})$$

$$M_X(z) = zG_X(z) - 1 \quad \text{Moment generating function}$$

$$M_X^{-1} \quad \text{Its inverse}$$

$$s_X(z) = \frac{1 + z}{zM_X^{-1}(z)} \quad \text{S-transform}$$

$$S_{AB}(z) = s_A(z)s_B(z)$$

In the other direction, use

$$\rho_X(\lambda) = -\frac{1}{\pi} \lim_{\varepsilon \rightarrow 0^+} \text{Im } G_X(\lambda + i\varepsilon).$$

Spherical CNNs

T.S. Cohen (2018)

Convolutional layers are translation-invariants; they could be computed with a fast Fourier transform (FFT) – in practice, they are not, because the FFT is slow for

small filters. The Fourier transform can be generalized to signals on the sphere \mathbf{S}^2 (drone vision, molecular structure, weather modeling) and rotation-invariant transformation, but since \mathbf{S}^2 is not a group, the Fourier transform yields a signal on $\text{SO}(3)$ (in further layers, we stay in $\text{SO}(3)$: it is already a group.)

For signals f, g on the sphere, one can define a “correlation” $f * g$.

$$x \in \mathbf{S}^2$$

$$f, g : \mathbf{S}^2 \rightarrow \mathbf{R}^k$$

$$Q, R \in \text{SO}(3)$$

$$\langle f, g \rangle = \int_{\mathbf{S}^2} \langle f(x), g(x) \rangle_{\mathbf{R}^k} dx$$

$$(L_R f)(x) = f(R^{-1}x) \quad \text{action of } \text{SO}(3) \text{ on } \mathbf{S}^2$$

$$(f * g)(R) = \langle L_R f, g \rangle = \langle f, L_R g \rangle \quad \text{correlation}$$

Those definitions extend to functions on $\text{SO}(3)$.

$$f, g : \text{SO}(3) \rightarrow \mathbf{R}^k$$

$$\langle f, g \rangle = \int_{\text{SO}(3)} \langle f(x), g(x) \rangle_{\mathbf{R}^k} dx$$

$$(L_R f)(Q) = f(R^{-1}Q)$$

$$(f * g)(R) = \langle L_R f, g \rangle$$

Spherical convolution can be computed with the generalized FFT.

L4: practical loss-based stepsize adaptation for deep learning

M. Rolínek and G. Martius (2018)

Choose the step size to have the same forecasted loss improvement at each step. If the loss were linear, we could go to the minimum in one step:

$$\begin{aligned} \text{loss}(\theta_0 + \eta v) &= \text{loss}(\theta_0) + \eta g' \cdot v = L_{\min} \\ \eta &= -\frac{\text{loss}(\theta_0) - L_{\min}}{g' \cdot b}. \end{aligned}$$

In practice, the step can be $\alpha \eta v$, where g is the gradient, v the direction (gradient, momentum, etc.), $\alpha = 0.15$ and where L_{\min} is some fraction (say, 0.9) of the lowest loss seen so far.

Stochastic hyperparameter optimization through hypernetworks

J. Lorraine and D. Duvenaud

Learn the function $w^*(\lambda) = \text{Argmin}_w \text{loss}(w, \lambda)$, where λ are the hyperparameters and w the parameters.

Reordering rows for better compression: beyond the lexicographic order

D. Lemire et al.

Lexicographic order does not give the optimal RLE compression: pick random elements close in Hamming distance (*i.e.*, get close to a Gray code).

***Geometric properties of local dynamics
in Hamiltonian systems: the generalized
alignment index (GALI) method***
C. Skokos et al. (2018)

The generalized alignment index (GALI), in a Hamiltonian system, is the volume of a parallelepiped of k initially orthogonal unit vectors, whose magnitude is normalized to 1 at each time step; for chaotic orbits, it tends exponentially fast to zero, with exponents related to Lyapunov exponents.

***Constant-step-size least-mean-square
bias-variance trade-offs
and optimal sampling distributions***
A. Défossez and F. Bach (2014)

Average (Cesàro) constant-step-size stochastic gradient descent.

***A practical tutorial on autoencoders
for nonlinear feature fusion:
taxonomy, models, software and guidelines***
C. Charte et al. (2018)

A **contractive autoencoder** has a penalty on the Frobenius norm of the Jacobian of the encoder.

Corentropy (minus a Gaussian kernel \mathbf{V}), as a loss function,

$$\text{loss}(u, v) = - \sum_k \phi\left(\frac{u_k - v_k}{\sigma}\right)$$

gives robust autoencoders.

Feature fusion is a synonym for dimension reduction (PCA, LDA, kernel PCA, MDS, Isomap, Laplacian eigenmaps, RBM)

***Analysis of multivariate time-series
using the MARSS package***
E.E. Holmes et al. (2018)

hidden $x_t = Bx_{t-1} + u + Cc_t + w_t \quad w_t \sim N(0, Q)$
observed $y_t = Zx_t + a + Dd_t + v_t \quad v_t \sim N(0, R)$

***Matrix profile I:
all pairs similarity joins for time series:
a unifying view that includes motifs,
discords and shapelets***
C.C.M. Yeh et al. (2016)

The **matrix profile** of a time series is the time series of distances to the nearest neighbour.

$$\text{mp}_t = \underset{|t-s|>a}{\text{Min}} \, d(x_{t:t+n}, x_{s:s+n})$$

It summarizes the information in the distance matrix $(d(x_t, x_s))_{t,s}$.

To be robust to outliers, take the k th nearest neighbour.

To convert DNA to a numeric sequence, add 2, 1, -1 , -2 for A, G, C, T.

Use weights to account for prior information (regions more or less likely to contain interesting motifs).

$$\text{cmp}_i = \text{mp}_i + (1 - \text{av}_i) \text{Max}(\text{mp})$$

Applications include:

- Motif detection: low values;
- **Discords** (outliers): high values;
- Segmentation, by looking at where the nearest neighbours are and finding the point with the fewest crossings.

The matrix profile can be computed efficiently ($n \log n$, thanks to the FFT, if we use the z -normalized Euclidean distance, *i.e.*, the correlation).

Implementations in Python (**stumpy**, etc.) and R (**tsmp**); 14 more papers in the series.

***A complexity-invariant distance measure
for time series***
G.E. Batista et al.

Pairs of complex objects tend to be more distant, for most distance measures, than pairs of simple objects. There are already distance measures invariant to offset, scale (correlation), warping (DTW), phase, occlusion (missing subsequence):

$$\text{CID}(f, g) = \|f - g\|_2 \frac{\text{Max}\{\|f'\|_2, \|g'\|_2\}}{\text{Min}\{\|f'\|_2, \|g'\|_2\}}$$

is invariant to complexity changes, if the complexity of f is measured as $\|f'\|_2$.

***A brief introduction to machine learning
for engineers***
O. Simeone (2017)

1. There are several approached to statistics:

- Frequentist (no prior; point estimate);
- Bayesian (prior; posterior distribution);
- MAP (prior distribution, *i.e.*, regularization; point estimate);
- MDL (penalty for complexity; point estimate).

2. **No free lunch theorem.** One cannot learn rules that generalize to unseen examples without making assumptions (*inductive bias*) about the data generation mechanism.

Supervised learning looks for a predictive algorithm minimizing generalization loss.

Discriminative models directly model $p(y|x)$.

Generative models model $p(x, y)$ (sometimes by separately modeling $p(y)$ and $p(x|y)$), from which we can compute $p(y|x)$ – there is a higher risk of incorrect assumptions, but it is easier to deal with missing values.

The Bayesian approach allows model selection without validation, with the **marginal likelihood**.

f_α	prior
$\theta \sim f_\alpha$	parameters
g_θ	model likelihood
$x \sim g_\theta$	data
$g(x) := E_\theta [g_\theta(x)]$	marginal likelihood

Empirical Bayes estimates the parameter prior from the data.

The **Kullback-Leibler divergence** is the expectation of the log-likelihood-ratio between two distributions, $\log p(x)/q(x)$, wrt the distribution in the numerator. It is non-negative; it is zero iff $p = q$. The log-likelihood is $\text{KL}(\text{data} \parallel \text{model})$.

$$\begin{aligned} \text{KL}(p \parallel q) &= \mathbb{E}_{x \sim p} \left[\log \frac{p(x)}{q(x)} \right] \\ H(p \parallel q) &= \mathbb{E}_{x \sim p} [-\log q(x)] && \text{cross-entropy} \\ H(p) &= \mathbb{E}_{x \sim p} [-\log p(x)] && \text{entropy} \end{aligned}$$

3. Exponential family (or **log-linear**) models are of the form

$$\begin{aligned} p(x|\eta) &\propto \exp(\eta' u(x)) m(x) \\ \log p(x|\eta) &= \eta' u(x) + \log m(x) - A(\eta) \end{aligned}$$

where

η	natural parameters
u	sufficient statistics
m	base measure
$\mu = \mathbb{E}_{x \sim p(\cdot \eta)} [u(x)]$	mean parameters.

The Gaussian model $N(\mu, \sigma^2)$ is exponential, with

$$u(x) = \begin{pmatrix} x \\ x^2 \end{pmatrix} \quad \eta = \begin{pmatrix} \mu/\sigma^2 \\ -1/2\sigma^2 \end{pmatrix} \quad m = 1.$$

The natural and mean parameters are related through the gradient of the partition function.

$$\begin{aligned} \nabla_\eta A(\eta) &= \mu \\ \nabla_\eta^2 A(\eta) &= \text{Cov } u(x) = I_\eta \end{aligned}$$

The exponential family $p(x|\eta)$ is the **maximum entropy** distribution under the constraints $E[u(x)] = \mu$ (and the natural parameters are the corresponding Lagrange multipliers).

The gradient of the log-likelihood is $\nabla_\eta \ell = \hat{\mu} - \mu$.

In Bayesian models, one often chooses *conjugate priors*, i.e., priors such that priors and posteriors belong to the same family (Beta-Bernoulli, Dirichlet-Categorical, Gaussian-Gaussian, etc.).

One can vary the prior, to see, for instance, how strong it should be to change the MAP estimator.

Energy-based models are of the form

$$p(x|\eta) \propto \exp - \sum_c E_x(x_c|\eta);$$

they generalize the exponential families (for which E_c is linear). For instance, $E(x|\eta) = \log(1 + (\eta'x)^2)$ gives a Student T distribution; Markov models are another example.

A **generalized linear model** (GLM) is a model from an exponential family whose parameter η depends linearly on the predictors, $\eta = Wx$ or $\eta = W\phi(x)$.

4. Classification

Discriminative deterministic (classification) models (SVM, k -NN) output binary results.

Discriminative probabilistic models (GLM) output probabilities $P[\text{label}|\text{feature}]$.

Generative probabilistic models model the joint probability $P(\text{label}, \text{feature})$, often separating $P(\text{label})$ and $P[\text{features}|\text{label}]$; examples include QDA

$$\begin{aligned} t &\sim \text{Bernoulli}(\pi) \\ x|t = k &\sim N(\mu_k, \Sigma_k) \end{aligned}$$

or LDA (when Σ_k does not depend on k).

5. Statistical learning theory. We want to minimize the *generalization error*

$$\mathbb{E}_{(x,y) \sim p} \text{loss}(t, \hat{t}(x))$$

but the data distribution p is not known. Instead, we can use the sample distribution and minimize the *empirical risk*

$$\mathbb{E}_{(x,y) \sim \text{Data}} \text{loss}(y, \hat{t}(x)).$$

A learning rule is **probably approximately correct** (PAC) if

$$\forall p \in \mathcal{H} \quad \mathbb{P}_{\substack{\text{Data} \sim p \\ \text{size}(\text{Data}) \geq N}} [\text{loss}_p(\hat{t}) \leq \text{loss}_p(t^*) + \varepsilon] \geq 1 - \alpha$$

where N , the *sample complexity*, only depends on ε and α (not p).

Finite hypothesis classes \mathcal{H} are **PAC-learnable** via empirical risk minimization (ERM) with sample complexity

$$\begin{aligned} N &= \frac{2 \log |\mathcal{H}| + 2 \log(2/\delta)}{\varepsilon^2} \\ N &= \frac{\log |\mathcal{H}| + \log(1/\delta)}{\varepsilon} (?) \\ N &= \Theta \left(\frac{\dim_{\text{VC}} \mathcal{H} + \log(1/\delta)}{\varepsilon^2} \right). \end{aligned}$$

Dimension- d (quantized) models have sample complexity proportional to $d + 1$.

The *minimax redundancy* is another measure of model capacity.

$$\Delta R(\mathcal{H}) = \min_{q \in \mathcal{H}} \max_{p \in \mathcal{H}} \text{KL}(p \parallel q)$$

Structural risk minimization combines model selection and hypothesis testing by minimizing an upper bound on the generalization loss

$$\text{loss}_p(\hat{t}) \leq \text{loss}_{\text{Data}}(\hat{t}) + \sqrt{\frac{\log 2 |\mathcal{H}| / \delta}{2N}}.$$

6. The EM algorithm

x : observed
 z : latent
 θ : parameters

alternates between two steps

- M step: point estimate of $\theta|x, z$;
- E step: distribution estimate of $z|x, \theta$;

It can also be motivated using the **evidence lower bound**(ELBO)

$$\begin{aligned} \log p(x|\theta) &= \log \sum_z p(x, z|\theta) \\ &= \log \sum_z q(z) \frac{p(x, z|\theta)}{q(z)} && \text{Importance sampling} \\ &> \sum_z q(z) \log \frac{p(x, z|\theta)}{q(z)} && \text{Jensen} \\ &= \mathcal{L}(q, \theta) \end{aligned}$$

- E step: $q \leftarrow \text{Argmax}_q \mathcal{L}(q, \theta)$ (with θ fixed), *i.e.*, $q(z) = p(z|x, \theta)$;
- M step: $\theta \leftarrow \text{Argmax}_\theta \mathcal{L}(q, \theta)$.

Probabilistic PCA (PPCA) can be estimated with the EM algorithm.

$$\begin{aligned} z &\sim N(0, I) \\ x|z &\sim N(Wx + \mu, \sigma^2 I) \end{aligned}$$

In unsupervised learning, the loss is often the divergence between the model and the data. The Kullback-Leibler divergence is not always the best choice: minimizing $\text{KL}(\text{data}||\text{model})$ tends to produce blurry estimates.

Generative adversarial networks (GAN) generalize generative directed models: they learn at the same time a divergence and a generative model,

$$\text{Min}_\theta \text{Max}_T \text{E}_{x \sim p} [T(x)] - \text{E}_{x \sim q_\theta} [g(T(x))]$$

with T a neural net and g fixed

$$\begin{aligned} g(t) &= -\log(1 - e^t) && \text{GAN} \\ g(t) &= 1 - t && \text{WGAN.} \end{aligned}$$

Helmoltz machines are multilayer extensions of generative directed models.

7. Probabilistic graphical models, directed (Bayesian networks) or not (Markov random fields, MRF) encode conditional independence relations.

8. Variational inference (VI) approximates the posterior as an I-projection.

$$\begin{aligned} p(z|x) &= \underset{q(z)}{\text{Argmin}} \text{KL}(q(z) || p(z|x)) \\ &= \underset{q(z)}{\text{Argmin}} \text{KL}(q(z) || p(z, x)) + \log p(x) \\ &= \underset{q(z)}{\text{Argmin}} \text{KL}(q(z) || p(z, x)) \\ &= \underset{q(z)}{\text{Argmin}} - \text{E}_{z \sim q} [\log p(z, x)] - H(q) \\ &= \underset{q(z)}{\text{Argmin}} - \mathcal{L}(q) \\ &\approx \underset{q \in \mathcal{F}}{\text{Argmin}} - \mathcal{L}(q) \end{aligned}$$

The I-projection is mode-seeking, the M-projection zero-avoiding.

$$\begin{aligned} \text{pr}_I(p) &= \underset{q \in \mathcal{F}}{\text{Argmin}} \text{KL}(q||p) \\ \text{pr}_M(p) &= \underset{q \in \mathcal{F}}{\text{Argmin}} \text{KL}(p||q) \end{aligned}$$

The α -divergence

$$D_\alpha(p||q) = \frac{\sum_x \alpha p(x) + (1 - \alpha)q(x) - p(x)^\alpha q(x)^{1-\alpha}}{\alpha(1 - \alpha)}$$

interpolates between $\text{KL}(p||q)$ (for $\alpha = 1$) and $\text{KL}(p||q)$ ($\alpha = 0$).

Most likely transformations: the mlt package
T. Hothorn (2018)

The regression function of $Y|X$ is often defined as $f(x) = E[Y|X = x]$, without any distributional assumption, but it could be written, with a Gaussian model,

$$Y|X = x \sim N(f(x), \sigma^2)$$

or (this immediately allows censored data)

$$P[Y \leq y|X = x] = F\left(\frac{y - f(x)}{\sigma}\right)$$

or, more generally

$$P[Y \leq y|X = x] = F(h(y) - f(x))$$

where $h(y) = \theta' a(y)$, with θ to be estimated and a basis functions.

Adaptive gradient methods
with dynamic bound of learning rate
L. Luo et al. (2019)

Adaptive optimization algorithms (Adam, RMSProp, etc.) can choose extreme learning rates, leading to poor performance – instead, bound the learning rates to a shrinking interval, *i.e.*, progressively move towards plain stochastic gradient descent.

The Bloom clock **L. Ramabaja**

The *vector clock* provides a partial order on the events in a distributed system:

- Each node keeps a vector of size n , with one coordinate for each node;
- When a node sends an event, it increments its coordinate and broadcasts its vector;
- When a node receives a vector, it increments its coordinate and replaces its vector with the elementwise maximum of the two.

The vector clock can be bloomified.

***f*-GAN: training generative neural samplers using variational divergence minimization**

An *f*-GAN looks for a generator g_θ minimizing the *f*-divergence

$$D_f(p_{\text{data}} \| q_\theta) = \mathbb{E}_{x \sim q} \left[f \left(\frac{p(x)}{q(x)} \right) \right].$$

Since

$$\begin{aligned} D_f(p \| q) &\geq \sup_T \mathbb{E}_{x \sim p} [T(x)] - \mathbb{E}_{x \sim q} [f^*(T(x))] \\ &= \mathbb{E}_{x \sim p} [T(x)] - \mathbb{E}_{x \sim q} [f^*(T(x))] \end{aligned}$$

for $T(x) = f'(p(x)/q(x))$, we can instead try the saddle points of

$$F(\omega, \theta) = \mathbb{E}_{x \sim p_{\text{data}}} [T_\omega(x)] - \mathbb{E}_{x \sim q_\theta} [f^*(T_\omega(x))]$$

which can be approximated with samples from p and q .

Holographic embeddings of knowledge graphs **M. Nickel et al.**

Knowledge graphs (RDF triples, SVO triples) can be embedded in a vector space by learning vector representations of subject, object and predicate,

$$\begin{aligned} \text{score}(s, p, o) &= -d(e_s + r_p, e_o) \\ \text{or } P[s, p, o] &= \sigma(r'(e_s \circ e_o)). \end{aligned}$$

The composition operator $\cdot \circ \cdot$ can be one of

$$\begin{aligned} a \circ b &= a \otimes b \\ a \circ b &= \psi(W(a \oplus b)) \quad \begin{array}{l} \text{concatenation, projection,} \\ \text{non-linearity} \end{array} \\ a \circ b &= a \star b = \left(\sum_i a_i b_{i+k \bmod d} \right)_k \end{aligned}$$

(for the tensor product, since $r'(a \otimes b) = a' R b$, one can ask that R be diagonal, but this makes all relations symmetric).

The **circular correlation** \star can be seen as a “compression” of the tensor product.

Distributed convex optimization with many non-linear constraints **J. Giesen and S. Laue**

ADMM

$$\begin{aligned} \text{Find} & \quad x, z \\ \text{To minimize} & \quad f(x) + g(z) \\ \text{Such that} & \quad Ax + Bz = c, \end{aligned}$$

often used (on a distributed infrastructure) to minimize separable functions $f(\theta) = \sum_i f_i(\theta)$,

$$\begin{aligned} \text{Find} & \quad x, z \\ \text{To minimize} & \quad \sum_i f_i(x_i) \\ \text{Such that} & \quad \forall i \ x_i = z \end{aligned}$$

can also handle nonlinear convex *inequalities* (they keep the problem convex).

Link prediction based on graph neural networks **M. Zhang and Y. Chen (2018)**

Link prediction heuristics (common neighbours, Katz index) make strong assumptions on when two nodes are linked; instead, learn a function mapping subgraph patterns to link existence (SEAL).

Discovering and deciphering relationships across disparate data modalities **Y.T. Vogelstein et al.**

To test if $X \perp\!\!\!\perp Y$:

- Compute the distance matrices (between observations) for X and Y ; center them: A, B ;
- Compute the corresponding k -NN graphs: G_k, H_k (binary matrices);
- Compute the local correlations

$$t_{k\ell} = \sum_{ij} A_{ij} B_{ij} G_{kij} H_{\ell ij};$$

- Smooth $(k, \ell) \mapsto t_{k\ell}$ and compute its maximum t^* ;
- Use a permutation test to see if it is significant.

Minimum Rényi entropy portfolios **N. Lassance and F. Vrans (2018)**

Rényi entropy combines variance, skewness and kurtosis (as shown by a Gram-Charlier expansion): it can be used as a risk measure.

DGM: a deep learning algorithm for solving partial differential equations **J. Sirignano and K. Spiliopoulos (2018)**

Deep learning tools can provide mesh-free solutions to PDEs – meshes quickly become unusable as dimension increases.

Statistical inference using the Morse-Smale complex **Y.C. Chen et al. (2015)**

The **Morse-Smale complex** of a function $f : X \rightarrow \mathbf{R}$ decomposes the space X with the intersections of the

ascending and descending manifolds, *i.e.*, the basins of attractions of the gradients of f and $-f$.

Mean-shift clustering (or **mode clustering**) uses the ascending manifolds as clusters.

Morse-Smale regression estimates a linear model in each cell of the Morse-Smale complex of a kernel estimator $f(x) = E[Y|X = x]$.

The **Morse-Smale signature graph** (of a density estimate, a regression function, or a difference of densities) has maxima and minima as nodes, Morse-Smale cells as edges, the slope of a linear approximation as edge weights, and uses multidimensional scaling (MDS) for node coordinates.

The **Morse-Smale energy test** compares two probability distributions, using half the data to estimate the Morse-Smale complex of the difference of densities, and the other half to perform an energy (distance correlation) test in each cell, with a Bonferroni correction.

Morse-Smale regression **S. Gerber et al. (2013)**

The **Morse-Smale complex** of a function $f : X \rightarrow \mathbf{R}$ known on a finite set of points can be computed from the k -nearest neighbour graph, following the paths of steepest descent or ascent (*quick-shift* algorithm).

The cell of a new point can be predicted using a kernel density estimator or a support vector machine (SVM).

Morse-Smale regression fits a linear model in each cell, either with discontinuities

$$\hat{f}(x) = a_i + b_i \quad \text{if } x \in C_i$$

or with weights from the cell prediction model

$$\hat{f}(x) = \sum_i P[x \in C_i](a_i + b_i x).$$

The *persistence* of a critical point x is $\text{Min}_y \|f(x) - f(y)\|$, where the minimum is over the set of critical points y in cells adjacent to x ; this defines a filtration of Morse-Smale complexes (use the BIC to select the persistence level, *i.e.*, the number of cells).

Visual exploration of high-dimensional scalar functions **S. Gerber et al. (2011)**

Dimension reduction can help understand high-dimensional clouds of points. For functions (scalar fields) defined on an intrinsically high-dimensional cloud of points (or models with many variables interacting in complicated ways):

- Build the k -nearest graph of the cloud of points (k should increase with dimension);
- Compute the corresponding Morse-Smale complex; one can fine-tune the level of detail – start at the coarsest level;

- For each Morse-Smale crystal, estimate an (inverse) local (kernel) regression $X \sim y$: it is a path from minimum to maximum;
- For each such path r , compute a few geometric summaries: sensitivity dr/dy , average distance to the curve, sampling density – these form bands around the curves;
- Project those curves onto the first principal component of the extrema.

Data analysis with the Morse-Smale complex: the msr package for R **S. Gerber et al.**

Implementation of Morse-Smale regression and inverse regression.

Link prediction in complex networks: a survey **L. Lü and T. Zhou (2010)**

Predict missing links in an (undirected, homophilic) network using local or global similarity measures:

- The number of common neighbours, $|\Gamma(x) \cap \Gamma(y)|$, divided by 1, $k_x + k_y$, $k_x k_y$, $\sqrt{k_x k_y}$, $\text{Max}\{k_x, k_y\}$, $\text{Min}\{k_x, k_y\}$, $|\Gamma(x) \cup \Gamma(y)|$;
- $k_x k_y$ (preferential attachment – this uses too little information);
- The number of common neighbours, with less weight for the more promiscuous ones,

$$\sum_{z \in \Gamma(x) \cap \Gamma(y)} \frac{1}{k_z}, \quad \sum_{z \in \Gamma(x) \cap \Gamma(y)} \frac{1}{\log k_z}$$

- PageRank (random walk with restarts);
- SimRank;
- Katz: $(I - \beta A)^{-1}$;
- The average commute time $(L^\dagger)_{xx} + (L^\dagger)_{yy} - 2(L^\dagger)_{xy}$, $L = D - A$;
- Matrix forest” $(I + \alpha L)^{-1}$;
- Cosine: $(L^\dagger)_{xy} / \sqrt{(L^\dagger)_{xx}(L^\dagger)_{yy}}$.

Statistical models are another (slow, inaccurate, not scalable) option:

- *Hierarchical structure model*: the nodes are the leaves of a dendrogram; each internal node x is assigned a number $p_x \in [0, 1]$, and the link probability is $P[x-y] = P_{x \wedge y}$, where $x \wedge y$ is the lowest common ancestor of the leaves x and y ;
- *Stochastic block model*.

The link prediction problem for social networks

D. Liben-Nowell and J. Kleinberg (2004)

Forecast new links in a (co-authorship network using node similarity (Katz, Adamic-Adar, etc.), computed from the adjacency matrix, or a low-rank approximation, or a cleaned version (pruned of low-similarity edges).

**Link prediction in evolving networks
based on popularity of nodes**
T. Wang et al.

To predict links in (homophilic) evolving networks, use the *popularity* of the nodes (proportion of recent edges): active nodes attract more links.

**Link prediction in complex networks:
a mutual information perspective**
F. Tan et al.

Nodes whose neighbours tend to be connected tend to be connected.

$$\Gamma(x) = \{\text{neighbours of } x\}$$

$$k_x = |\Gamma(x)|$$

$$M = \text{Number of edges}$$

$$N_{\Delta z} = \# \text{ of connected pairs of neighbours of } z$$

$$N_{\Lambda z} = \# \text{ of disconnected pairs of neighbours of } z$$

$$p_{xy} = \frac{1 - \binom{M-k_y}{k_x}}{\binom{M}{k_x}}$$

$$I_{xy} = -p_{xy} \log p_{xy}$$

$$I_z = \text{Mean}_{x,y \in \Gamma(z)} \log \frac{\binom{M}{k_x}}{\binom{M}{k_x} - \binom{M-k_y}{k_x}} + \log \frac{N_{\Delta z}}{N_{\Delta z} + N_{\Lambda z}}$$

$$S(x, y) = \sum_{z \in \Gamma(x) \cap \Gamma(y)} I_z - I_{xy}$$

**Supervised random walks: predicting
and recommending links in social networks**
L. Backstrom and J. Leskovec (2011)

Personalized-PageRank-like measure of similarity computed from a weighted graph, where the (learned) edge weights are computed from edge and node features; train with a hinge loss on $P_{i \rightarrow j} < P_{i \rightarrow k}$, where $i \rightarrow k$ is an edge and $i \rightarrow j$ is not.

**DeepWalk:
online learning of social representations**
B. Perozzi et al. (2014)

Apply *word2vec* (skipgram with negative sampling) to random walks on a graph to get a vertex embedding. Use a Huffman-coding-based *hierarchical softmax* to deal with the large number of nodes.

**node2vec:
scalable feature learning for networks**
A. Grover and J. Leskovec (2016)

Random walks on a graph (depth-first search, DFS) provide an alternative to the traditional notion of neighbourhood (breadth-first search, BFS). Use a *biased random walk* with different probabilities for going back, moving to a neighbour common to the previous node, moving to another neighbour.

Structural deep network embedding
D. Wang et al. (2016)

Learn an *autoencoder* $x_i \mapsto y_i \mapsto \hat{x}_i$ where x_i is the i th row of the adjacency matrix, with

$$\text{loss} = \sum_{(ij) \in E} \|y_i - y_j\|^2 + \sum_{(ij) \in E} \|\hat{x}_{ij} - x_{ij}\|^2 + \text{regularizer};$$

the hidden layer y provides a node embedding.

LLE, IsoMap, Laplacian eigenmaps provide other (shallower) embeddings.

**LINE:
large-scale information network embedding**
J. Tang et al.

Find a low-dimensional embedding u_i of the nodes to minimize

$$- \sum_{(ij) \in E} w_{ij} \log \frac{1}{1 + e^{-u_i' u_j}} \quad \text{or} \quad w_{ij} \log \frac{e^{u_i' u_j}}{\sum_k e^{u_i' u_k}}$$

(KL divergence between the probability distributions inside the logarithms and $\hat{p}_{ij} = w_{ij} / \sum_{k \ell} w_{k \ell}$ or $\hat{p}_{ij} = w_{ij} / \sum_k w_{ik \cdot}$)

**Link prediction via subgraph embedding-based
convex matrix completion**
Z. Cao et al. (2018)

Compute node representations using word2vec (on random walks) or GloVe (on PPMI = $(A + A^2)/2$) on the graph whose nodes are egonets (of radius r) and with edges between egonets in the radial context (of radius R) of a node.

**GraRep: learning graph representations
with global structural information**
S. Cao et al.

Word2vec for node embedding cannot distinguish between $\circ \circ \circ$ and $\circ \circ \circ$ (the contexts are the same): replace the center word and the context with the first and last vertices of a length- k random walk; setting the gradient of the loss function to zero yields a matrix factorization problem,

$$W_i C_j = \log \frac{(A^k)_{ij}}{(A^k)_{\cdot j}} - \log \beta$$

(replace negative values with zero, to reduce noise); and concatenate all k -step representations, $k \in \llbracket 1, K \rrbracket$.

**New perspectives and methods
in link prediction**
R.N. Lichtenwalter et al. (2010)

Use *ensembles* of classifiers to reduce variance (C45, J48, naive Bayes, random forests). Try the following features:

- A variant of rooted PageRank: the probability that a random walk with no duplicates, starting at x , visits y in at most k steps;

- The maximum flow that can travel from x to y in at most 5 steps.

Computationally efficient link prediction in a variety of social networks

M. Fire et al. (2013)

Use a decision tree (J48) with node features (degree, Katz, number of paths of length 3, shared communities, etc.) to forecast missing links.

Link prediction with personalized social influence

Z. Huo et al. (2018)

Given a directed social network (e.g., Twitter), prune it to keep only significant connections, measured by the *mutual information* between the timing of user j 's tweets and the timing of user i 's retweets of user j 's tweets, and find node embeddings S and T (source and target) to model the link probability as

$$P[i \rightarrow j] = \frac{e^{S_i' T_j}}{\sum_k e^{S_i' T_k}}.$$

Link prediction in social networks: the state of the art

P. Wang et al. (2015)

Broken English

Connected patterns inspire link prediction in complex networks

M.Y. Zhou et al. (2017)

Do not use a raw node similarity score to predict missing links: learn a nonlinear transformation of the score. [Better: learn a nonlinear way of combining several of those scores.]

Link prediction via matrix factorization

A.K. Menon et al. (2011)

Model the link probabilities as

$$P[i \rightarrow j] = \sigma(u_i' \Lambda u_j + b_i + b_j + w' z_{ij} + x_i' V x_j)$$

where σ is the logistic function, $u_i' \Lambda u_j$ is a matrix factorization, x_i are the node features, w_{ij} the edge features and $x_i' V x_j$ a bilinear model (which works better than a linear one, $v' x_i + v' x_j$); add a regularizing penalty for U, V, Λ, W .

To overcome class imbalance, directly optimize the AUC by training on pairs of positive and negative samples – indeed, $\text{AUC} = P[f(i) > f(j) \mid y_i = 1, y_j = 0]$ (either arbitrary pairs, or pairs that share a node).

Link prediction based on graph neural networks

M. Zhang and Y. Chen (2018)

Graph neural networks can approximate node similarity measures and forecast missing edges.

Link prediction through deep learning

X.W. Wang et al. (2018)

Consider the adjacency matrix of a network as an image; reorder the nodes to make patterns more visible, using

- (Multiresolution) community detection;
- Consensus-based relabeling, which minimizes

$$\sum_i \frac{1}{k_i} \sum_j |r_{i,j+1} - r_{i,j} - 1|$$

where r_{ij} is the index of the j th neighbour of node i ;

- Or any matrix reordering algorithm;

apply a deep generative model (convolutional VAE or GAN – the latter works better) on perturbed copies of the adjacency matrix (obtained by removing 5% of the edges).

Link prediction: fair and effective evaluation

R. Lichtenwalter and N.V. Chawla

When the data is unbalanced, prefer the area under the precision-recall curve to that under the TPR-FPR one (ROC).

Evaluating link prediction methods

Y. Yang et al. (2013)

Idem

Link propagation: a fast semi-supervised learning algorithm for link prediction

H. Kashima et al.

Given a node similarity matrix W and a matrix indicating the presence (+1) or absence (−1) of edges F^* (unknown edges are left at 0, and the weights can be $|E|/|E^+|$ and $-|E|/|E^-|$ if the classes are unbalanced), **link propagation** completes the graph by minimizing

$$\sum_{ijk\ell} w_{ijk\ell} (f_{ij} - f_{k\ell})^2 + \lambda \sum_{(ij) \in E} (f_{ij} - f_{ij}^*)^2 + \mu \sum_{(ij) \notin E} f_{ij}^2$$

where the edge similarities are $W \otimes W$; this can be generalized to multiple edge types (we then have order-3 tensors), expressed with linear algebra operations, and optimized with gradient descent.

Link prediction in very large directed graphs: exploiting hierarchical properties in parallel

D. Garcia-Gasulla and U. Cortés

To infer missing links in directed graphs, generalize the neighbourhood-based similarity measures by separating ancestors and descendants, $N(x) = A(x) \sqcup D(x)$, e.g.,

$$\frac{\|A(x) \cap D(y)\|}{\|A(x)\|} + \frac{\|D(x) \cup D(y)\|}{\|D(x)\|}.$$

**Modeling relational data
with graph convolutional networks**
M. Schlichtkrull et al.

Graph convolutional networks (GCN) can be augmented with node and edge attributes or *types* (relational GCN).

**Graph convolutional neural networks
for web-scale recommender systems**
R. Ying et al.

To scale graph convolutional networks to large graphs, use samples of the neighbourhoods instead of the whole Laplacian.

Probabilistic relational models
L. Getoor et al.

A **probabilistic relational model** (PRM) is a *template* for Bayesian networks, linking node *types* rather than nodes (it can be seen as a Bayesian network on a graph with typed nodes, and parameters (or Bayesian priors on those parameters) shared among all nodes of the same type). Links can also be probabilistic and modeled from node attributes.

**Probabilistic entity-relationship models,
PRMs and plate models**
D. Heckman et al.

Probabilistic relational models (PRM) probabilistic entity-relation (ER) models (DAPER – contrary to PRMs, they distinguish between entities and relations) and plate models are equivalent.

Relational learning with Gaussian processes
W. Chu et al.

Model links as $P[i-j] = \sigma(f(x_i)'f(x_j)\varepsilon_{ij})$, where i, j are nodes, $f \sim \text{GP}$, $\varepsilon \in \{\pm 1\}$ and estimate $P[\varepsilon | \text{links}]$.

**Stochastic relational models
for discriminative link prediction**
K. Yu et al.

In a user-movie recommendation problem, the ratings are a function $\text{Users} \times \text{Movies} \rightarrow \mathbf{R}$ which can be modeled by a *tensor Gaussian process*, i.e., a Gaussian process whose kernel is a Kronecker product $\Sigma_{\text{Users}} \otimes \Sigma_{\text{Movies}}$.

**Dependency networks for inference,
collaborative filtering and data visualization**
D. Heckerman et al. (2000)

Dependency networks, in which the parents of a node are its Markov blanket,

$$\forall Y \notin \text{pa}(X) \quad X \perp\!\!\!\perp Y \mid \text{pa}(X),$$

are a potentially cyclic alternative to Bayesian networks, which do not lead to causal misinterpretations.

**Discriminative probabilistic models
for relational data**
B. Taskar et al.

Undirected graphical model template, i.e., graphical model with shared parameters.

**BPR: Bayesian personalized ranking
from implicit feedback**
S. Rendle et al. (2009)

The classification problem with three types of items, known positives, unknown positives and unknown negatives, is sometimes tackled by learning to separate known positives from the rest. Instead, one can look for a total order such that known positives dominate unknown items. This is similar to AUC optimization, but with the Heaviside objective

$$\sum_{\substack{i \text{ positive} \\ j \text{ unknown}}} \mathbf{1}_{x_i(\theta) > x_j(\theta)}$$

replaced with a differentiable (penalized) likelihood

$$\sum_{\substack{i \text{ positive} \\ j \text{ unknown}}} \log \sigma(x_i(\theta) - x_j(\theta)) + \lambda \|\theta\|^2,$$

corresponding to a logistic model

$$P[i > j] = \sigma(x_i(\theta) - x_j(\theta)).$$

For the item recommendation problem (one more index, for users, x_{ui}), the model can be a low-rank matrix factorization $X = WH'$ or an adaptive k -nearest neighbour model,

$$x_{ui} = \sum_{\substack{u \text{ likes } \ell \\ \ell \neq i}} c_{i\ell}, \quad C = HH'.$$

**Optimizing area under the ROC curve
using gradient descent**
A. Herschtal and B. Raskutti (2004)

Replace the Heaviside loss $\mathbf{1}_{x_i(\theta) > x_j(\theta)}$ with a differentiable approximation $\sigma(x_i(\theta) - x_j(\theta))$.

Naive Bayes for regression
E. Frank et al. (1999)

Naive Bayes does not work well for regression, unless there is really a lot of data.

$$\begin{aligned} P(Y|X_1, \dots, X_n) &\propto P(X_1, \dots, X_n, Y) \\ &= P(X_1|X_2 \dots)P(X_2|X_3 \dots) \dots P(Y) \\ &\approx P(X_1|Y) \dots P(X_n|Y)P(Y) \end{aligned}$$

**Neural variational inference
for text processing**
Y. Miao et al. (2016)

Variational autoencoders can model topics (neural variational document model).

**Discovering discrete latent topics
with neural variational inference**
Y. Miao et al. (2018)

Replace the Dirichlet prior for word distributions in LDA with neural-network-friendly distributions, e.g.,

- Gaussian softmax

$$x \sim N(0, I)$$

$$p = \text{softmax}(Ax)$$

- Gaussian stick-breaking ($\eta \sim \text{Beta}$ would give a Dirichlet distribution)

$$x \sim N(0, I)$$

$$\eta = \text{sigmoid}(Ax)$$

$$p_k = \eta_k \prod_{i=1}^{k-1} (1 - \eta_i)$$

$$p_n = \prod_{i=1}^n (1 - \eta_i)$$

- Recurrent stick-breaking

$$x \sim N(0, I)$$

$$\eta = \text{RNN}(x)$$

$$p = \text{StickBreaking}(\eta)$$

**TopicRNN: a recurrent neural network
with long-range semantic dependency**
A.B. Dieng et al.

Use a Gaussian distribution instead of a Dirichlet prior for the topic distribution of each document.

Instead of modeling each topic as a distribution on words, use a *language model* parametrized by the topic vector (RNN).

Model stopwords (problematic, in topic models, because they do not carry any information) using a mixture between the topic model and a distribution of stopwords (from a list).

**Deep learning for assessing banks' distress
from news and numerical financial data**
P. Cerchiello et al.

Feed the 600-dimensional doc2vec embedding and 12 financial ratios to a binary classifier (with one 50-neuron hidden layer).

**Empath:
understanding topic signals in large-scale text**
E. Fast et al.

MIT-licensed replacement for LIWC, with 200 categories selected from ConceptNet and the words obtained using cosine similarity with a skipgram embedding trained on amateur fiction (Wattpad – fiction is better for sentiment) and manually reviewed.

**Automatic keyword extraction
from individual documents**
S. Rose et al. (2010)

To extract multi-word keywords from an isolated document (not in a corpus), the RAKE algorithm proceeds as follows:

- Split the text on punctuation and stopwords to get keyword candidates (but allow candidates with one stopword if they are frequent enough);
- For each word, compute the frequency (number of occurrences), degree (number of words in the same candidates) and degree/frequency ratio;
- Define the keyword score by summing the word scores.

Also check TextRank.

To find stopwords from (manually generated) keywords, look for words at the boundary of keywords and rarely inside.

Interpretable machine learning
C. Molnar (2018)

Interpretability is needed:

- The problems we are solving are not completely specified – we do not really want to optimize a single metric but several, and the model output is not the final goal, just an intermediate step before some decision;
- We want to convince stakeholders that the model is safe, robust unbiased and fair.

But interpretability may make the system gamable.

Interpretability methods can be:

- Intrinsic (how the model actually works) or post hoc (as human explanations are);
- Local (only valid for observations similar to a given one) or global.

The output can be:

- Some feature summary (importance, contribution, visualization);
- Model internals (weights);
- Data points (prototypes, counterfactuals);
- An interpretable model.

Good explanations should

- Be contrastive, *i.e.*, explain why we got an output and not another;

- Be short (1 to 3 reasons, even if the model is more complex);
- Highlight abnormal or unusual inputs (outliers);
- Be consistent with prior beliefs (e.g., monotonicity);
- Be general (apply to a large number of instances).

1. Interpretable models include linear models (with a sparsity constraint), logistic regression, decision trees, decision rules, regression trees, naive Bayes, k -nearest neighbours.

2. Model-agnostic methods include:

- Individual conditional expectation (ICE) plots,

$$f(x, x_2, \dots, x_n) \sim x, \quad \text{for } (x_1, \dots, x_n) \in \text{Data};$$

- Partial dependency plots (PDP),

$$E[f(X_1, \dots, X_n) | X_1 = x] \sim x,$$

i.e., the average of the ICE curves; it can also be used for pairs of variables;

- Friedman's H statistic looks for interactions by comparing the partial dependency functions of X_1, X_2, X_{12}, X_{-1} ,

$$\begin{aligned} \text{PD}_I(x) &= E[\hat{f}(X) | X_I = x_I] \\ H^2 &= \frac{E[\text{PD}_{12}(X) - \text{PD}_1(X) - \text{PD}_2(X)]}{E[\text{PD}_{12}(X)^2]} \\ H^2 &= \frac{E[\hat{f}(X) - \text{PD}_1(X) - \text{PD}_{-1}(X)]}{E[\hat{f}(X)^2]} \end{aligned}$$

- Feature importance: permute the feature's values, and check the drop in performance;
- Global surrogate model;
- Local surrogate model (LIME), e.g., with a sparse linear model:
 - For text, randomly remove some of the words;
 - For images, segment them into superpixels;
- Shapley values

$$\begin{aligned} \phi_j &= \sum_{\substack{I \subseteq [1,p] \\ j \notin I}} \binom{p}{|I|} (v(I \cup \{j\}) - v(I)) \\ v(I) &= E[\hat{f}(X) | X_I = x_I] - E[\hat{f}(X)]. \end{aligned}$$

3. Example-based explanations include

- Counterfactual explanations: smallest changes to the features to change the outcome to a predefined value;
- Adversarial examples: small, insignificant perturbations of the input which nonetheless change the output;
- MMD critic: greedily select *prototypes* to reduce the maximum mean discrepancy between prototypes and data,

$$\text{MMD}(X, Y) = E[\kappa(X, X) - 2\kappa(X, Y) + \kappa(Y, Y)],$$

where κ is an RBF kernel, then greedily select *criticisms* where the prototypes and

the data distributions differ, *i.e.*, maximizing $|\text{witness}(x, \text{prototypes}, \text{data})|$

$$\text{witness}(x, X, Y) = E[\kappa(x, X) - \kappa(x, Y)],$$

with a diversity-inducing submodular penalty

$$\log \det(\kappa(x_i, x_j))_{i,j} \in \text{criticism};$$

- Influential instances (DFBETA, Cook's distance, influence function).

Peeking inside the black box: visualizing statistical learning with plots of individual conditional expectation
A. Goldstein et al. (2014)

The partial dependency plot integrates out X_2, \dots, X_n ,

$$E_{X_2, \dots, X_n} [f(x_1, X_2, \dots, X_n)]$$

while the ICE plots fix x_2, \dots, x_n (one curve for each observation)

$$f(x_1, \dots, x_n) \sim x_1.$$

Visualizing the effects of predictor variables in black box supervised learning models
D.W. Apley

The *partial dependency plot*

$$E_{X_2} [\hat{f}(X_1, X_2) | X_1 = x_1]$$

uses the marginal distribution of X_2 , and estimates the predictor \hat{f} very far away from the data, where it is unlikely to extrapolate well.

The *marginal plot*

$$E_{X_2 | X_1 = x_1} [\hat{f}(X_1, X_2) | X_1 = x_1]$$

uses the conditional distribution $X_2 | X_1 = x_1$ instead, but it suffers from the omitted variable bias: if X_2 plays a role, its impact will be included in the model intercept.

The *accumulated local effects* (ALE) plot

$$\int_{-\infty}^{x_1} E_{X_2 | X_1 = x_1} \left[\frac{\partial f}{\partial x_1}(X_1, X_2) \mid X_1 = x \right] dx$$

has the same interpretation without bias. For non-differentiable models (e.g., trees), use differences and sums instead of derivatives and integrals.

A unified approach to interpreting model predictions
S.M. Lundberg and S.I. Lee (2017)

Shapley values estimate all models on a subset of the variables $I \subset S$ and compares those with and without variable i .

***The separation plot: a new visual method
for evaluating the fit of binary models***
B. Greenhill et al. (2011)

To assess the quality of a logistic model, look at the ROC curve, the AUC, the Brier score

$$\frac{1}{n} \sum (\hat{p}_i - X_i)^2,$$

the pseudo- R^2 (likelihood ratio), the expected proportion of correct predictions

$$\text{EPCP} = \frac{1}{n} \left[\sum_{y_1=1} \hat{p}_i + \sum_{y_1=0} (1 - \hat{p}_i) \right],$$

the *separation plot* (1-dimensional tile plot, with one colour for each outcome, the cells ordered by the forecast, with the forecasted probability curve overlaid, and the expected number of events $\sum \hat{p}_i$ highlighted).

Deep learning: a critical appraisal
G. Marcus

Deep learning

- Needs infinite data;
- Cannot leverage background data, integrate prior knowledge, or learn abstractions from explicit verbal descriptions;
- Has limited transfer learning capabilities;
- Struggles with hierarchical structures;
- Is a black box;
- Cannot distinguish causation from correlation;
- Assumes the world is stationary;
- Has (frightening) non-human “failure modes”.

We need more unsupervised learning and hybrid symbolic-statistical systems.

***Understanding and simplifying
one-shot architecture search***
G. Bender et al. (2018)

Learn a single large model, from which all the models to test can be obtained (an exponentially large number of them) by switching off some of the connections, à la dropout.

***Efficient neural architecture search
via parameter sharing***
H. Pham et al.

Search for an optimal subgraph in a large computational graph, seen as an ensemble of models sharing parameters.

***You only search once:
single-shot neural architecture search
via direct sparse optimization***
X. Zhang et al. (2019)

Learn a complete DAG with a sparsity penalty.

Convolutional neural fabrics
S. Saxena and J. Verbeek

To choose the hyperparameters of a CNN, represent possible architectures as *paths* in a large network (dropout uses subgraphs instead of paths).

***FBNet:
hardware-aware efficient ConvNet design
via differentiable neural architecture search***
B. Wu et al.

Consider a “supernet” whose operators execute stochastically and look for the optimal architecture as a *distribution* (rather than a subnet).

***Mixed-precision quantization of convnets
via differentiable neural architecture search***
B. Wu et al.

Neural architecture optimization
R. Luo et al. (2018)

Use an autoencoder to map the discrete search space to a continuous one and predict the performance of an architecture from that continuous representation.

***Neural architecture search with
Bayesian optimization and optimal transport***
K. Kandasamy et al. (2018)

Gaussian-process-based Bayesian optimization can be used for network architecture search, with optimal transport to define a kernel to compare architectures (align the two networks and add penalties for mismatches) and an evolutionary algorithm to optimize the acquisition function.

Neural architecture search: a survey
T. Elsken et al. (2018)

**Neural architecture search
with reinforcement learning**
B. Zoph and Q.V. Le (2016)

Visualizing the loss landscape of neural nets
H. Li et al.

Plot the loss landscape of a neural net using one or two random directions in weight space, after *filter normalization* (normalize the weights in each filter (or each layer, for non-CNNs) to make them comparable – BatchNorm or ReLU units make the network scale-invariant).

- Small batch sizes lead to wider minima and better generalization;
- The loss landscape has a central convex region around the minimum, but is chaotic and non-convex beyond it – it is important to initialize the network in the convex region;
- Skip connections, small batches and wide networks (many filters) enlarge this region;
- The optimization path is very low-dimensional: use PCA rather than random dimensions to examine it.

Multi-dimensional graph Fourier transform
T. Kurokawa et al.

The **graph Fourier transform** (GFT) decomposes a signal $f : V \rightarrow \mathbf{R}$ on the eigenvectors of the Laplacian matrix $L = D - W$. It can be generalized to *cartesian product graphs* (e.g., time series for sensor networks, which have space and time dimensions), for which eigenvalues tend to be multiple: the eigenvalues (eigenvector) of the Kronecker sum $L_1 \oplus L_2$ are the sums (products) of those of L_1 and L_2 . It can be used, for instance, for signal filtering, to remove some frequencies in some directions:

$$\hat{f}_{\text{out}}(\lambda_1, \lambda_2) = h(\lambda_1, \lambda_2) \hat{f}_{\text{in}}(\lambda_1, \lambda_2).$$

**PassGAN: a deep learning approach
for password guessing**
B. Hitaj et al.

GAN to learn the distribution of real passwords from password leaks, to replace or complement rule-based password crackers (hashcat, johntheripper).

**WESPE: Weakly supervised photo enhancer
for digital cameras**
A. Ignatov et al.

GAN-based style transfer for photo enhancement, trained with highly liked Flickr images.

Multi-dimensional sparse super-resolution
C. Poon and G. Peyré (2017)

The **total variation norm** of a measure μ ,

$$\sup_{\substack{\eta \in \mathcal{C}(X) \\ \|\eta\|_{L^\infty} \leq 1}} \int_X \eta(x) d\mu(x)$$

generalizes the ℓ^1 and L^1 norms of vectors and functions. The corresponding penalty (BLASSO) can be used for *sparse superresolution*, i.e., to recover (position and amplitude of) spikes.

**StarGAN:
unified generative adversarial networks
for multi-domain image-to-image translation**
Y. Choi et al.

To translate images between domains (gender, hair colour, mood, age, etc.), use a single (conditional) generator $G : (\text{image}, \text{domain}) \mapsto \text{image}$, separate discriminators for the source and target domains, and a cycle loss to preserve image contents.

Datasets: CelebA (40 labels), RaFD (8 labels).

**DeblurGAN: blind motion deblurring using
conditional adversarial networks**
O. Kupyn et al.

To remove motion blur, use a Wasserstein **conditional GAN**

with *gradient penalty* and *perceptual loss* (L^2 norm of the difference of CNN features).

Improved training of Wasserstein GANs
I. Gulrajani et al.

Replace the weight clipping used to make the WGAN critic Lipschitz with a penalty on the norm of its gradient.

Non-local neural networks
X. Wang et al.

Self-attention, for images, is a generalization of non-local means,

$$y_i \propto \sum_j w(x_i, x_j) g(x_j)$$

with, e.g., $w(x_i, x_j) = \exp(Ax_i)'(Bx_j)$.

**Constructing unrestricted adversarial
examples with generative models**
Y. Song et al. (2018)

Train a GAN to model the class-conditioned distribution over inputs, then search its latent space (conditional on the desired class) for an adversarial example (of the desired class according to the GAN, but misclassified by the target classifier).

MolGAN: an implicit generative model for small molecular graphs
N. De Cao and T. Kipf

Use a GAN (WGAN with gradient penalty) to generate molecules (a vector for the atom types, a matrix for the link types, for a fixed number of atoms) and add a loss to force the generator to output molecules with desirable properties (e.g., easy to synthesize, using the RDKit cheminformatics software).

GAIN: missing data imputation using generative adversarial nets
J. Yoon et al. (2018)

Twin networks: matching the future for sequence generation
D. Serdyuk et al. (2018)

To encourage planning in a RNN, train (independently) a forward and a backward RNN to the same task, and add a penalty to match their hidden states.

Fraternal dropout
K. Źołna et al. (2018)

Train two identical copies of a RNN, with shared parameters, with different dropout masks, while minimizing the difference between their outputs.

Dilated recurrent neural networks
S. Chang et al. (2017)

Slight variant on the skip connection.

A universal music translation network
N. Mor et al.

To change the instrument or style of a piece of music, use a WaveNet autoencoder, with one encoder and one decoder per style.

EraseReLU: A simple way to ease the training of deep convolutional networks
X. Dong et al.

There might be too many nonlinearities in some neural nets: removing the last ReLU of all basic modules may improve performance.

Shifting mean activation towards zero with bipolar activation functions
L.H. Eidner and A. Nøkland (2018)

Replace the nonlinearity $x \mapsto \sigma(x)$ with $x \mapsto (\sigma(x), -\sigma(-x))$ or with

$$x_i \mapsto \begin{cases} \sigma(x_i) & \text{if } i \equiv 1 \pmod{2} \\ -\sigma(-x_i) & \text{if } i \equiv 0 \pmod{2} \end{cases}$$

The *orthogonal partition linear unit* (OPLU) partitions the coordinates into pairs and sorts them.

$$(x_i)_{1 \leq i \leq 2n} \mapsto \begin{pmatrix} \text{Max}(x_{2i-1}, x_{2i}) \\ \text{Min}(x_{2i-1}, x_{2i}) \end{pmatrix}_{1 \leq i \leq n}$$

SMASH: one-shot model architecture search through hypernetworks
A. Brock et al.

Encode neural network topologies as binary vectors, from a few building blocks (ResNet, FractalNet, etc.), and map them to weights.

DARTS: differentiable architecture search
H. Liu et al.

Search for computation cells with two inputs (previous two layers in a non-RNN, input and previous state in an RNN) by modeling them as DAGs on n nodes (n fixed), each connected to the previous ones, where the edges implement a linear combination of simple operations (zero, convolution, max pooling, etc.). Alternate between gradient steps in the architecture and weight spaces; for each edge, keep the most likely operation.

Differentiable learning-to-normalize via switchable normalization
P. Luo et al.

Successive normalization layers need not be identical: try linear combinations of normalizations (batch, layer, channel) with learned weights.

***Efficient neural architecture search
with neural morphism***
H. Jin et al.

Search for a good network architecture “morphing” it, by adding or removing layers or skip-connections, by changing the layer sizes, etc. (training is fast if we start from the previous, trained architecture).

For Bayesian optimization with Gaussian processes, use a kernel of the form $\kappa(a, b) = \exp -d(a, b)$, for some measure of distance d between the candidate architectures.

Regularization learning networks
I. Shavitt and E. Segal

Use a different regularization coefficient for each weight and replace the loss $\text{Loss}(w, \lambda) = \text{Loss}[w] + \exp(\lambda)' |w|$ with

$$\text{Loss}[w - \eta \nabla_w \text{Loss}(w, \lambda)].$$

***AutoAugment:
learning augmentation policies from data***
E.D. Cubuk et al.

Parametrized data augmentation procedures can be learnt.

***Explainable neural networks
based on additive index models***
J. Vaughan et al. (2018)

Generalized additive models $f(x) = \sum f_i(x_i)$ and **additive index models**

$$f(x) = \sum g_i(\beta'_i x)$$

are interpretable and can be modeled by neural networks.

***Training deep autoencoders
for collaborative filtering***
O. Kuchaiev and B. Ginsburg

Use an autoencoder, with SELU units, tied weights (the decoder’s weights are the transpose of the encoder’s) and masked mean square error loss, for collaborative filtering. Since the input is sparse and the output $f(x)$ dense, re-feed the output to the autoencoder to have $f(f(x)) \approx f(x)$.

***A meta-learning perspective on cold-start
recommendations for items***
M. Vartak et al. (2017)

Meta-learning can replace matrix factorization for recommendation systems, when new items arrive continuously (tweet recommendation):

$$\text{user} \mapsto (\text{tweet} \mapsto \text{score}).$$

The meta-learning learns, for a user’s history (items liked or not), the weights of a neural network (either all the weights of a linear network, or the biases of a nonlinear one, the other weights being shared across users).

Tropical geometry of deep neural networks
L. Zhang et al.

Neural networks with ReLU activations are just tropical rational maps.

***Deep learning works in practice.
But does it work in theory?***
L.N. Hoang and R. Guerraoui (2018)

At equivalent Kolmogorov complexity, deeper neural networks compute functions with larger “non-parallelizable logical depth”.

***Generalizing Hamiltonian Monte Carlo
with neural networks***
D. Levy et al. (2018)

Neural networks can learn a reparametrization to speed up HMC, maximizing the expected squared jumped distance.

***Backpropagation through the void:
optimizing control variates
for black-box gradient optimization***
W. Grathwohl et al. (2018)

To minimize a function of the form

$$\text{Loss}(\theta) = \mathbb{E}_{b \sim p_\theta} [f(b)],$$

SGD needs gradients \hat{g} such that

$$E[\hat{g}] = \frac{\partial \text{Loss}}{\partial \theta}$$

and (ideally) $\text{Var} \hat{g}$ small. Common choices include

$$\begin{aligned} \hat{g}_{\text{reinforce}} &= f(b) \frac{\partial}{\partial \theta} \log p_\theta(b) \\ \hat{h}_{\text{reparam}} &= \frac{\partial f}{\partial b} \frac{\partial b}{\partial \theta}, \quad \text{where } b = b(\theta, \varepsilon), \varepsilon \sim p_\varepsilon. \end{aligned}$$

Control variates can reduce variance:

$$\hat{g}_{\text{new}}(b) = \hat{g}(b) - c(b) + \mathbb{E}_{b \sim p_\theta} [c(b)].$$

They can also deal with non-differentiable f and discrete b ,

$$\begin{aligned}\hat{g}_{\text{lax}} &= \hat{g}_{\text{reinforce}}[f] - \hat{g}_{\text{reinforce}}[c_\phi] + \hat{g}_{\text{reparam}}[c_\phi] \\ &= [f(b) - c_\phi(b)] \frac{\partial \log p_\theta(bv)}{\partial \theta} + \frac{\partial c_\phi(b)}{\partial \theta}\end{aligned}$$

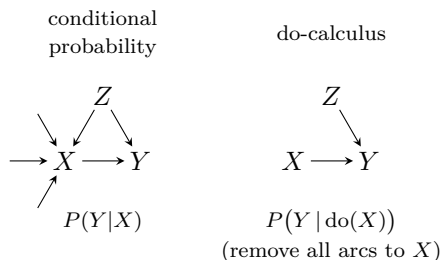

where c_ϕ is a neural network approximating f .

$$\begin{aligned}\hat{g}_{\text{DLAX}} &= f(b) \frac{\partial}{\partial \theta} \log p_\theta(b) - c_\phi(z) \frac{\partial}{\partial \theta} \log p_\theta(z) + \frac{\partial}{\partial \theta} c_\phi(z) \\ \hat{g}_{\text{RELAX}} &= [f(b) - c_\phi(\tilde{z})] \frac{\partial}{\partial \theta} \log p_\theta(b) + \frac{\partial}{\partial \theta} c_\phi(z) - \frac{\partial}{\partial \theta} c_\phi(\tilde{z}) \\ b &= H(z), \quad z \sim p_\theta(z), \quad \tilde{z} \sim p_\theta(z|b)\end{aligned}$$

Beyond power calculations: assessing type S (sign) and type M (magnitude) errors **A. Gelman and J. Carlin (2014)**

Besides the p -value and the *power*, also consider the *type S error rate*, *i.e.*, the probability that the sign is incorrect given that the parameter is significantly different from zero, and the *exaggeration ratio*, *i.e.*, the expectation of the absolute value of the estimate over the effect size, given it is significantly different from zero. (R code provided)

Implicit causal models for genome-wide association studies **D. Tran and D.M. Blei**

How many random seeds? Statistical power analysis in deep reinforcement learning experiments **C. Colas et al.**

The significance (often, $\alpha = 0.05$) of a statistical test only controls the type I errors. Compute the sample size needed to achieve the desired power (e.g., type II error $\beta = 0.20$), for the desired effect size ε , and the estimated variances.

In practice, to compare deep learning or reinforcement learning algorithms, run them at least 20 times with different random seeds.

Measuring scientific broadness **T. Price and S. Hossenfelder**

To measure the “broadness” of a researcher:

- Retrieve Arxiv abstracts using the API;

- Extract “keywords”: sequences of at most 10 words appearing in at least 20 papers; clean them (remove s’s, spaces; stem);
- Compute the “rank” of the keywords:

$$\text{KL}(P[\text{category}|\text{keyword} = k] \parallel P[\text{category}]) \times \left(1 - \exp - \frac{P[\text{keyword}]}{r}\right)$$

- Estimate an LDA model on the top 40,000 keywords (50 topics, 5 passes);
- Define the “broadness” of an author as the entropy of the topic distribution of her papers.

A network approach to topic models **A. Gerlach et al.**

Topic modeling is similar to community detection on the bipartite graph of documents and words. The *stochastic block model* (DBM) is equivalent to pLSI (frequentist LDA, *i.e.*, LDA without a prior), but has too many parameters to be used without a prior. The *hierarchical SBM* provides such a prior and removes the unimodality assumption inherent in LDA.

Implementation in `graph-tool` and `TopSBM`.

A high-reproducibility and high-accuracy method for automated topic classification **A. Lancichinetti et al.**

TopicMapping is an initialization method for LDA:

- Eliminate non-discriminative words by looking at all the pairwise cosine similarities;
- Run a clustering (community detection) algorithm, e.g., InfoMap, on the bipartite graph of words and documents (if the vocabularies used by the topics were disjoint, the topics would be the connected components);
- Use the clusters to estimate a PLSA model;
- Use this model as a starting point to estimate an *asymmetric LDA* model (LDA with a penalty for topic distribution entropy).

Robust PLSA performs better than LDA **A. Potapenko and K. Vorontsov (2013)**

Variants of LDA can be estimated in the same way:

- LDA uses a Dirichlet prior and defines topics as distributions on words and documents as mixtures of topics;
- PLSA replaces the Bayesian priors with maximum likelihood estimation (the priors can be seen as a penalty);
- SWB (specific words and background) is similar, but models documents as a mixture of topics, a corpus-wide background word distribution, and a document-specific distribution.

The map equation
R. Rosvall et al. (2009)

Infomap looks for a community decomposition of a graph minimizing the Huffman encoding of a random walk using community×node pairs. The code length is easy to compute.

$$\begin{aligned}\alpha &: \text{node} \\ p_\alpha &: \text{node visit probability} \\ i &: \text{community} \\ q_{i\curvearrowright} &: \text{exit probability} \\ q_{\curvearrowright} &= \sum_i q_{i\curvearrowright} \\ p_{i\cup} &= q_{i\curvearrowright} + \sum_{\alpha \in i} p_\alpha \\ L(M) &= q_{\curvearrowright} H(Q) + \sum_i p_{i\cup} H(P_i)\end{aligned}$$

To minimize it, start with each node in its own community; at each iteration, move a random node to the community decreasing the description length the most; when nothing can be improved, collapse each community into a node, and start again.

**Community detection and visualization
of networks with the map equation framework**
L. Bohlin et al.

Incorporating lexical priors into topic models
J. Jagarlamudi et al.

To force some (rarer) topics to appear, model each topic as a mixture of a regular topic (a distribution on words) and a seed topic, *i.e.*, a distribution on a user-specified set of words (SeededLDA).

**Paper abstract writing
through editing mechanism**
Q. Wang et al.

Use seq2seq with attention to generate an abstract draft from a title, and then a final abstract from the draft.

A simple method for commonsense reasoning
T.H. Trinh and Q.V. Le

To disambiguate pronouns, substitute them with all possible candidates and use a language model (trained on a massive amount of unlabeled data) to choose the most probable sentence.

Unsupervised neural machine translation
M. Artetxe et al. (2018)

Use a pre-trained, frozen, shared embedding and attention-based denoising decoders, trained with back-

translation.

**Unsupervised machine translation
using monolingual corpora only**
G. Lample et al. (2018)

Use denoising autoencoders.

Word translation without parallel data
A. Conneau et al. (2018)

To align word embeddings for two different languages, given a dictionary of 5000 pairs of words, find an orthogonal transformation W that maps one to the other (Procrustes problem),

$$W^* = \underset{W \in O}{\operatorname{Argmin}} \|WX - Y\|_F = UV',$$

where $YX' = U\Sigma V'$ is the SVD.

With no bilingual dictionary, learn an orthogonal transformation W and a discriminator to distinguish a random sample from $\{Wx_1, \dots, Wx_n\}$ from one from $\{y_1, \dots, y_m\}$. The orthogonality constraint can be enforced by alternating the gradient updates with

$$W \leftarrow (1 + \beta)W - \beta WW'W, \quad \beta = 10^{-2}.$$

The alignment can be improved by selecting the most frequent words, assuming their nearest neighbour is the correct translation and using the Procrustes method.

The notion of nearest neighbour is not symmetric: some points are the nearest neighbour of many points (hubs), others of no points (anti-hubs).

The similarity between source and target words can be measured as

$$\text{CSLS}(Wx, y) = 2 \cos(Wx, y) - \langle \cos(Wx, \cdot) \rangle - \langle \cos(\cdot, y) \rangle,$$

where the average cosine similarities are computed over neighbourhoods of Wx and y in the bipartite graph of k -nearest neighbours.

On the tree-likeness of hyperbolic spaces

M. Hamann

An \mathbf{R} -tree is a topological space X such that there exists a unique arc between any two points.

Two geodesic rays (unbounded geodesics, isometric images of $(0, \infty)$), π_1 , π_2 are equivalent if, for all sequences $(x_n)_n$ in π_1 , there exists M such that $\lim d(x_n, \pi_2) \leq M$. The *hyperbolic boundary* ∂X of X is the set of equivalence classes of geodesic rays. There are geodesic (double) rays between boundary points and between boundary points and interior points.

Given a proper hyperbolic space X (the closed balls are compact and there is a geodesic between any two points), there exists a topological \mathbf{R} -tree T whose rays are quasi-geodesics and such that every geodesic ray in X lies eventually close to a ray of T ; the embedding $T \hookrightarrow X$ extends to $\partial T \hookrightarrow \partial X$ (no longer an embedding).

The *Assouad dimension* is defined by

$$S(\alpha, \beta) = \{\#V : \forall x \neq y \in V \quad \alpha \leq d(x, y) \leq \beta\}$$

$$\dim_A(X) = \inf\{s \geq 0 : \forall 0 < \alpha \leq \beta \quad \exists c \geq 0$$

$$S(\alpha, \beta) \leq c(\beta/\alpha)^s\}.$$

Hyperbolic deep learning for Chinese natural language understanding

M.V. Micic and H. Chu

The *hyperbolic skipgram* character embedding replaces the Euclidean product with the Lorentzian product in the hyperboloid model $\mathbf{H}^n \subset \mathbf{R}^{(n,1)}$

$$\langle x, y \rangle_{\mathcal{L}} = \sum_{i=1}^n x_i y_i - x_{n+1} y_{n+1}$$

$$\mathbf{H}^n = \{x \in \mathbf{R}^{(n,1)} : \langle x, x \rangle_{\mathcal{L}} = -1 \text{ and } x_{n+1} > 0\}$$

(with an additive shift $\langle x, y \rangle \rightsquigarrow \langle x, y \rangle_{\mathcal{L}} + \theta$).

Transform the character embedding from the hyperboloid model to the Poincaré model and apply a *hyperbolic transformer* to an *intent classification* dataset (text-based commands to an Alexa-like machine).

Train the character embedding on the linguistic data consortium corpus and the word embedding (form comparison) on the People's daily corpus (both commercial).

Analytic hyperbolic geometry defines a scalar product and a (non-commutative, non-associative) sum between points in a hyperbolic space (*gyrovectors*):

$$\lambda \otimes x = \exp_0(\lambda \log_0 x)$$

$$x \oplus y = \exp_x(P_{0 \rightarrow x} \log_0 y)$$

State-of-the-art Chinese word segmentation with bi-LSTMs

J. Ma et al.

Stacked biLSTM, with characters and bigrams as inputs, pre-trained embeddings, dropout (for the LSTM parameters) and hyperparameter tuning; data from the Chinese Penn treebank, Chinese universal treebank and SIGHAN2005.

Long short-term memory neural networks for Chinese word segmentation

X. Chen et al.

1- or 2-layer LSTM, with character of n -grams as inputs, and character embeddings.

Hyperbolic neural networks

O.E. Ganea et al.

Logistic regression

$$P[y = 1 | x] \propto \exp(\langle a, x \rangle - b)$$

can be generalized to hyperbolic space by noticing

$$\langle a, x \rangle - b = \text{sign}(\langle a, x \rangle - b) \|a\| d(x, H_{a,b})$$

$$= \text{sign}(\langle -p + x, a \rangle) \|a\| d(x, H_{a,b})$$

where $b = \langle a, p \rangle$ and

$$H_{a,b} = \{x : \langle a, x \rangle = b\}$$

$$H_{a,p} = \{x : \langle -p + x, a \rangle = 0\} = p + \{a\}^\perp$$

and replacing $+$ with \oplus .

The linear (and affine, non-linear) transformations $x \mapsto Ax$ used in neural networks can be generalized to hyperbolic space as $x \mapsto \exp_0(A \log_0 x)$.

There is no Riemannian Adam: use Riemannian SGD (projected SGD is less stable).

Hyperbolic attention networks

C. Gulcehre et al.

Using millions of emoji occurrences to learn any-domain representations for detecting sentiment, emotion and sarcasm

B. Felbo et al.

DeepMoji is a 2-layer LSTM network with attention trained to forecast the presence of 64 common emojis from the text of tweets; use it for transfer learning or provide sentiment-aware sentence embeddings.

Pretrained model available.

**PlusEmo2Vec at SemEval-2018 task 1:
exploiting emotion knowledge
from emoji and hashtags**
J.H. Park et al.

Use a biLSTM to forecast (emotion-related) emoji clusters. Use the resulting sentence representation to forecast emotions, using a training set built from hashtags (from a sentiment lexicon).

This gives an *emotional word embedding*, very different from the traditional ones (word2vec, glove), which struggle to distinguish sentiment – indeed, positive and negative words are used in the same context (e.g., “a good/bad movie”).

日本語単語の難易度推定の試み
Y. Mizutani et al.

Measure the difficulty of a word by that of its context, initially estimated from vocabulary lists for middle, junior high and senior high school.

What is... a spectrahedron?
C. Vinzant

A *spectrahedron* is a set of the form

$$\{x \in \mathbf{R}^n : A_0 + x_1 A_1 + \cdots + x_n A_n \succcurlyeq 0\}$$

where the A_i ’s are symmetric matrices; they generalize polytopes.

Semidefinite programming maximizes a linear function over a spectrahedron; it generalizes linear programming.

The *elliptope* is the spectrahedron of correlation matrices of size n .

Spectrahedra are not closed under projections.

**Fréchet distance based approach
for searching online handwritten documents**
R. Sriraghavendra et al.

The *Fréchet distance* between two curves P and Q is

$$\min_{\alpha, \beta} \max_{t \in [0, 1]} \|P \circ \alpha(t) - Q \circ \beta(t)\|_2$$

where the reparametrizations $\alpha, \beta : [0, 1] \rightarrow [0, 1]$ are nondecreasing and surjective. (Think of a man and his dog, walking along P and Q , never going backwards – the distance is the minimum leash length.)

The discrete Fréchet distance can be computed with dynamic programming.

The *prefix Fréchet distance* can be used to retrieve handwriting, *i.e.*, time series (t, x, y) .

R Journal (2018-2)

The generalized autoregressive score (**GAS**) model models time-varying distributions $p(\cdot, \theta_t)$ whose parameters θ_t follow an AR(1) process driven by the

score function

$$\nabla_t = \frac{\partial \log p(y, \theta)}{\partial \theta} \Big|_{y_t, \theta_t}$$

$$\theta_{t+1} = \kappa + A(\text{Var}_{t-1} \nabla_t)^{-\gamma} \nabla_t + B\theta_t, \quad \gamma \in \{0, \frac{1}{2}, 1\}.$$

The maximum likelihood estimation is straightforward.

The **dynamac** package estimates and tests **autoregressive distributed lag models** (ARDL)

$$y \text{ or } \Delta y \sim f(\text{time}) + x + \Delta x + \log(y) + \log(x) + \log(\Delta y) + \log(\Delta x),$$

where the series can be stationary or (co)integrated.

In a semi-Markov model, sojourn times are arbitrarily distributed (in a Markov model, they are exponential or geometric). Check **SMM** (discrete-time SMMs), **semiMarkov**, **hsmm**, **mhsmm**.

The **lmridge** package provides ridge regression diagnostics.

The **BNSP** and **bamlss** packages provide Bayesian GAMLSS with spike-and-slab priors for variable selection.

Differential item functioning looks for unfairness in item response theory (IRT) models: even if they have the same ability, different groups may respond differently to the same distractor.

The **nsROC** package provides confidence bands for the ROC curve (**ROCbands**) and compares ROC curves (**compareROCdep**). Also check **pROC**, **ROCR** (estimators, with smoothing, and confidence intervals for the AUC); **plotROC**; **fbroc** (bootstrap); etc.

The k -means algorithm, can be generalized to mixed data types (k -prototypes):

$$d(x, y) = \sum_{i \text{ continuous}} (x_i - y_i)^2 + \lambda \sum_{i \text{ discrete}} \mathbf{1}_{x_i \neq y_i}.$$

Check **clustMixType**, **gower**, **cluster** (**daisy**, **hclust**, **agnes**), **CluMix**, **flexclust** **fpc**, **clustMD**, **kamila**, **klar**.

Instead of forward or backward variable selection, the *feasible solutions algorithm* (FSA) starts with a random set of variables and replaces them, one at a time, to increase the criterion (AIC, etc.), until this is no longer possible (repeat several times with different starting points).

There are several implementations of FastICA in **fICA**, **fastICA**, **ica**.

The **testforDEP** package provides more independence tests, beyond correlation, rank correlation, Kendall’s τ and Hoeffding’s test (comparing $F_{X,Y}$ and $F_X F_Y$), not limited to linear or monotonic dependence.

The **clikcorr** estimates bivariate correlation with censored or missing data. The **revenge** package estimates the parameters of a Poisson or binomial distribution from censored data.

Two-dimensional density estimation is available in `kde2d`, `bkde2D` (binned – significantly faster), `pointdensityP`.

Uncertainty can be propagated using Monte Carlo simulations or Taylor expansions: `errors`, `propagate`, `metRology`.

The `wrapr` package generalizes `matrittr`'s pipe.

The `qqplotr` package provides confidence intervals for quantile plots (computed from normal approximation, a KS test, bootstrap, etc.).

The `utilml` and `mldr` packages deal with *multilabel classification* (each observation can have several labels); the algorithms are built using decision trees, k -nearest neighbours, naive Bayes classifiers, support vector machines (SVM) or `xgboost`.

Many packages provide interpretations of complex, black-box models: `lime` (simple, interpretable model estimate on similar observations), `iml` (Shapley values, *i.e.*, contributions of a (local) linear model on binary variables), `DALEX`, `live` (locally interpretable visual explanations, *i.e.*, LIME after perturbing the instance one coordinate at a time), `breakDown` (additive contribution of each variable,

$$f(x, y) = \langle f(\cdot, \cdot) \rangle + \langle f(x, \cdot) \rangle - \langle f(\cdot, \cdot) \rangle + \langle f(x, y) \rangle - \langle f(x, \cdot) \rangle,$$

ordering the variables from the least to the most important, as measured by $\langle f(x, \cdot) \rangle - \langle f(\cdot, \cdot) \rangle$), `pdp` (partial dependency plots, ICE), `ALEPlot`, `FactorMerger`.

The `bnclassify` package learns (structure and parameters of) **Bayesian network classifiers (augmented naive Bayes models)**; it is similar to `bnlearn`, but focuses on $p(c|x)$ rather than $p(c, x)$, and drops variables irrelevant for the classification task.

Vertex bootstrap resamples the vertices of a graph, with replacement, and returns a new adjacency matrix; for duplicated vertices, since there are no self-edges, take a random element of the initial adjacency matrix. **Patchwork bootstrap** uses the subgraph of nodes at most n steps away from a random set of seed vertices (egonets); for bootstrap estimates of the degree distribution, adjustments are needed for the degrees of the vertices and the time(s) at which they enter the patch (use each directed edge exactly once). Check the `snowboot` package.

NetworkToolbox:
methods and measures for brain, cognitive

and psychometric network analysis in R
A.P. Christensen (R Journal 2018)

A correlation (or partial correlation) matrix can be turned into a graph using the *graphical lasso* (`bootnet`, `glasso`, `IsingFit`) or *information filtering* (maximum spanning tree, planar/triangulated maximally filtered graph (PMFG/TMFG)), *e.g.*,

- Start with the tetrahedron with the largest sum of weights;
- Add the node and 3 edges maximizing the sum of weights;
- Iterate until all the nodes have been added.

The (asymmetric) *dependency matrix* is

$$D(i, j) = \text{Mean}_{k \neq j} \text{Cor}(i, k) - \text{pCor}(i, k|j).$$

The *randomized shortest path betweenness centrality* has fewer outliers than the betweenness centrality. The *node impact* is the difference between the average shortest path length without and with it – if positive, its presence makes communities closer together. Community detection can be used as a replacement for PCA. Measures of centrality can also be computed within each community. Also check EGA.

Two betweenness centrality measures based on randomized shortest paths
I. Kivimäki et al. (2016)

The randomized shortest path betweenness is the expected number of visits of a node, for the probability distribution on paths between two given nodes

$$P[\text{path}] \propto \exp - \frac{\text{path length}}{\text{temperature}}.$$

UMAP: uniform manifold approximation and projection for dimension reduction
L. McInnes et al. (2018)

A *set* is a functor $* \rightarrow \mathbf{Set}$. A *fuzzy set* is a functor $([0, 1], \leq) \rightarrow \mathbf{Set}$ (the classical definition of fuzzy sets, as maps $X \rightarrow [0, 1]$ measuring “membership strength”, only provides subsets).

A *simplicial set* is a functor $\Delta^{\text{op}} \rightarrow \mathbf{Set}$. A *fuzzy simplicial set* is a functor $\Delta^{\text{op}} \rightarrow \mathbf{Fuzz}$.

Extended pseudometric spaces (they allow $d(x, y) = \infty$ and do not require $d(x, y) = 0 \implies x = y$) and non-expansive maps form a category \mathbf{EPMet} .

There is an adjunction between (finite) simplicial fuzzy sets and (finite) EPM spaces

$$\begin{array}{ccc} \mathbf{sFuzz} & & \\ \downarrow \text{metric realization} & \dashv & \uparrow \text{singular complex} \\ \mathbf{EPMet} & & \end{array}$$

which allows us to glue, as fuzzy simplicial sets, metric spaces that cannot be glued together in the category of metric spaces.

The UMAP algorithm computes the weighted k -nearest neighbour (the 1-skeleton of the fuzzy simplicial set obtained by glueing the local neighbourhoods of all points), with exponentially decaying weights (the weights are given by the adjunction), and applies a force-directed graph layout algorithm (the repulsive forces are only applied to a sampling of the vertices).

Efficient k -nearest neighbour graph construction for generic similarity measures
W. Dong et al. (2011)

The *nearest neighbour descent* algorithm builds an approximate k -nearest neighbour graph by starting with a random neighbourhood for each point and improving the estimate by looking at neighbours of neighbours.

Visualizing large-scale and high-dimensional data
J. Tang et al. (2016)

LargeViz computes an approximate k -nearest neighbour graph, using a few random projection trees (built from hyperplanes equidistant from two random points in each non-leaf node), refines it by looking at neighbours of neighbours, assigns t -SNE weights to the edges, and lays out the graph by maximizing

$$\prod_{(i,j) \in E} f(\|y_i - y_j\|)^{w_{ij}} \prod_{(i,j) \notin E} [1 - f(\|y_i - y_j\|)]^\gamma$$

using gradient descent and edge sampling (proportionally to the weights), with $f(x) = (1 + e^{x^2})^{-1}$ or $f(x) = (1 + ax^2)^{-1}$.

Homology-preserving dimensionality reduction via manifold landmarking and tearing
L. Yan et al. (2018)

Isomap reduces the dimension of a point cloud by computing its k -nearest neighbour (k -NN) graph and applying multidimensional scaling (MDS) to the geodesic distance.

L-Isomap (landmark isomap) only applies MDS to a set of (often randomly selected) “landmarks”; the other points are added using the geodesic distance to the landmarks.

The **Reeb graph** of a function $f : X \rightarrow \mathbf{R}$ from a manifold X is obtained by contracting each connected component of the level sets $f^{-1}(\{a\})$ to a point. From a cloud of points, use the inverse image of intervals $f^{-1}((a, b))$ instead (Mapper algorithm) and some clustering algorithm (e.g., DBSCAN) to approximate the connected components. The centroids of the components can be used as landmarks. The function f is often the distance to some fixed point.

Try to cut the K -NN graph with a plane orthogonal to one of the edges of the Reeb graph, and check if this preserves more of the topology by looking at the Wasserstein distance, or the bottleneck distance, between the persistence diagrams of the original point cloud and the dimension-reduced one.

A physical model for efficient ranking in networks
C. de Bacco et al.

To estimate a hierarchy (to assign a real-valued rank to each node) from a directed graph (in which most edges are top-down or between nodes of similar rank),

$$\begin{aligned} \text{Find} \quad & (s_i)_{i \in V(G)} \in \mathbf{R}^{|V(G)|} \\ \text{To minimize} \quad & \sum_{(i \rightarrow j) \in E(G)} (s_i - s_j - 1)^2 \end{aligned}$$

The social bow tie
H. Mattie et al.

Use the Jaccard similarity of the neighbourhoods of the ends of an edge as a measure of its “strength”.

Ctrl+Z: Recovering anonymized social graphs
Y. Zhang et al.

To anonymize graphs, one can add edges to ensure that nodes cannot be identified by their degree (there are at least k other nodes with the same degree), or add edges to add noise to the dk2 series (number of edges between nodes of degree i and j).

Word2vec on random walks on the graph provide a node embedding. The cosine similarity between the embeddings of the ends of an edge measures its plausibility, and can be used to deanonymize the graph.

Few-shot learning with graph neural networks
V. Garcia and J. Bruna (2018)

A **graph neural network** (GNN) takes an input signal on its vertices, learns a linear combination of local linear operators (e.g., the adjacency matrix and its first powers), and applies a non-linearity – the output is another weighted graph.

Message-passing algorithms suggest to also learn edge features, e.g., $\phi(x_i, x_j) = \text{MLP}(|x_i - x_j|)$ for $i \sim j$.

Towards gene expression convolutions using gene interaction graphs
F. Dutil et al.

To take gene interactions into account, use a *network-regularized sparse regression*, with penalty $\lambda |w|^L |w|$, where L is the graph Laplacian, or a graph convolution network.

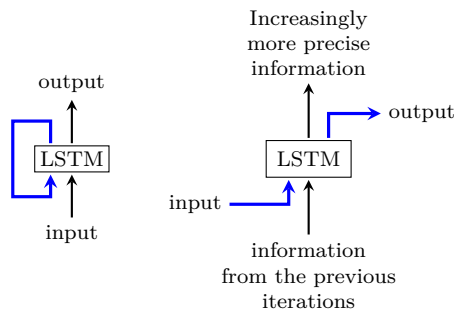

Graph convolutional neural networks for web-scale recommender systems
R. Ying et al. (2018)

To train graph convolutional networks (GCN) on large graphs, do not use the whole neighbourhood bonds, but use random walks to sample them (rather than random neighbours)

Feedback networks

A.R. Zamir et al.

Add feedback in (otherwise non-recurrent) networks.

Dilated residual networks

F. Yu et al.

Remove striding and (to keep large receptive fields) use *dilated* convolutions. It is possible to remove the gridding artefacts by removing the remaining pooling layers and adding more convolutional layers, without residual convolutions, at the end.

Learning scalable deep kernels with recurrent structure

M. Al-Shedivat et al. (2017)

To get a deep Gaussian process (GP) kernel with a recurrent structure, transform the input with an LSTM and build a kernel in the transformed space. The loss function no longer factorizes over the data: either pre-train the network separately and fine-tune with full batches, or use semi-stochastic alternating gradient descent.

Unsupervised neural machine translation

M. Artetxe et al.

Denoising autoencoders can provide decent translations even in the absence of any crosslingual data.

language 1 \rightarrow language 2 \rightarrow language 1
language 2 \rightarrow language 1 \rightarrow language 2

Differentiable plasticity: training plastic neural networks with backpropagation

T. Miconi et al. (2018)

In a **Hebbian network**, connections between neurons that tend to fire together are reinforced. Allow for both baseline and *plastic* (Hebbian) behaviour,

$$\text{weight}_{ij} = w_{ij} + \alpha_{ij} \text{Hebb}_{ij}$$

where the *Hebbian trace*, reset at the beginning of each episode, (when switching to a new problem) is one of

$$\text{Hebb}_{ij}(t+1) = \text{EWMA}_{\eta}[x_i(t)x_j(t)]$$

$$\text{Hebb}_{ij}(t+1) = \text{EWMA}_{\eta}[x_i(t-1)x_j(t)]$$

$$\text{Hebb}_{ij}(t+1) = \text{Hebb}_{ij}(t) + \eta x_j(t)[x_i(t-1) - x_j(t)\text{Hebb}_{ij}(t)]$$

and w_{ij} , α_{ij} and η are learnt by gradient descent.

Variance networks: when expectation does not meet your expectations

K. Neklyudov et al.

Stochastic neural nets (e.g., Bayesian neural nets) replace deterministic weights with probability distributions; often, at test time, only the means are used. Try a **variance layer**, *i.e.*, stochastic weights with zero mean and learned variances.

Tensor regression networks with various low-rank tensor approximations

X. Cao et al.

Constrain the weights of a layer to have low rank or low tensor rank by parametrizing them as a product of rectangular matrices, or as a tensor decomposition (CP, Tucker, TensorTrain).

Independently recurrent neural network (IndRNN): building a longer and deeper RNN

S. Li et al.

Replace the RNN updates

$$h_t = \sigma(Wx_t + Uh_{t-1} + b)$$

with

$$h_t = \sigma(Wx_t + u \odot h_{t-1} + b).$$

Max-Mahalanobis linear discriminant analysis networks

T. Pang et al. (2018)

The last layer of a neural net for classification is usually a (multi)logistic regression: try linear discriminant analysis (LDA) instead.

A flexible approach to automated RNN architecture generation
M. Schrimpf et al.

A DSL for automated RNN architecture search with reinforcement learning suggests an alternative (BC3) to LSTM and GRU cells.

Progressive neural architecture search
C. Liu et al.

Bayesian optimization (SMBO), on a hierarchical cell-based search space, to choose the structure of a CNN.

Learning to learn by gradient descent by gradient descent
A. Andrychowicz et al.

Momentum-like learning rules of the form

$$\theta_{t+1} \leftarrow \theta_t + \text{RNN}(\nabla f(\theta_t)),$$

where f is a random function, can be learnt by stochastic gradient descent. Use coordinate-wise LSTM units, with a few “global averaging cells”, whose output is averaged across all dimensions.

Neural optimizer search with reinforcement learning
I. Bello et al. (2017)

Idem.

Learning to optimize
K. Li and J. Malik

Gradient-descent-like optimization algorithms can be learnt by reinforcement learning (guided policy search): the state space contains the previous 25 gradients and improvements in the objective; the action is the step size.

Guided policy search
S. Levine and V. Koltun (2013)

The gradient of the policy can be estimated from sample trajectories (“likelihood ratio methods”). Importance sampling (with some regularization) allows off-policy learning. A guiding distribution can be obtained as the Gaussian i -projection of the Boltzmann distribution ρ on trajectories ζ with the negative reward as energy,

$$\underset{q \text{ Gaussian}}{\text{Argmin}} \text{KL}(q \parallel \rho) = \underset{q \text{ Gaussian}}{\text{Argmin}} \mathbb{E}_{\zeta \sim q} [-r(\zeta)] - H(q)$$

twisted with the current policy $\bar{r}(x, a) = r(x, a) + \log \pi_\theta(a|x)$.

Learning neural network policies with guided policy search under unknown dynamics
S. Levine and P. Abbeel

Sample trajectories from the current policy; use them to compute a linear Gaussian approximation of the model; compute the corresponding optimal policy (“iterative linear Gaussian regulator”, iLGR), but constrain them to be close (for the KL divergence) to the previous ones.

An intriguing failing of convolutional neural networks and the CoordConv solution
R. Liu et al.

Add the coordinates to the inputs of a convolutional layer.

IGLOO: slicing the feature space to represent long sequences
V. Sourkov

To achieve long-term memory with a CNN, compress the output of a convolutional layer with *sparse reservoir computing* (L times, pick a channel and $p = 4$ points in time, concatenate, feed to a fully-connected layer).

K-beam minimax: efficient optimization for deep adversarial learning
J. Hamm and Y.K. Noh (2018)

When $f(\cdot, \cdot)$ is convex in its first argument and concave in the second, saddlepoints coincide with minimax points:

$$f(u^*, v^*) = \text{Max}_v \text{Min}_u f(u, v) = \text{Min}_u \text{Max}_v f(u, v).$$

Use alternating gradient descent, but track k candidate solutions, to account for the discontinuities and multiple solutions to the maximization problem.

Averaging weights leads to wider optima and better generalization
P. Izmailov et al.

A cyclical, linearly decreasing learning rate $\backslash \backslash \backslash \backslash$ yields an ensemble of solutions: one can average their forecasts or, since they tend to be dispersed on the edge of a low-cost region, their weights – wider optima generalize better (cf. entropy-SGD).

Cyclical learning rates for training neural networks
L.N. Smith (2015)

The *learning rate (LR) range test* estimates minimum and maximum values for the learning rate by computing the accuracy of the model for various learning rates (e.g., from 0 to 5 – you may go beyond 1) after just a few epochs.

The *cyclical learning rate* schedule linearly increases and decreases the learning rate between those bounds,

with 2 to 10 epochs per half-period: the learning rate will be close to the optimal value most of the time, but higher values will help escape saddle points (as in simulated annealing).

The idea is very similar to stochastic gradient descent with restarts, and related to adaptive learning rate methods (AdaDelta, AdaGrad, RMSProp, Adam, etc.).

Super-convergence: very fast training of neural networks using large learning rates
L.N. Smith and N. Taupin

The cyclical learning rate method can speed up training by up to an order of magnitude.

The optimal learning rate can be estimated as

$$\varepsilon^* = \varepsilon \frac{\theta_{i+1} - \theta_i}{2\theta_{i+1} - \theta_i - \theta_{i+2}}.$$

Constant step size stochastic gradient descent for probabilistic modeling
D. Babichev and F. Bach

Stochastic gradient descent with constant step size does not converge but, for exponential families, averaging the moment parameters (e.g., the probability $p \in [0, 1]$ for a Bernoulli distribution, *i.e.*, a logistic regression), rather than the natural parameters (the log-odds ratio) restores convergence.

Dropout is a special case of the stochastic delta rule: faster and more accurate deep learning
N. Frazier-Logue and S.J. Hanson

The *stochastic delta rule* (SDR) represents the weights of a neural net as Gaussian random variables $w_{ij} \sim N(\mu_{ij}, \sigma_{ij}^2)$, sampled on each forward iteration, whose parameters are updated. Dropout uses (fixed-parameter) Bernoulli distributions.

Measuring the intrinsic dimension of objective landscapes
C. Li et al. (2018)

Train your model on a random subspace of the space of weights (the model remains the same, but the weights are constrained to a linear subspace) and progressively increase the dimension: that at which the performance reaches 90% of the full network is the *intrinsic dimension*. It may depend on the network structure: for images, CNNs give a lower dimension.

Those random projections can also be used to compress networks.

Neural networks should be wide enough to learn disconnected decision regions
Q. Nguyen et al. (2018)

If no hidden layer (in a network with ReLU activations) is wider than the input, the decision regions are connected.

The lottery ticket hypothesis: finding small, trainable networks
K. Frankle and M. Carbin

A large network is an ensemble of smaller overlapping networks: some of those subnetworks have won the “initialization lottery” and, once pruned, can be trained – they work better than the initial, large network.

Harmonic analysis of neural networks
E.J. Candès (1996)

Continuous and discrete wavelets can be seen as (infinite and finite) 1-layer neural networks – they model functions as

$$f = \int \langle f, \psi_\gamma \rangle \psi_\gamma \mu(d\gamma)$$

$$\text{or } f = \sum \alpha_\gamma \psi_\gamma, \text{ where } \psi_\gamma(x) = \alpha^{-1/2} \psi\left(\frac{\langle u, x \rangle - b}{a}\right).$$

Manifold regularization with GANs for semisupervised learning
B. Lecouat et al. (2018)

GANs can be leveraged for semi-supervised learning: have the discriminator determine the class of the input or whether it was generated. (Self-training is also sometimes used: label the unlabeled data with a classifier trained on the labeled data, then re-train on the expanded dataset.)

Manifold regularization ensures the classifier does not change as we move away from the data (orthogonally), with a penalty of the form

$$\int \|\nabla_{\mathcal{M}} f\| dp \approx \frac{1}{n} \sum_i \nabla_z f(g(z^{(i)}))$$

$z^{(i)}$: latent generator variables

g : generator

f : discriminator, classifier

\mathcal{M} : data manifold

p : distribution of the data on \mathcal{M} .

The relativistic discriminator: a key element missing from standard GAN
A. Jolicoeur-Martineau

The generator and discriminator of a GAN minimize their loss functions

$$\text{loss}_D = \mathbb{E}_{x \sim \text{Data}} [f_1(D(x))] + \mathbb{E}_{z \sim \text{noise}} [f_2(DGz)]$$

$$\text{loss}_G = \mathbb{E}_{x \sim \text{Data}} [g_1(D(x))] + \mathbb{E}_{z \sim \text{noise}} [g_2(DGz)],$$

often with $g_1 = f_1$, $g_2 = -f_2$, *i.e.*, the loss is the same, up to the sign (saturating GAN) or with $g_1 = f_2$,

$g_2 = f_1$, i.e., the loss is the same, but the real and simulated data have been swapped (non-saturating GAN).

The “relativistic GAN” uses

$$\begin{aligned}\text{loss}_D &= - \mathbb{E}_{\substack{x \sim \text{Data} \\ z \sim \text{Noise}}} [\log \sigma(Dx - DGz)] \\ \text{loss}_D &= - \mathbb{E}_{\substack{x \sim \text{Data} \\ z \sim \text{Noise}}} [\log \sigma(DGz - Dx)]\end{aligned}$$

to ensure that the probability of real data decreases as that of the fake data increases.

χ^2 generative adversarial network C. Tao et al. (2018)

GANs can be trained with:

- f -divergences

$$P(p||q) = \int f \left(\frac{p(x)}{q(x)} \right) p(x) dx$$

where p is the data and q the generator – but this is numerically unstable;

- Integral probability metrics (IPM), such as Wasserstein 1 (earth mover’s distance)

$$\sup_{\|D\| \leq 1} \mathbb{E}_{X \sim \text{Data}} D(X) - \mathbb{E}_{X \sim q} D(X)$$

- RKHS distances,

$$\text{MMD}(p, q) = \left\| \mathbb{E}_{X \sim p} \kappa(\cdot, X) - \mathbb{E}_{X \sim q} \kappa(\cdot, X) \right\|_H.$$

The χ^2 GAN is a special case of all three.

First order generative adversarial networks C. Seward et al.

An *adversarial divergence* between probability distributions p, q on X is a function of the form

$$\tau(p||q) = \sup_{g \in \mathcal{G}} E_{p \otimes q}[g]$$

for some $\mathcal{G} \subset \mathcal{C}^0(X \times X)$.

A *critic-based adversarial divergence* is of the form

$$\tau(p||q) = \sup_{f \in \mathcal{F}} E_{p \otimes q}[m_f - r_f]$$

where $\mathcal{F} \subset \mathcal{C}^0(X)$ (e.g., 1-Lipschitz), $m_f(x, y) = m_1(f(x)) - m_2(f(y))$, $m_1, m_2 : \mathbf{R} \rightarrow \mathbf{R}$ and $r : \mathcal{F} \rightarrow \mathcal{C}^0(X \times X)$.

The Wasserstein divergence between Dirac masses

$$\tau(\delta_a||\delta_b) = \sup_{f \in \mathcal{F}} f(a) - f(b) = |a - b|$$

can be written

$$4\tau(\delta_a||\delta_b) = \sup_{f \in \mathcal{F}} f(a) - f(b) - |a - b| \left(\frac{f(a) - f(b)}{a - b} \right)^2;$$

this motivates the *penalized Wasserstein divergence*,

$$\tau(p||q) = \sup_{f \in \mathcal{F}} \mathbb{E}_{x \sim p} f(x) - \mathbb{E}_{y \sim q} f(y) - \lambda \mathbb{E}_{\substack{x \sim p \\ y \sim q}} \frac{(f(x) - f(y))^2}{\|x - y\|}$$

(one can also add another penalty, involving ∇f).

Evolutionary generative adversarial networks C. Wang et al.

Evolve a population of generators to adapt to the environment (discriminator), mutating them by running a few gradient descent steps for the following loss functions

$$\begin{aligned}\text{loss}(G) &= \mathbb{E}_{z \sim \text{noise}} \log(1 - DGz) \\ \text{loss}(G) &= \mathbb{E}_{z \sim \text{noise}} -\log(DGz) \\ \text{loss}(G) &= \mathbb{E}_{z \sim \text{noise}} (DGz - 1)^2\end{aligned}$$

where the first (second) minimizes (maximizes) the log-probability of the discriminator being correct (mistaken).

To promote diversity and avoid mode collapse, note that the discriminator labels collapsed points as fake, with obvious counter-measure, i.e., big gradients, and use those gradients as a diversity measure.

Large scale GAN training for high-fidelity natural image synthesis A. Brock et al.

To train large-scale GANs:

- Increase the batch size;
- Train with Gaussian noise but sample using a truncated Gaussian;
- Use orthogonal regularization, $\|W'W - I\|_F^2$, without the diagonal $\|W'W \odot (1 - I)\|_F^2$.

Synthesizing programs for images using reinforced adversarial learning Y. Ganin et al.

GAN to generate programs (sequences of graphical primitives) to generate images, instead of raw pixels (deep reinforced adversarial learning).

Globally and locally consistent image completion S. Iizuka et al. (2017)

Use a GAN for image completion, with both a global and a local discriminator.

Learning to see in the dark C. Chen et al.

Instead of using separately learned algorithms for denoising, deblurring, etc., learn an end-to-end image processing pipeline.

**DeepMasterPrints: generating MasterPrints
for dictionary attacks
via latent variable evolution**
P. Bontrafer et al.

Use a GAN to generate fingerprints, then explore the latent space with CMA-ES to find a master print.

Small fingerprint sensors (on mobile phones), which only image part of the finger, are very vulnerable to that attack.

Learning deep generative models of graphs
Y. Li et al. (2018)

To sequentially generate random graphs (molecules, parse trees, graphical model structures), use a GRU graphnet to decide, at each step, where to add an edge or a node.

**Meta-learning for semi-supervised
few-shot classification**
M. Ren et al. (2018)

A **prototypical network**, for a classification problem, learns an embedding, defines prototypes as the averages of the embeddings of the observations in each class, and uses the squared distances to the prototypes in a softmax, $p \propto \exp(-d^2)$.

For semi-supervised learning, compute the prototypes from the labeled data, estimate the class of the unlabeled items (soft- k -means, with a “distraction cluster” for potential unknown labels, or soft-masking of far-away observation) and refine the prototypes.

Learning to generate classifiers
N. Guttenberg and R. Kanai

Meta-learning (*i.e.*, learning a mapping from datasets of predictors and labels to classifiers) with attention outperforms SVM, random forests, k -NN, or xgboost.

**Fastfood – approximating kernel expansions
in loglinear time**
Q. Le et al.

The decision function, in an SVM, is of the form

$$f(x) = \sum_1^N \alpha_i k(x_i, x),$$

where N is the number of observations and the nonzero α_i correspond to the support vectors. We usually prefer to compute the kernel directly, without explicitly computing the embedding, $k(x, y) = \langle \phi(x), \phi(y) \rangle$, but, for large datasets, a random embedding (*random kitchen sink*) may be preferable:

$$Z_{ij} \sim N(0, \sigma^{-2})$$

$$\phi_j(x) = \frac{1}{\sqrt{n}} \exp[i(Zx)_j]$$

is an approximation of a RBF (radial basis function) kernel. Instead of a fully Gaussian kernel, consider

$$Z = \frac{1}{\sigma\sqrt{d}} SHG\Pi HB$$

where $H = \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}^{\otimes d}$, B is a random diagonal matrix with entries ± 1 , G is a random diagonal Gaussian, and S is diagonal.

Using matrices to model symbolic relationships
I. Sutskever and G. Hinton

A **linear relational embedding** (LRE) learns vector and matrix representations of objects and relations such that $x\mathcal{R}y$ corresponds to a matrix product $\mathcal{R}x = y$; a *matrix relational embedding* uses matrices for both objects and relation: the relation matrices are smaller, and one can also consider higher-order relations (relations between relations).

**Monotonic calibrated interpolated
look-up tables**
M. Gupta et al. (2016)

Lattice regression approximates a function by interpolating it on a grid – the values on the vertices are chosen to minimize the loss, *after interpolation*, at the points already observed. Multilinear interpolation uses 2^D points, e.g.,

$$f(x, y) = (1-x)(1-y)\theta_{00} + x(1-y)\theta_{10} + (1-x)y\theta_{01} + xy\theta_{11}$$

(for $D = 2$), where the weights $x^\delta(1-x)^{1-\delta}y^\varepsilon(1-y)^{1-\varepsilon}$, $\delta, \varepsilon \in \{0, 1\}$, are known, and the model is linear in its parameters θ . Monotonicity is easy to check. One could use any other way of writing (x, y) as a barycenter of $(0, 0)$, $(1, 0)$, $(0, 1)$, $(1, 1)$. **Simplex interpolation** uses only $D + 1$ vertices, corresponding to a partition of the hypercube along the hyperplanes $x_k = x_\ell$. The simplex containing a point can be obtained by sorting its coordinates (in $O(D \log D)$ time). The model is not rotationally invariant: all the simplices contain $(0 \cdots 0)$ and $(1 \cdots 1)$; for a better fit, ensure all the constraints go in the same direction, e.g., everything increasing.

Add penalties such as

$$\sum \left(\frac{\partial f}{\partial x_i} \right)^2, \quad \sum \left(\frac{\partial^2 f}{\partial x_i^2} \right)^2, \quad \text{or} \quad \sum \left(\frac{\partial^2 f}{\partial x_i \partial x_j} \right)^2$$

to make the function flatter or more linear.

Add coordinatewise, piecewise (but still monotonic) transformations, with k knots, at equally spaced quantiles.

To deal with missing values, replace the lattice $\{0, 1\}^D$ with $\{0, 1, \text{NA}\}^D$ and interpolate on $([0, 1] \sqcup \{\text{NA}\})^D$.

There are many constraints and penalties: try sampling from them at each iteration to speed up the computations.

Lattice regression
E.K. Garcia and M.R. Gupta

***Fast and flexible monotonic functions
with ensembles of lattices***
K. Canini et al. (2016)

Build an ensemble of (monotonic) lattice regression models, each using a small number of variables:

- Train lattices on all pairs of features and compute their “torsion”, $[(x_{11} - x_{10}) - (x_{01} - x_{00})]^2$, a measure of nonlinear interaction;
- Assign the features to the different models, with each feature used at least once, and the feature count otherwise proportional to the median torsion, and maximize the weighted torsion of the ensemble (where the weight decreases as a pair is repeated).

***Deep gradient compression:
reducing the communication bandwidth
for distributed training***
Y. Lin et al. (2018)

Most of the gradient exchanges in distributed stochastic gradient descent are not needed:

- Only send large gradients;
- Accumulate them locally, and clip them, before sending;
- Do not use momentum for old (unsent) gradients – it would be stale;
- During training, use little sparsification and a low training rate.

***meProp: sparsified backpropagation
for accelerated deep learning
with reduced overfitting***
X. Sun et al. (2017)

Sparsified backpropagation, *i.e.*, only backpropagating the k largest gradients (1% to 4%) does not slow down training.

Deep image prior
D. Ulyanov et al.

Use untrained networks (reservoir computing, random projections).

***Secure ML: a system for scalable
privacy-preserving machine learning***
P. Mohassel and Y. Zhang

Machine learning models can be trained even if the data is (and should remain) on separate servers (e.g., financial and medical data).

***Trainable calibration measures for neural
networks from kernel mean embeddings***
A. Kumar et al. (2018)

Neural networks for classification problems are not calibrated: the scores cannot be interpreted as probabilities – we would like $P[\text{correct}] = \text{Max}_k p_k(x)$. The calibration error could be added to the loss function, but it is discontinuous. Instead, use

$$\text{MMCE} = \sum_{ij} \frac{(c_i - s_i)(c_j - s_j)\kappa(s_i, s_j)}{N^2}$$

where $c_i = \mathbf{1}_{\text{correct}} = \mathbf{1}_{y_i = \text{Argmax}_k p_k(x_i)}$ and $s_i = \text{Max}_k p_k(x_i)$.

Machine learning for trading
G. Ritter (2017)

Reinforcement learning on simulated data can help devise trading strategies with arbitrary transaction cost models (e.g., given by an algorithmic blackbox).

Algorithms for inverse reinforcement learning
A.Y. Ng and S. Russell

The reward function of a known, finite-state MDP can be recovered from its (deterministic) optimal policy, via a linear program; to avoid degenerate solutions, e.g., $R \equiv 0$, maximize the difference between the optimal policy and the others,

$$\sum_{s \in S} Q(s, \pi(s)) - \text{Max}_{a \neq \pi(s)} Q(s, a).$$

For large state spaces, approximate the reward function as a linear combination of basis functions, $R(s) = \sum \alpha_i \phi_i(s)$, ϕ_i fixed. This approach is still applicable if the optimal policy is only known through sample trajectories (but requires iteratively solving linear programs, to progressively improve the fit).

***Solving the Rubik’s cube
without human knowledge***
S. McAleer et al.

Only one state, the final state, has a reward: start there and estimate the value and optimal policy for states farther and farther away from it.

***Independent interpretable lasso:
a new regularizer for sparse regression
with uncorrelated variables***
M. Takada et al. (2018)

To avoid selecting correlated variables, ease interpretation, and recover correct signs, use a penalty of the form $\lambda \|\beta\|_1 + \mu |\beta|' R |\beta|$, where $R_{ij} \geq 0$ measures the similarity between i and j .

$$\lambda = 1, \mu = \frac{1}{2}, R = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}$$

***High-dimensional regression in practice:
an empirical study of finite-sample prediction,
variable selection and ranking***
F. Wang et al. (2018)

Prefer the lasso. Other penalized regression, variable selection and variable ranking algorithms include the elastic net, ridge regression, SADC (an ℓ^1 penalty for small values, ∇), the Dantzig selector

$$\underset{\beta: \|X'(Y-X\beta)\|_\infty \leq \lambda}{\text{Argmin}} \quad \|\beta\|_1,$$

stability selection (run a variable selection on resampled datasets and keep the variables selected at least $\tau\%$ of the time).

R implementations in `glmnet`, `ncvreg` (SADC), `flare` (Dantzig), `c060` (stability selection).

***Identifying groups
of strongly correlated variables
through smoothed ordered weighted ℓ_1 norms***
R. Sankaran et al. (2017)

The ordered weighted L^1 norm (OWL) is

$$\Omega(w) = \sum c_i |w|_{(i)}$$

where $|w|_{(i)}$ is the i th largest absolute value of the coordinates of w and c_i is a fixed non-increasing sequence (e.g., an arithmetic sequence: OSCAR).

As a penalty, it has a sparsifying effect, selecting groups of variables with the same coefficients

It is the Lovász extension of the cardinality-based modular function $P(A) = f(|A|)$, where $f(i) = c_1 + \dots + c_i$.

The ℓ^2 relaxation is similar, but does not force the coefficients to be exactly equal.

***Finite-time analysis
of the multiarmed bandit problem***
P. Auer et al. (2002)

For the multiarm bandit problem, UCB_1 , which plays the machine j maximizing

$$x_j + \sqrt{\frac{2 \log n}{n_j}},$$

UCB_2 (similar, with a division in epochs), and ε -greedy, with $\varepsilon \propto 1/n$, achieve logarithmic regret.

***Multi-fidelity blackbox optimization
with hierarchical partitions***
R. Sen et al. (2018)

UCB-style multi-arm bandit algorithms can be applied to black-box optimization of expensive functions for

which cheap, coarse approximations (early stopping) are available, by hierarchically partitioning the domain.

Contextual memory trees
W. Sun et al.

Store key-value pairs in the leaves of a (balanced, binary) tree, with a classifier at each node; at query time, update the classifiers to improve retrieval.

The case for learned index structures
T. Kraska et al.

Many data structures can be replaced by learned models, leveraging GPUs/TPUs.

B-trees (range indices, in databases) map a key to a position in a sorted array, *i.e.*, estimate a cumulative distribution function (CDF); they can be replaced with a neural net. The maximum error measured on the whole dataset defined the size of the window to examine (the B-tree is actually similar: it retrieves a whole “page”, instead of the single value it actually needs). It is possible to replace only part of the data structure with a neural net, or arrange several neural nets in a tree.

Hash functions can also be replaced by learning the CDF of the key, and dilating it to get a hash map.

A good hash function for a Bloom filter would have many key/key and non-key/non-key collisions, but few key/non-key collisions. Bloom filters can be replaced by a key/non-key classifier, with a smaller Bloom filter for the set of false negatives, to keep the false negative rate to zero.

***Clustering by passing messages
between data points***
B.J. Frey and D. Dueck

Use exemplars:

$$\begin{aligned} s_{ij} &: \text{similarity} \\ r_{ik} &\leftarrow s_{ik} - \text{Max}_{k' \neq k} a_{ik'} + s_{ik'} \\ a_{ik} &\leftarrow \text{Min} \left\{ 0, r_{kk} + \sum_{i' \neq i, k} (r_{ik'})_+ \right\} \\ a_{kk} &\leftarrow \sum_{j' \neq k} (r_{ik'})_+ \\ \text{exemplar}(i) &= \text{Argmax}_k a_{ik} + r_{ik} \end{aligned}$$

with damping (*i.e.*, updates of the form $x \leftarrow (1 - \lambda)x + \lambda x_{\text{new}}$) and only exchanging messages between nearby or similar points.

***Distributional regression forests
for probabilistic precipitation forecasting
in complex terrain***
L. Schlosser et al.

Linear regression models the mean of the response variable as a function of the predictors.

Non-homogeneous Gaussian regression (NGR) models both mean and variance.

GAMLSS uses a GAM for location, scale and shape (`gamlss`, `gamboostLSS`).

To account for interactions and non-smooth dependencies, one can use a random forest of regression trees with GAMLSS leaves (`disttree`).

***Statistical detection
of systematic election irregularities***
P. Klimek et al. (2012)

Ballot stuffing (only one type of election irregularity) can be detected by looking at:

- The winner votes vs turnout density plot, which should not show an abnormal high-turnout, high rate cluster;
- The cumulative number of votes as a function of turnout, which should end with a plateau.

***A fast and objective multidimensional
kernel density estimation method: fastKDE***
T.A. O'Brien et al. (2016)

The choice of kernel and bandwidth, for kernel density estimation (KDE), is often arbitrary. Use κ , where

$$\tilde{\kappa}(t) = \frac{n}{2(n-1)} \left[1 + \sqrt{1 - \frac{4(n-1)}{n^2 |\mathcal{C}(t)|^2} I(t)} \right]$$

$$\mathcal{C}(t) = \frac{1}{n} \sum e^{ix_j \cdot t} \text{ empirical characteristic function}$$

$$\tilde{\kappa} = \mathcal{F}^{-1} \kappa \text{ inverse Fourier transform}$$

and I filters out frequencies t with $|\mathcal{C}(t)| \leq 2\sqrt{n-1}/n = \mathcal{C}_{\min}$ and possibly a few more (e.g., outside $[-t^*, t^*]$, where for half the t in $[-t^*, t^*]$, $\mathcal{C}(t) \geq \mathcal{C}_{\min}$). The optimal kernel can be computed with the nuFFT (non-uniform FFT).

This can be generalized to multivariate KDE.

***Controllable conformal maps
for shape deformation and interpolation***
O. Weber and C. Gotsman (2010)

To deform a (simply-connected) shape Ω , use a conformal transformation f . It suffices to specify the *angular factor* $\theta = (\log f')|_{\partial\Omega}$. the conformal transformation can be recovered as follows:

- Extend θ harmonically on Ω ;
- Compute its harmonic conjugate ϕ (Hilbert transform);
- Consider the holomorphic function $g = \phi + i\theta$;

- Solve $f' = \exp g$ – since f' does not vanish, f is conformal.

Generalized Cauchy coordinates use the Cauchy formula, a polynomial discretization of $\partial\Omega$, a quadratic approximation of f on each edge, with two values at each corner.

An invitation to noncommutative algebra
C. Walton

Noncommutative algebra studies *representations* of noncommutative algebras, e.g., the quaternions, or the *Weyl algebra*

$$\frac{k\langle x, y \rangle}{(yx - xy - 1)}$$

(which models differential operators, with $y = d/dx$, and does not have finite-dimensional representations – to see it, take the trace), *deformations* of commutative structures, e.g.,

$$\mathbf{C}_q[x, y] = \frac{k\langle x, y \rangle}{yx - qxy}, \quad q \in \mathbf{C}^\times,$$

and deformations of group actions (into Hopf algebra actions), e.g.,

$$H_q = \frac{\mathbf{C}\langle g, g^{-1}, h \rangle}{(gg^{-1} - 1, g^{-1}g - 1, gh - q^2hg)}$$

(as $q \rightarrow 1$, $g, g^{-1} \rightarrow 1$, $h \rightarrow \partial_y$).

***An empirical evaluation of
generic convolutional and recurrent networks
for sequence modeling***
S. Bai et al. (2018)

Use *temporal convolutional networks* (TCN) to model sequences: no pooling, causal dilated convolutions and residual connections.

***Detecting malicious PowerShell commands
using deep neural networks***
D. Hendler et al.

To detect malicious commands in the logs, use an ensemble of:

- 3-grams tf-idf logistic regression;
- bag-of-words tf logistic regression;
- (CNN,MaxPool)²CNN⁴MaxPool(FC,Dropout)⁴FC;
- CNN, MaxPool, (FC, Dropout)²,

on a dataset of 100,000 commands, 10% malicious.

BERT: pre-training of deep bidirectional transformers for language understanding
J. Devlin et al.

Most language models only rely on the left context, *i.e.*, model $P[w_{n+1}|w_{1:n}]$; BERT uses *transformers* (*i.e.*, attention-based networks) conditioned on both the left and right context, $P[w_n|w_{1:n-1}, w_{n+1:N}]$. ELMo is similar, but uses separate left-to-right and right-to-left LSTMs, which are only concatenated at the end.

Are distributional representations ready for the real world? Evaluating word vectors for grounded perceptual meaning
L. Lucy and J. Gauthier

Word embeddings cannot recover *semantic norms*, *i.e.*, entailments such as *alligator* \rightarrow *is green, animal, reptile, eats people, has teeth, etc.*

Morph-fitting: fine-tuning word vector spaces with simple language-specific rules
I. Vulić et al.

To modify a trained word embedding to account for known synonym and antonym pairs (e.g., different word endings in morphologically rich languages), use the following loss function

$$\begin{aligned} & \sum_{x_\ell \sim x_r} \text{ReLU}(\delta + x_\ell t_\ell - x_\ell x_r) + \text{ReLU}(\delta + x_r t_r - x_\ell x_r) \\ & + \sum_{x_\ell \not\sim x_r} \text{ReLU}(\delta + x_\ell t_r - x_\ell x_\ell) + \text{ReLU}(\delta + x_\ell t_r - x_r x_r) \\ & + \lambda \sum_x \|x^{\text{init}} - x\|_2^2 \end{aligned}$$

where t_i is the word closest to x_i (in the current mini-batch).

BLEU: a method for automatic evaluation of machine translation
K. Papineni et al.

TextRank: bringing order into texts
R. Mihalcea and P. Tarau

To extract keywords from a text, apply undirected PageRank to the cooccurrence graph (vary the window size) between words or sequences of words (try different POS, e.g., nouns and adjectives).

For sentence extraction (summarization), use sentences as nodes and similarity (number of common words, divided by the log of the lengths) as weights.

Multimodal word distributions
B. Athiwaratkun and A.G. Wilson

Extend the skipgram model by replacing the point representation of words with Gaussian mixtures, allowing for both polysemy and entailment (e.g., *jazz* \subset *music*).

Enriching word vectors with subword information
P. Bojanowski et al.

FastText fits a skipgram model to n -grams and represents words as the sum of their n -grams – it is aware of word morphology and can deal with unknown words.

A simple but tough-to-beat baseline for sentence embeddings
S. Arora et al. (2017)

Turning word embeddings into sentence embeddings by naively averaging the embeddings of the words in the sentence does not work that well; try the following simple modification:

- Use a weighted average, $w = \frac{a}{a + P(\text{word})}$;
- Remove the first principal component (it contains stopwords and other non-informative words).

In the word2vec (CBOW) model

$$P[w|w_1 \cdots w_5] \propto \exp\left(v_w \cdot \frac{1}{5} \sum_i v_{w_i}\right)$$

frequent words are under-sampled when computing the gradient, to speed up training and give more regular embeddings.

Supervised learning of universal sentence representations from natural language inference data
A. Conneau et al. (2018)

InferSent uses a supervised task, *natural language inference* (recognizing if a sentence entails, contradicts or is unrelated to another) with a bidirectional LSTM RNN with max pooling to compute sentence embeddings.

Skip-thought vectors
R. Kiros et al.

To compute sentence embeddings, forecast a sentence from nearby sentences (as in word2vec's CBOW) using a GRU RNN trained on the BookCorpus dataset (unpublished authors).

For out-of-vocabulary words, learn a mapping from the word2vec space (using unpenalized least squares).

Vader: a parsimonious rule-based model for sentiment analysis of social media text
C.J. Hutto and E. Gilbert (2014)

Vader is an MIT-licensed sentiment lexicon, targeted at short, Twitter-like sentences, augmented with a few simple rules for all-caps, punctuation (exclamation marks), degree modifiers (extremely, marginally, etc.), contrastive conjunctions (but) and negations, available in NLTK.

Deep contextualized word representations
C. Clark et al. (2018)

ELMo uses, as sentence embedding, all the internal layers (not just the first and the last ones) of a deep bidirectional LSTM network trained as a language model (*i.e.*, to predict the next/previous/missing word).

Universal sentence encoder
C. Cer et al. (2018)

Train a model, e.g., a **transformer** (attention-based network, instead of an LSTM) or a **deep averaging network** (DAN: the embeddings of the inputs words and bigrams are averaged and fed to a deep neural network – the word embeddings are trained so that their averages be useful as sentence embeddings) on several tasks (skip-thought, conversation input-response, classification).

Pretrained models are available on TFHub.

Semantic specialization of distributional word vector spaces using monolingual and cross-lingual constraints
N. Mrkšić et al. (2017)

Attract-Repel modifies a word embedding to account for synonyms and antonyms (some come from cross-lingual sources, which can also provide multilingual embeddings) using a margin loss on positive (actual synonyms or antonyms) or negative pairs.

Morph-fitting: fine-tuning word vector spaces with simple language-specific rules
I. Vulić et al. (2017)

Modify a vector embedding to account for synonyms (inflections, e.g., V, V-ed, V-ing, in English) and antonyms (derivations, e.g., negative English prefixes: dis, un, in, im, il, ir, mis, non, anti) with margin loss.

Concatenated power mean word embeddings as universal cross-lingual sentence representations
A. Rückle et al. (2018)

To compute a sentence embedding, concatenate several “averages” (arithmetic, maximum, minimum) of several pretrained word embeddings (GloVe, word2vec, Attract-Repel, MorphSpecialized).

A neural probabilistic language model
J. Bengio et al. (2003)

The first layer of an n -gram neural language model (predicting the next word from the previous n) can be used as a word embedding.

Deep-learning-based cryptocurrency sentiment construction
S. Nasekin and C.Y.S. Chen (2018)

Word2vec and RNN-based sentiment index, trained with StockTwits data – users often label their messages with “bullish” or “bearish”.

Modeling snow crystal growth I
J. Gravner and D. Griffeath (2006)

Packard’s digital snowflake model is a cellular automaton on a hexagonal lattice in which a site with one (or at least one, or between 1 and 3, etc.) occupied neighbour becomes occupied.

A deep learning framework for financial time series using stacked autoencoders and long-short-term memory
W. Bao et al. (2016)

Try to forecast six equity indices from prices, volumes, technical indicators and macro variables, denoised with a wavelet transform [doesn’t this introduce some look-ahead bias?], dimension-reduced with an auto-encoder, and fed to an LSTM.

Optimal timing and tilting of equity factors
H. Dichtl et al. (2018)

To time factors,

- Take
 - Some (US) macroeconomic indicators;
 - Some technical indicators of those factors;
 - Some cross-sectional factor characteristics, e.g., earning yields of the long-short quintile portfolios, momentum, volatility [these are technical indicators], centrality in the (weighted) complete correlation graph [they use the MST], distance to market [just a beta];
- Perform some dimension reduction (only keep the first principal component) in each group;
- Find the solution of the mean-variance optimization problem of the form $w = \theta z'$ where w are the (unknown) portfolio weights, z are the principal components (and an intercept) and θ are the new unknowns (Brandt–Clara parametric portfolio policy).

Big data and AI strategies: ML and alternative data approach to investing
M. Kolanovic (JPM, 2017)

The big data revolution is made possible by the combination of data, algorithms and hardware. Alternative data can be classified from their origin: humans, business processes or machines (sensors). Beware of seasonality, sampling bias and short history. Examples include sentiment (for instance, stocks, regions, sectors, indices), Twitter, news, Wikipedia, company websites, web traffic (Alexa), search (Google trends), job postings (Glassdoor, LinkedIn), purchase receipts.

- Twitter sentiment, for 100 stocks in the S&P 500, aggregated every minute and smoothed with a 10-day exponential moving average, to forecast the S&P 500 returns for the next 2 days, with time-changing betas (Kalman), for a long-short strategy;

- Ravenpack news data, average daily sentiment score (ESS) for currencies, commodities, countries, where relevance > 75, for a daily long-short strategy;
- Email receipts, for 30 companies in the S&P 500: weekly change of dollar spent, number of orders, number of buyers;
- Mobile phone location, assuming sales are proportional to traffic, to predict if a company will beat expectations;
- Satellite images to monitor retail traffic, real estate traffic, metal production and storage, factory employment (Bollinger bands on quarterly traffic);
- Penalized regression to forecast S&P, 10y, DXY, gold returns (daily), from their 1m, 3m, 6m, 12m lagged values, on a 2-year window;
- k -NN to forecast risk premia from macro indicators
- Kalman filter (time-varying beta) for pairs trading;
- Xgboost to forecast daily sector returns from macro factors;
- Logistic regression to forecast if call overwriting will outperform a long-only strategy, from 10 investment factors;
- SVM to forecast if the P&L of a rolling long 1m ATM EURUSD will be > 20bp, or < -20bp, from the first 50 to 200 principal components of 400 predictors (volatility, skew, spot, basis, interest rate, equity/commodity/bond indices, economic activity, IMM position; their levels and 1w, 1m changes);
- Random forest to forecast 1-month returns from investment factors;
- 2-class hidden Markov model (HMM) to identify up and down states (low and high volatility): buy the S&P 500 in up markets, keep cash in down markets;
- Hierarchical risk parity;
- PCA on daily changes in the USDJPY implied volatility to help describe its variations;
- Statistical risk models;
- Multilayer perceptron to forecast next day sector returns from 8 macro factors (just 8 predictors: oil, gold, dollar, bonds, economic surprise, 10y-2y spread, IG and HY credit spreads);
- LSTM to forecast monthly returns from the past 3 years (does not work);
- SVM to forecast daily FX returns from 20 features, obtained by dimension reduction with a restricted Boltzman machine (RBM) using 10 days of daily returns for 10 commodities (100 predictors);
- Reinforcement learning (combined with supervised learning to forecast returns), for trading.

The report also includes R and Python sample code (web scraping and simple models), a long list of data providers, and 16 pages of references.

***Essentially no barriers
in neural network energy landscape***
F. Draxler et al. (2018)

Neural networks have many local minima. Linear interpolation between them suggests they are separated by high-loss barriers, but the AutoNEB algorithm can find paths of almost constant loss.

The *elastic band* model finds points minimizing $\sum \text{loss}(p_i) + \frac{1}{2} \sum k \|p_{i+1} - p_i\|^2$ (where k is the spring stiffness). In the *nudged elastic band* model, the loss force only acts perpendicularly to the path, and the spring force parallelly, $g = \nabla \text{loss}|_{\perp} + \nabla \text{spring}|_{\parallel}$, so that the spring force redistribute the points on the path without straightening it. Instead of choosing the spring stiffness k , one can remove the springs altogether and simply redistribute the points on the path at each iteration. The *AutoNEB* algorithm progressively increases the number of points.

While the algorithm finds *local* minimum energy paths, the loss may increase too much: this may be remedied by considering a graph of low-energy paths between several local minima.

***Quickshift++: provably good initializations
for sample-based mean shift***
H. Jiang et al. (2018)

The **MeanShift** clustering algorithm is a gradient ascent on a kernel density estimator f .

The *QuickShift* algorithm is a discretized variant, moving each sample to the closest one with a higher density in a radius τ ball.

The *QuickShift++* algorithm is a variant stopping when it reaches a cluster core, rather than a local mode.

A *cluster core* M of a topological space X is a connected component of

$$\left\{ x \in X : f(x) \geq (1 - \beta) \max_{y \in M} f(y) \right\}.$$

The k -NN density estimator in \mathbf{R}^d is $f(x) \propto d_k(x)^{-d}$, where $d_k(x)$ is the distance to the k th nearest neighbour.

***Representation tradeoffs
for hyperbolic embeddings***
C. De Sa et al. (2018)

To embed a tree in the Poincaré ball (Sarka's construction), start by placing the root a at the origin,

- Apply a reflection, if needed, to put a at the origin;
- Add a 's children on a radius τ circle centered on a , equally-spaced, but as far away from a 's parent as possible;
- Apply the reflexion to go back to the original position (we still have a circle and equal angles, but the circle is no longer centered on a);
- Iterate with a 's children.

In higher dimensions, use *spherical encoding* to put the points on the sphere (e.g., using vertices of a hypercube).

For a general graph, add *Steiner nodes*.

Reconstructing approximate tree metrics
I. Abraham et al. (2007)

Instead of embedding your data (e.g., a graph) in a Euclidean space, try embedding it in a tree.

To embed a graph in a tree:

- Choose a “root” node r ;
- Find nodes p, q maximizing the *Gromov product*

$$(p|a)_r = \frac{1}{2}(p(p, q) + d(q, r) - d(p, q))$$

and add a **Steiner node** $\triangle \rightsquigarrow \circ$ at distances $(q|r)_p, (p|r)_q, (p|q)_r$ of p, q, r ;

- Remove q and iterate.

Learning continuous hierarchies in the Lorentz model of hyperbolic geometry
M. Nicket and D. Kiela (2018)

Graphs, especially trees, are more naturally embedded in hyperbolic spaces, e.g., the Poincaré disk, or the *hyperboloid model*.

Anonymous walk embeddings
S. Ivanov and E. Burnaev (2018)

An **anonymous walk** on a graph is a random walk (of length ℓ) with the nodes replaced with numbers (for instance, both ABCBC and CDBDB map to 12323). They give a sparse embedding and, with word2vec (anonymous walks are words, sets of walks starting at the same node sentences, graphs documents), a dense one.

Bayesian optimization of combinatorial structures
R. Baptista and M. Poloczek (2018)

To maximize a function f on $\{0, 1\}^d$, model it using only interactions of order up to k , e.g.,

$$f(x) = \alpha_0 + \sum_i \alpha_i x_i + \sum_{i < j} \alpha_{ij} x_i x_j \quad (k = 2),$$

estimate α from the points already evaluated with a sparse Bayesian regression (and a Horseshoe prior), sample a value for α , and approximately maximize f_α (with an L^1 or L^2 penalty) with a SDP relaxation.

Accurate uncertainties for deep learning using calibrated regression
V. Kuleshov et al. (2018)

Bayesian uncertainties are often inaccurate (variational inference is an approximation): to recalibrate a Bayesian deep learning model, *i.e.*, a model $x \mapsto F_x = \text{cdf of } y$, learn an auxiliary model (isotonic regression) $R : [0, 1] \rightarrow [0, 1]$ such that $R \circ F_x$ be calibrated.

Large-scale sparse inverse covariance estimation via thresholding and max-det matrix completion
R.Y. Zhang et al. (2018)

The *graphical lasso*

$$\underset{X \succ 0}{\text{Minimize}} \text{tr} CX - \log \det X + \lambda \sum_{ij} |X_{ij}|$$

to find a sparse concentration matrix X from a sample covariance matrix C can be approximated with a simple heuristic, first soft-thresholding ~~the~~ the covariance $C \mapsto C_\lambda$, then solving the *maximum determinant matrix completion* (MDMC) problem.

$$\begin{aligned} \text{Find} \quad & X \succ 0 \\ \text{To minimize} \quad & \text{tr} C_\lambda X - \log \det X \\ \text{Subject to} \quad & X_{ij} = 0 \text{ if } (C_\lambda)_{ij} = 0, \text{ i.e., if } |C_{ij}| \leq \lambda \end{aligned}$$

(There is a recursive closed form solution if the graph is chordal but, in practice, that rarely happens unless it is a tree.)

Conditional neural processes
M. Garnelo et al. (2018)

Neural nets can replace Gaussian processes to model functions $y = f(x)$:

$$\begin{aligned} h_\theta : \begin{cases} \mathbf{R}^N \times \mathbf{R} \rightarrow \mathbf{R}^d \\ (x, y) \mapsto r \end{cases} & a : \begin{cases} \mathbf{R}^d \times \dots \times \mathbf{R}^d \rightarrow \mathbf{R}^d \\ (r_1, \dots, r_d) \mapsto r \end{cases} \\ g_\theta : \begin{cases} \mathbf{R}^N \times \mathbf{R}^d \rightarrow \mathbf{R}^p \\ (x, r) \mapsto \phi \end{cases} \end{aligned}$$

where h_θ and g_θ are neural nets, a is some aggregation function, r summarizes the information so far, ϕ are the parameters of the distribution of y , e.g., $\phi = (\mu, \sigma^2)$ for a Gaussian.

Optimization, fast and slow: optimally switching between local and Bayesian optimization
M. McLeod et al. (2018)

- Use Bayesian optimization, with *predictive entropy search* (PES: maximize the expected change in information content), to find a convex region likely to contain the global minimum;
- Use Bayesian optimization, with a different acquisition function, to ensure the region indeed contains a global minimum;
- Find the minimum, using local search (L-BFGS).

Adaptive three operator splitting
F. Pedregosa and G. Gidel (2018)

To minimize a function of the form $f + g + h$, where f is smooth (with a known gradient), and g and h have a closed form proximal operator (even though $g + h$ does not), use the three operator splitting (TOS) method,

$$\begin{aligned} x &\leftarrow \text{prox}_{\gamma g}(z - \gamma u - \gamma \nabla f(x)) \\ z &\leftarrow \text{prox}_{\gamma h}(x + \gamma u) \\ u &\leftarrow u + \gamma^{-1}(x - z) \end{aligned}$$

where the step size γ is sufficiently small:

$$f(x) \leq f(z) + \langle \nabla f(z), x - z \rangle + \frac{1}{2\gamma} \|x - z\|^2$$

(i.e., such that the rhs be a quadratic majorizer of f).

Shampoo:
preconditioned stochastic tensor optimization
V. Gupta et al. (2018)

Preconditioning ignores the matrix or tensor structure of the parameters; Shampoo is a generalization of AdaGrad (a diagonal preconditioner) using a separate (dense) preconditioning matrix for each dimension of the gradient tensor. For matrices:

$$\begin{aligned} W_1 &= 0 & L_0 &= \varepsilon I & R_0 &= \varepsilon I \\ G_t &= \nabla f(W_t) & & & & \text{gradient} \\ L_t &\leftarrow L_{t-1} + G_t G_t' & & & & \text{preconditioners} \\ R_t &\leftarrow R_{t-1} + G_t' G_t & & & & \\ W_{t+1} &\leftarrow W_t - \eta L_t^{-1/4} G_t R^{-1/4} & & & & \text{parameters} \end{aligned}$$

Fairness without demographics
in repeated loss minimization
T.B. Hashimoto et al. (2018)

Minority groups contribute less to the loss function and suffer higher loss and higher attrition – disparity increases. *robust optimization* (minimizing the worst case risk over distributions close to the empirical ones for the χ^2 divergence,

$$D_{\chi^2}(P\|Q) = \int \left(\frac{dP}{dQ} - 1 \right)^2 dQ,$$

using the dual formulation) prevents *disparity amplification*.

Augmented CycleGAN: learning
many-to-many mappings from unpaired data
A. Almahairi et al. (2018)

CycleGAN learns 1-to-1 mappings. For 1-to-many mappings, add a latent space

and consider two generators and two encoders

$$\begin{aligned} A \times Z_b &\longrightarrow B \\ B \times Z_a &\longrightarrow A \\ A \times B &\longrightarrow Z_a \\ A \times B &\longrightarrow Z_b \end{aligned}$$

Is generator conditioning
causally related to GAN performance?
A. Odena et al. (2018)

To evaluate the quality of a GAN, check the *inception score*

$$\exp \mathbb{E}_{\text{image} \sim \text{generator}} \text{KL}(p(\text{label}|\text{image}) \| p(\text{label}))$$

or the *Fréchet inception distance*, i.e., the Wasserstein distance W_2 between Gaussian fits of the activations,

$$W_2 = \|\mu_1 - \mu_2\|_2^2 + \text{tr}(V_1 + V_2 - 2(V_1 V_2)^{1/2}).$$

Poor quality is linked to the condition number of the Jacobian of the generator. *Jacobian clamping* feeds two minibatches to the generator, differing by small perturbations, computes the relative changes $\|\Delta G(z)\| / \|\Delta z\|$, and adds a penalty if they are not all in some predefined interval $[\lambda_{\min}, \lambda_{\max}]$.

MAGAN: aligning biological manifolds
M. Amodio (2018)

To align two domains, use two GANs

and add reconstruction losses for $G_{12} \circ G_{21} \approx \text{Id}$ and $G_{21} \circ G_{12} \approx \text{Id}$.

Learning longer-term dependencies in RNNs
with auxiliary losses
T.H. Trinh et al. (2018)

To have RNNs learn longer-term dependencies, use truncated BPTT with auxiliary losses, to forecast past (and/or future) observations.

Attention-based deep multiple instance learning
M. Ilse et al. (2018)

In *multiple instance learning* (MIL), labels are not assigned to instances but to bags of instances (labels may exist for instances, though, aggregated in each bag with a max or a sum). A function $S : \mathcal{P}(\text{Data}) \rightarrow \mathbf{R}$ is *symmetric* if it can be written $S(X) = g(\sum_{x \in X} f(x))$, for some functions f and g ; it can then be approximated arbitrarily close as $S(x) \approx g(\text{Max}_{x \in X} f(x))$. For a binary output, model f and g as neural nets and maximize the Bernoulli likelihood.

Mixed batches and symmetric discriminators
for GAN training
T. Lucas et al. (2018)

To reduce *mode collapse* in GANs, feed the discriminator a batch of true and generated samples and have it forecast the proportion of true samples.

Equivariant and invariant layers can be obtained as

$$\begin{aligned}(x_1, \dots, x_n) &\longmapsto (f x_1, \dots, f x_n) \\ (x_1, \dots, x_n) &\longmapsto A \rho(f x_1, \dots, f x_n)\end{aligned}$$

where ρ is the (elementwise) mean, standard deviation or maximum (or a basis of symmetric polynomials). The following layers suffice:

$$(x_1, \dots, x_n) \mapsto (\sigma(\beta + A x_1 + B \bar{x}), \dots, \sigma(\beta + A x_n + B \bar{x})).$$

CoVeR: learning covariate-specific vector representations with tensor decompositions

K. Tian et al. (2018)

The GloVe vector embedding can be generalized to deal with covariates

A : co-occurrence matrix

i, j : words

k : covariates (context)

$$f : \text{weight function, e.g., } 1 \text{ or } \left(\frac{\text{Min}(100, x)}{100} \right)^{.75}$$

$$\text{Argmin}_{v, c, b} \sum_{i, j, k} ((c_k \odot v_i)'(c_k \odot v_j) + b_{ik} + b_{jk} - \log A_{ijk})^2$$

Learning in integer latent variable models with nested automatic differentiation

D. Sheldon et al. (2018)

The forward algorithm, for hidden Markov models,

k : time

n_k : population size

z_{ik} : offspring of individual $i \in \llbracket 1, n_{k-1} \rrbracket$

m_k : immigration

$$n_k = \sum_{i=1}^{n_{k-1}} z_{k,i} + m_k \text{ (hidden)}$$

$$y_k \sim \text{Binomial}(n_k, p) \text{ (observed)}$$

can be formulated with probability generating functions.

Born-again neural networks

T. Furlanello et al. (2018)

Knowledge distillation trains a small (student) network to mimic a larger (teacher) network; try with two similarly-sized networks.

Differentiable dynamic programming for structured prediction and attention

A. Mensch and M. Blondel (2018)

To make dynamic programming (Viterbi, dynamic time warp (DTW)) differentiable, replace the (Max, +) semiring with (Max $_{\Omega}$, +)

$$\text{Max}_{\Omega}(x) = \text{Max}_{q \in \Delta^D} \langle q, x \rangle - \Omega(q)$$

$$\nabla \text{Max}_{\Omega}(x) = \text{Argmax}_{q \in \Delta^D} \langle q, x \rangle - \Omega(q)$$

where Ω is the negentropy $-H$ (Max $_{\Omega} = \log \text{sum exp}$, $\nabla \text{Max}_{\Omega} = \text{softmax}$), or the squared ℓ^2 norm ($\nabla \text{Max}_{\Omega}$ is then sparse).

Analysis of minimax error rate for crowdsourcing and its application to worker clustering model

H. Imamura et al. (2018)

The **Dawid and Skene** model of crowdsourcing uses the EM algorithm to estimate the confusion matrix of the workers $P[\text{worker } i \text{ gives label } k \text{ instead of } \ell]$ and the true labels.

Neural networks should be wide enough to learn disconnected decision regions

Q. Nguyen et al. (2018)

If no layer has more units than the input, the decision regions are connected (for ReLU activations).

A hierarchical latent vector model for learning long-term structure in music

A. Roberts et al. (2018)

The second term in the ELBO

$$E[\log p(x|z)] - \text{KL}(q(z|x) \| p(z)) \leq p(x)$$

can be seen as a penalty and replaced with $\lambda \cdot \text{KL}$ or $(\text{KL} - \tau)_+$.

Learning long-term dependencies via Fourier recurrent units

J. Zhang et al.

Statistical recurrent units (SRU) keep moving averages of past hidden states; Fourier recurrent units keep their (truncated) Fourier transform.

Learning in reproducing kernel Kreĭn spaces

D. Oglic and T. Gärtner (2018)

A **Kreĭn space** is a vector space H with a non-degenerate symmetric but indefinite bilinear form admitting a decomposition $H = H_+ \oplus H_-$ into orthogonal Hilbert spaces such that $\langle f, g \rangle_H = \langle f_+, g_+ \rangle_{H_+} - \langle f_-, g_- \rangle_{H_-}$. The inner product $\langle \cdot, \cdot \rangle_{H_+} + \langle \cdot, \cdot \rangle_{H_-}$ makes H a Hilbert space; its topology does not depend on the choice of decomposition.

A *reproducing kernel Kreĭn space* is a Kreĭn space $K \subset \mathbf{R}^X$ for which the evaluation is continuous. If $k : X \times X \rightarrow \mathbf{R}$ is a difference of positive kernels (not every non-degenerate symmetric kernel is), it defines a reproducible kernel Kreĭn space.

Goodness-of-fit testing for discrete distributions via Stein discrepancy
J. Yang et al. (2018)

To characterize convergence in distribution towards p , the **Stein method** uses a “Stein operator” \mathcal{A}_p , usually defined from the score function of p (which can be computed from an unnormalized probability distribution), e.g.,

$$\mathcal{A}_p f(x) = \nabla \log p(x) f(x) + \nabla f(x),$$

and a set of test functions \mathcal{F} , e.g., $W^{2,\infty}$, or the unit ball of a RKHS, such that

$$\forall f \in \mathcal{F} \quad \mathbb{E}_{x \sim q} [\mathcal{A}_p f(x)] = 0 \quad \text{iff} \quad q = p.$$

The *Stein discrepancy*

$$\sup_{f \in \mathcal{F}} \mathbb{E}_{x \sim q} [\mathcal{A}_p f(x)]$$

can be used as a goodness of fit statistic for unnormalized distributions.

For discrete distributions, use

$$\Delta_i f(\mathbf{x}) = f(\mathbf{x}) - f(\sigma_i \mathbf{x})$$

$$\Delta_i^* f(\mathbf{x}) = f(\mathbf{x}) - f(\sigma_i^{-1} \mathbf{x})$$

$$s_i(\mathbf{x}) = \frac{\Delta_i p(\mathbf{x})}{p(\mathbf{x})}$$

$$\mathcal{A}_p f(\mathbf{x}) = s(\mathbf{x}) f(\mathbf{x})' - \Delta^* f(\mathbf{x})$$

where $\mathbf{x} \in X^d$, X is finite, σ is a cyclic permutation of X , σ_i only acts on the i th component, $f : X^d \rightarrow \mathbf{R}^m$, p is a distribution on X^d . For the unit ball of a RKHS,

$$D(q \| p) = \sup_f \mathbb{E}_{x \sim q} [\text{tr} \mathcal{A}_p f(x)]$$

can be computed as

$$D(q \| p) = \mathbb{E}_{x, y \sim q} [\kappa_p(x, y)].$$

A spline theory of deep networks
R. Balestrierio and R.G. Baraniuk (2018)

To make the features learned by a neural net more orthogonal, add a penalty

$$\lambda \cdot \sum_{i \neq j} |\langle w_i, w_j \rangle|^2.$$

Non-overlap-promoting variable selection
P. Xie et al. (2018)

The multilogistic model has a vector of parameters w_i for each class i . Easy-to-interpret sparse vectors with little overlap can be obtained with an ℓ^1 penalty and a penalty encouraging the vectors w_i to be orthogonal or orthonormal, *i.e.*, encouraging the Gram matrix $G_{ij} = w_i' w_j$ to be close to the identity.

The **log-determinant divergence** measures how close two matrices are.

$$D(X, Y) = \text{tr}(XY^{-1}) - \log \det(XY^{-1})$$

Variable selection via penalized neural network: a drop-out-one loss approach
M. Ye and Y. Sun (2018)

Variant of backward elimination (stepwise regression), with a neural network, for variable selection: fit a complete model, drop one variable *without re-fitting*, discard it if the change in loss is small.

Nonparametric variable importance using an augmented neural network with multitask learning
J. Feng et al. (2018)

To estimate (local) variable importance

$$(E[Y|X] - E[Y|X_{-i}])^2$$

in a neural network, augment its input with a mask indicating which variables to use.

Accelerated spectral ranking
A. Agarwal et al. (2018)

Pairwise or multiway comparisons (sports ranking, recommendation systems, social choice) can be aggregated: the Bradley-Terry model weights

$$P[i \succ j] = \frac{w_i}{w_i + w_j}$$

are the centralities of a graph, and can be estimated with random walks.

Ranking distributions based on noisy sorting
A. El Mesaoudi-Paul et al. (2018)

Define a probability distribution of \mathfrak{S}_n by using a sorting algorithm (insertion, quicksort) with comparisons replaced by Bernoulli trials; the Bernoulli parameters are pairwise preferences. Other distributions on \mathfrak{S}_n include:

- **Mallows:** $P[\sigma] \propto \exp -k\tau(\sigma)$, where τ is Kendall's tau (it can be centered on a permutation $\sigma_0 \neq \text{Id}$ by using $\tau(\sigma_0 \sigma \sigma_0^{-1})$);
- **Generalized Mallows:** $P[\sigma] \propto \exp - \sum k_i d_i(\sigma)$, where $d_i(\sigma) = \sum_{j>i} \mathbf{1}_{\sigma^{-1}(j) < \sigma^{-1}(i)}$ (it can be further generalized to account for a hierarchical structure on $\llbracket 1, n \rrbracket$);
- **Plackett-Luce:** $P[\sigma(i) = k | \sigma(1), \dots, \sigma(i-1)] \propto \theta_k$, *i.e.*,

$$P[\sigma] = \prod_i \frac{\theta_{\sigma^{-1}(i)}}{\theta_{\sigma^{-1}(i)} + \theta_{\sigma^{-1}(i+1)} + \dots + \theta_{\sigma^{-1}(n)}}$$

- **Babington-Smith:** the orderings of pairs are independent Bernoulli trials, rejected if they do not give an order relation,

$$P[\sigma] \propto \prod_{i < j} P_{\sigma^{-1}(i), \sigma^{-1}(j)},$$

A probabilistic theory of supervised similarity learning for pointwise ROC curve optimization
R. Vogel et al. (2018)

Pointwise ROC optimization maximizes the TPR (true positive rate) for a fixed FPR (false positive rate).

Pairwise bipartite ranking learns to recognize if two observations x, x' have the same label $y = y'$ (e.g., if two photographs are of the same person), $(x, x') \mapsto \mathbf{1}_{y=y'}$.

Fast stochastic AUC maximization with $O(1/n)$ convergence rate
M. Liu et al. (2018)

The AUC is often maximized using a surrogate square loss

$$\text{AUC} = P[f(x_1) < f(x_2) \mid y_1 = +1, y_2 = -1]$$

$$\text{Loss}(f) = E[(f(x_1) - f(x_2) - 1)^2 \mid y_1 = +1, y_2 = -1];$$

this can be turned into a saddle point problem.

Accelerated stochastic mirror descent: from continuous-time dynamics to discrete-time algorithms
P. Xu et al. (2018)

Stochastic mirror descent (SMD)

$$y_{k+1} \leftarrow \nabla h(x_k) - \eta \nabla f(x_k)$$

$$x_{k+1} \leftarrow \nabla h^*(y_{k+1})$$

minimizes $E[f]$, where h is convex on X , e.g., $h(x) = \|x\|_2^2$ on \mathbf{R}^2 or $h(x) = \sum x_i \log x_i$ on Δ_n , and $h^*(y) = \sup_{x \in X} \langle y, x \rangle - h(x)$.

Batch Bayesian optimization via multi-objective acquisition ensemble for automated analog circuit design
W. Lyu et al. (2018)

Multiobjective optimization of multiple acquisition functions leads to (single-objective) *batch* optimization.

Subspace embedding and linear regression with Orlicz norm
A. Andoni et al. (2018)

Orlicz norms generalize ℓ^p norms and (when used for losses rather than penalties) provide robust estimators (not unlike ℓ^p , $1 \leq p < 2$).

$$f(x) = \begin{cases} \frac{1}{2}x^2 & \text{if } |x| \leq \delta \\ \delta(|x| - \frac{1}{2}\delta) & \text{otherwise} \end{cases} \quad (\text{Huber})$$

$$G(x) = f(f^{-1}(1)x)$$

$$\|x\|_G = \inf \left\{ \alpha > 0 : \sum G(|x_i|/\alpha) \leq 1 \right\}$$

Differentiable compositional kernel learning for Gaussian processes
S. Sun et al. (2018)

Since linear combinations and products of Gaussian process kernels are still kernels, a neural network, starting with primitive kernels and alternating those two operations, can be used to model them – this replaces the automated statistician’s discrete search on a context-free grammar with an end-to-end differentiable optimization problem.

Network global testing by counting graphlets
J. Jin et al. (2018)

The degree-corrected mixed membership model generalizes the *stochastic block model* (SBM)

$$P[A_{ij} = 1] = \theta_i \theta_j \sum_{1 \leq k, \ell \leq K} \pi_{ik} \pi_{j\ell} P_{k\ell},$$

where θ is the degree heterogeneity and π measures the mixed membership of the K communities; it can be written as $A = \Omega - \text{diag } \Omega + \text{noise}$, with $\Omega = \Theta \Pi \Pi' \Theta$.

The *graphlet count* statistic tests for $H_0 : K = 1$.

L_m : density of length- m self-avoiding paths

C_m : density of length- m self-avoiding cycles

$$\chi_m = C_m = (L_{m-1}/L_{m-2})^m \quad (m \geq 3)$$

Online convolutional sparse coding with sample-dependent dictionary
Y. Wang et al. (2018)

Sparse coding is a sparse matrix decomposition.

Given $X \in \mathbf{R}^{n \times N}$ (columns = observations)
Find $Y \in \mathbf{R}^{n \times d}$ (columns = filters)
 $W \in \mathbf{R}^{d \times N}$ (columns = weights)

$$\text{To minimize } \|X - YW\|_2^2 + \lambda \sum_i \|W_{\cdot i}\|_1$$

GAIN: missing data imputation using generative adversarial nets
J. Yoon et al. (2018)

GANs can be used to impute missing data: the generator fills in missing values, while the discriminator tries to find which values were imputed.

**Inter and intra topic structure learning
with word embeddings
H. Zhao et al. (2018)**

Hierarchical topic models generalizing *Poisson factor analysis* model texts as mixtures of subtopics, subtopics as mixtures of topics, and topics as distributions on words.

$$\begin{aligned} X &\sim \text{Poisson}(\Phi_1 \Theta_1) && (\text{words}) \\ \Theta_1 &\sim \text{Gamma}(\Phi_2 \Theta_2) \\ \Theta_2 &\sim \text{Gamma}(\Phi_3 \Theta_3) \\ &\vdots \\ \Phi_i &\sim \text{Dir}(\beta_i) \end{aligned}$$

They can also use a vector embedding f :

$$\beta \sim \text{Gamma}(\alpha, e^{f'w}).$$

**Improving regression performance
with distributional losses
E. Imani and M. White (2018)**

Do not forecast values $E[y|x]$ but distributions $y|x$, e.g., forecast the histogram density q_x to minimize $D(p_y||q_x)$, where $p_y = N(y, \sigma^2)$, with σ fixed.

**Comparison-based random forests
S. Haghir et al. (2018)**

A **comparison tree** is a decision tree whose boundaries are obtained by choosing two points x_1, x_2 with different labels and splitting the data with $d(x, x_1) < d(x, x_2)$.

To use a comparison random forest, one only needs to be able to actively tell if the new item A is closer to items B or C .

**QuantTree: histograms for change detection
in multivariate data streams
G. Boracchi et al. (2018)**

To detect distributional changes in multivariate time series, use histogram statistics, but build those histograms on kd-trees rather than grids.

**Deep learning
I. Goodfellow et al. (2016)**

3. The probability theory needed to deal with probabilistic graphical models boils down to two rules.

$$\begin{aligned} \text{Sum rule} & \quad P(x) = \sum_y P(x, y) \\ \text{Product rule} & \quad P(x, y) = P(x)P(y|x) \end{aligned}$$

The Kullback-Leibler divergence is the extra amount of information needed to send a message from P using

a code for Q .

$$\begin{aligned} \text{Information} & \quad I(x) = -\log p(x) \\ \text{Entropy} & \quad H(X) = E[-\log p(X)] \\ \text{KL divergence} & \quad D(P||Q) = E_{x \sim P} \log \frac{P(x)}{Q(x)} \geq 0 \\ \text{Cross-entropy} & \quad H(P, Q) = E_{x \sim P} [-\log Q(x)] \\ & \quad = H(P) + D(P||Q) \end{aligned}$$

Log-likelihood and cross-entropy are the same thing, and the Kullback-Leibler divergence only differs by a constant: minimizing $D(\text{data}||\text{model})$ is equivalent to minimizing $H(\text{data}, \text{model})$.

4. Gradient descent fails to exploit the curvature information in the Hessian – it “wastes time repeatedly descending canyon walls because they are the steepest feature”.

5. Balancing over- and under-fitting requires to both make the training error small and the gap between training and test error small.

The **Bayes error** is the error made by the best predictor possible, *i.e.*, that knowing the true data generation process (the error is not zero because of the error in the data generation process): it is the minimum test set error.

To fight the no free lunch theorem, incorporate preferences into the learning algorithm (prior, regularization).

There are implicit priors in many machine learning algorithms: locally constant (k -means), locally smooth, but deeper algorithms allow for more complex priors – non-local generalization, hierarchical structures.

6. You may need to clip gradients for *mixture density networks* (MLP with Gaussian mixtures in their output).

From the *universal approximation theorem*, one layer is enough, but deeper networks require fewer units.

7. Regularization trades bias for variance. Neural networks may use a separate penalty for each layer.

L^2 regularization shrinks towards zero, but more in the “imprecise” directions (where the Hessian eigenvalues are large). Early stopping, for a linear model, is equivalent to L^2 regularization.

L^1 regularization has a sparsifying effect.

You can add noise to:

- Input (denoising auto-encoder);
- Activations (dropout corresponds to multiplicative noise);
- Weights (this makes the network Bayesian);
- Output (label smoothing replaces 0 and 1 with $\varepsilon/(k-1)$ and $1-\varepsilon$).

Parameter sharing forces parameters to be equal (CNN) or close (transfer learning).

To predict with dropout, you could average over several masks; alternatively, just rescale the weights (there is no theoretical justification for nonlinear models: it is an approximation, but it works well). Multiplying the weights by a random number $\mu \sim N(1,1)$ is another form of dropout, but since $E[\mu] = 1$, no rescaling is necessary.

If you do not have enough data, prefer Bayesian neural nets or semisupervised learning.

To generalize well, neural nets should be locally constant around (orthogonally to) the data manifold – instead, they tend to be linear. Try data augmentation with adversarial examples, or a penalty for $\|\nabla_{\theta} f\|$.

8. The ideal objective function, the expected loss over the data generation process, is not available: instead, we minimize the *empirical risk*, *i.e.*, the average loss over the training set. Non-differentiable loss functions (e.g., 0-1 loss) are often replaced by differentiable surrogates (e.g., negative log-likelihood). Optimization algorithms often converge faster with *mini-batches* ($n \geq 100$ for gradient-based methods, $n \geq 10,000$ for Hessian-based ones), *i.e.*, with frequent though imprecise updates. The mini-batches should be selected randomly.

Gradient descent may not arrive at a critical point – plot the gradient norm: it often fails to decrease. The concern that we may end up at a local minimum or a saddle point is moot.

Models with latent variables are not identifiable: they have many (sometimes uncountably many) local minima – but most minima have a low cost value.

Cliffs in the loss function landscape can be avoided with *gradient clipping*.

Momentum addresses the high variance of the stochastic gradient and bad conditioning of the Hessian. *Nesterov momentum* computes the gradient after the momentum step.

Weight initialization is usually random (to break symmetries) and normalized.

AdaGrad and *RMSProp* decrease the learning rate using the sum or exponential moving average of past gradient norms; *Adam* combines momentum and RMS-Prop.

Second-order methods often assume the Hessian is positive definite, which is not the case around saddle points: the Hessian can be regularized, $H \rightsquigarrow H + \lambda I$ (Levenberg-Marquardt). With gradient descent (and line search), each gradient direction is perpendicular to the previous one, resulting in a zigzag motion. *Conjugate gradient* (CG) replaces this orthogonality condition $d_t' d_{t-1} = 0$ with $d_t' H d_{t-1} = 0$, where $d_t = \nabla J + \beta_t d_{t-1}$ ($\beta_t = 0$ gives the gradient). Some approximations of β_t do not require the Hessian, e.g.,

$$\beta = \frac{\text{current } (\nabla J)'(\nabla J)}{\text{previous } (\nabla J)'(\nabla J)}$$

$$\text{or } \beta = \frac{(\text{change in } \nabla J)'(\text{current } \nabla J)}{\text{previous } (\nabla J)'(\nabla J)}.$$

The gradients tell how to update each parameter if the others remain fixed; *batch normalization* helps decouple the layers.

Polyak averaging (Cesàro summation) can help convergence.

Greedy supervised pretraining builds up an increasingly deeper network.

FitNets train a wide and shallow “teacher” network, and then a deeper “student” network, to forecast both the output and the middle layer of the teacher network, providing hints for its middle layers.

Gradients flow more easily through linear functions: ReLU are easier to train than sigmoids.

Skip-connections (ResNets) reduce the length of the shortest path to the output.

Auxilliary heads are an alternative to pre-training.

Continuation methods use a sequence of increasingly more difficult loss functions (blurring non-convex functions makes them more convex); *curriculum learning* (e.g., stochastic curriculum learning, with a mixture of easy and hard samples), is an example.

9. Convolution (same notion as in math, but without flipping the kernel) can be expressed as multiplication by a structured matrix (circulant and sparse). CNNs are sparsely connected: each neuron is only linked to nearby neurons (small receptive field – but it grows with depth).

Max pooling can be interpreted as a summary statistic of nearby inputs, or as a prior that the output of the layer should be invariant under small translations.

Locally-connected layers are sparsely connected, but do not share weights. *Tiled convolutions* only share weights locally.

“Recurrent” convolutional networks are progressively refined.

For separable kernels, the convolution can be computed separately in each dimension.

To speed up training, skip it, and use random features, hand-crafted features, features from k -means clustering of image patches, greedy layer-wise pretraining.

Real-world convnets use more branching.

10. One-dimensional convolution provides parameter sharing, but it is shallow: each output only depends on the recent past. Recurrent neural nets (RNN) use

a different form of sharing. Back-propagation through time (BPTT) is backpropagation on the unrolled network.

Instead of feeding \hat{y}_t to the network at time $t + 1$, *teacher forcing* uses y_t (during training – otherwise it is not available) and progressively switches to actual forecasts.

Deep recurrent networks can stack layers vertically or horizontally, use skip connections, or remove connections.

Echo state networks (reservoir computing) are similar to kernel machines.

The linear maps $x \mapsto Wx$ can be replaced with bilinear (product) or multilinear (tensor) ones.

Recursive neural nets are tree-shaped neural nets.

Attention and bidirectional RNNs can help.

To deal with exploding gradients, clip them (or take a random step when they are too large); for vanishing gradients, use LSTMs. Try adding a penalty to keep the gradient norm approximately constant.

To improve memory, add skip connections, remove some short connections, and use leaky memory, $m_t \leftarrow (1 - \lambda)m_{t-1} + \lambda v_t$, with different time scales λ .

If LSTMs and attention do not provide enough memory, add explicit memory (neural Turing machine, NTM).

11. Learning rate is the most important parameter.

Increase capacity to reduce training error; increase regularization to reduce the gap between training and testing errors.

Visualize the worst mistakes; fit a tiny dataset; monitor histograms of activations and gradients (parameter updates should be around 1% of the parameter values).

Allow the model to refuse to make a decision if it is too uncertain.

12. Cascades (using a fast high-recall model followed by a more expensive high-precision one) are a form of hard attention.

In an *expert network*, a top-level model decides which expert (model) or, better, combination of experts to use.

Beware of low-contrast, uninformative images when using contrast normalization.

NLP inputs can be preprocessed with n -grams, smoothing, or word embeddings. The hierarchical softmax can help generate high-dimensional outputs.

The gradient of a language model can be decomposed as

$$\begin{aligned}\frac{\partial}{\partial \theta} \log \frac{\exp a_y}{\sum_i \exp a_i} &= \frac{\partial a_y}{\partial \theta} - \sum p_i \frac{\partial a_i}{\partial \theta} \\ &= \frac{\partial a_y}{\partial \theta} - E_i \left[\frac{\partial a_i}{\partial \theta} \right]\end{aligned}$$

(positive and negative phases) and the second term, a huge sum, can be approximated by sampling (but this requires knowing all the $p_i = P[Y = i]$), importance sampling (but this still requires the p_i/q_i) or *biased importance sampling* (normalize the importance weights to sum to 1).

If the output is a bag of words, minimize the loss for the positive words and an equal number of negative words (sampled randomly, with a focus on words likely to be mistaken, and importance weights). Alternatively, forecast a score rather than a probability, and make that of the correct output at least one more than those of the incorrect ones.

Recurrent neural nets (RNNs) for translation first learn a sentence embedding, and then generate a translation, often with an attention mechanism.

Use t-SNE to plot word embeddings.

Collaborative filtering is a low-rank matrix factorization (SVD with missing values), *Content-based recommendation systems* address the cold-start problem by learning an embedding of user and/or item features. Recommender systems are contextual bandits.

Other applications include embeddings (of words, phrases, relations, etc.), and learning structured data (knowledge base) for link prediction and question answering.

13. Nor all learning problems are supervised: generative models, outlier/anomaly detection, missing values, semi-supervised learning, unsupervised learning.

PCA has many variants.

PCA	$X \sim N(b, WW')$
Probabilistic PCA	$X \sim N(b, WW' + \sigma^2 I)$
Factor analysis	$X \sim N(b, WW' + \Delta)$

Equivalently,

$$\begin{aligned}h &\sim N(0, I) & h &\sim N(0, I) & h &\sim N(0, I) \\ X = b + Wh & & \varepsilon &\sim N(0, \sigma^2 I) & \varepsilon &\sim N(0, \Delta) \\ & & X &= b + Wh & X &= b + Wh\end{aligned}$$

$$\begin{aligned}h &\sim p \text{ non-Gaussian} \\ X &= b + Wh \quad W \text{ orthogonal (ICA)}\end{aligned}$$

Nonlinear variants replace $h \mapsto b + Wh$ with $h \mapsto f(h)$, a nonlinear mapping given by, e.g., a neural net.

Slow feature analysis generalizes PCA

$$\begin{aligned}\text{Find} & \quad u \in \mathbf{R}^n \\ \text{To maximize} & \quad E(u'X)^2 \\ \text{Such that} & \quad u'u = 1\end{aligned}$$

to time series

$$\begin{aligned}\text{Find} & \quad u \in \mathbf{R}^n \\ \text{To maximize} & \quad E(u'x_{t+1} - u'x_t)^2 \\ \text{Such that} & \quad E[u'x_t] = 0 \\ & \quad E(u'x_t)^2 = 1.\end{aligned}$$

The mapping $x \mapsto u'x$ can be replaced with an affine transform $x \mapsto u'x + b$. To learn several features, add a constraint $E[(u'_i x_t)(u'_j x_t)] = \delta_{ij}$. Apply on a nonlinear transform (e.g., a quadratic kernel) of x .

Sparse coding generalizes PPCA by using a prior with a sharp peak at 0 (not sparse, but still sparsifying).

$$\begin{aligned}h &\sim \text{Laplace, Cauchy or Student} \\ \varepsilon &\sim N(0, \sigma^2 I) \\ X &= b + Wh + \varepsilon\end{aligned}$$

Sparse coding can learn good features, but not how to combine them.

14. Autoencoders are nonlinear generalizations of PCA.

One can add a regularizer on the local features. To avoid trivial solutions ($f = \varepsilon \text{Id}$, $g = \varepsilon^{-1} \text{Id}$), impose $g = f^T$.

Contrastive autoencoders (CAE) add a penalty on $\|\nabla_{\text{input}} \text{latent}\|^2$ – large derivatives will only be kept if they are tangent to the data manifold.

In a *stochastic autoencoder* (SAE), the decoding function is replaced by a probability distribution

$$\text{input} \xrightarrow{f} \text{latent} \xrightarrow{p_\theta(\text{output}|\text{latent})} \text{output}$$

(f and p_θ are learnt). Both steps could be stochastic.

encoder: $p_{\theta_1}(h|x)$
decoder: $p_{\theta_2}(x|h)$

Denoising autoencoders (DAE) try to reconstruct their input from a noisy version of it:

$$\text{Maximize}_{p,f} \mathbb{E}_{x \sim \text{data}} \mathbb{E}_{\varepsilon \sim \text{noise}} p[x|h = f(x + \varepsilon)].$$

It is not possible to remove the noise if $x + \varepsilon$ is still on the data manifold, but if it is away from it, the denoising autoencoder will project it onto the data manifold: it learns a vector field that moves towards the manifold, $\nabla_x \log p_{\text{data}}(x)$.

Predictive sparse decomposition (PSD)

$$\begin{aligned} x &\mapsto f(x) \\ h &\mapsto g(h) \end{aligned}$$

minimizes (alternatively h and f, g in)

$$\|x - g(h)\|^2 + \lambda \|h\|_1 + \gamma \|h - f(x)\|^2.$$

15. *Unsupervised (greedy, layerwise) pretraining* is sometimes helpful (e.g., when there is not enough data), but often detrimental (it assumes some features useful for the unsupervised task are also useful for the supervised one; it relies on a regularizing effect of the choice of starting point to avoid “bad local minima” – but those are extremely rare and this could drastically reduce exploration). Prefer dropout and batchnorm (big data) or Bayesian methods (small data) – unsupervised pretraining is only still useful in NLP.

Transfer learning (same input, different tasks) and *domain adaptation* (different inputs, same tasks) are forms of *supervised pretraining*. One-shot learning uses a single labeled example for the new task. Zero-shot learning uses none, e.g.:

- Given textual descriptions of animals and photographs of some of them, learn to recognize those you have never seen;
- Given models for languages A and B and a bilingual $A \leftrightarrow B$ lexicon, learn to translate sentences.

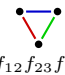

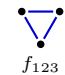

Semi-supervised learning looks for a representation of the input x that disentangles its causes, in the hope that the output y is one of them – this will not work if there is no structure in x , e.g., $x \sim N(0, 1)$.

16. An *energy-based model* (or *Boltzman machine*) is a probability distribution of the form $p(x) \propto \exp -E(x)$ (a *Boltzman distribution* – it just says that $\forall x p(x) \neq 0$). In a *product of experts*, the energy is a sum of “experts”, each checking if some constraint is satisfied, using a subset of the variables.

Undirected models cannot represent “immoral” dependencies; directed models cannot represent “non-chordal” dependencies.

Undirected models are ambiguous: does  represent

 or , i.e., in terms of *factor graphs*

Directed models can be sampled by *ancestral sampling* (after choosing a topological ordering of the nodes). Undirected models can be sampled, approximately, by Gibbs sampling. Introducing hidden variables can replace many dependencies.

In general, computing the marginal probability of a probabilistic graphical model is #P-hard (NP problems are decision problems, #P problems are the corresponding counting problems); they can be approximated by variational inference.

Loopy belief propagation is not supposed to work with arbitrary graphs (non-trees), but works well with sparsely-connected graphs – neural networks are densely connected.

Restricted (i.e., bipartite) Boltzman machines (RBM) can be efficiently sampled from (block Gibbs sampling).

17. Expectations can be approximated with averages:

$$\mathbb{E}_{x \sim p} f(x) \approx \frac{1}{n} \sum_{x_i \sim p} f(x_i)$$

or weighted averages (*importance sampling*)

$$\begin{aligned} \mathbb{E}_{x \sim p} f(x) &= \int f(x)p(x)dx = \int \frac{f(x)p(x)}{q(x)}q(x)dx \\ &= \mathbb{E}_{x \sim q} \frac{f(x)p(x)}{q(x)} \\ &\approx \frac{1}{n} \sum_{x_i \sim q} \frac{f(x_i)p(x_i)}{q(x_i)} \end{aligned}$$

whose variance can be lower (it is minimal for $q \propto p \cdot |f|$) or *biased importance sampling*

$$\mathbb{E}_{x \sim p} f(x) \approx \sum_{x_i \sim q} \frac{\tilde{p}(x_i)}{\tilde{q}(x_i)} f(x_i) \Big/ \sum_{x_i \sim q} \frac{\tilde{p}(x_i)}{\tilde{q}(x_i)}$$

(with unnormalized probabilities, $p \propto \tilde{p}$, $q \propto \tilde{q}$ – the estimator is only asymptotically unbiased).

For MCMC, use 100 chains. Mixing time is determined by the second eigenvalue (the first is 1 – Perron-Frobenius).

Gibbs sampling has mixing problems in presence of several modes: increase the temperature (*tempering*). MCMC is less useful when the distribution has a manifold structure: good learning leads to high $\text{MI}(h, x)$, low entropy $p(x|h)$, which is hard to sample from and leads to bad mixing

18. To compute the gradient of the likelihood, we need that of the partition function (*negative phase* – the other tem, the unnormalized log-likelihood, is the positive phase).

$$p = \frac{\tilde{p}}{Z} \quad \nabla_{\theta} \log p = \nabla_{\theta} \log \tilde{p} - \nabla_{\theta} \log Z$$

It can be estimated with Monte Carlo:

$$\begin{aligned} \nabla_{\theta} \log Z &= \frac{\nabla_{\theta} Z}{Z} \\ &= \frac{\sum \nabla_{\theta} \tilde{p}(x)}{Z} \\ &= \frac{\sum \nabla_{\theta} \exp \log \tilde{p}(x)}{Z} \\ &= \sum p(x) \nabla_{\theta} \log \tilde{p}(x) \\ &= \mathbb{E}_{x \sim p} \nabla_{\theta} \log \tilde{p}(x). \end{aligned}$$

The positive phase increases \tilde{p} for x drawn from the data; the negative phase decreases $\tilde{p}(x)$ for x drawn from the model.

While $\nabla_{\theta} \log Z = \mathbb{E} \nabla_{\theta} \log \tilde{p}(x)$ could be estimated with MCMC, with a burn-in period, this would have to be done anew at each gradient step. *Contrastive divergence* (CD) uses k Gibbs steps, with no burn-in, after initialization from the data – but it is unaware of high-probability regions away from the data. It only works for shallow models (e.g., RBM) – the latent variables are not in the data and require a burn-in period. CD is not the gradient of any function (there could be cycles)

Stochastic maximum likelihood is CD, but it initializes the chain from the previous gradient; the gradient steps should be small and/or the chain long. *Parallel tempreing* can help.

Pseudo-likelihood uses

$$\log p(\mathbf{x}) = \sum \log p(x_i | x_1 \cdots x_{i-1}) \approx \sum \log p(x_i | \mathbf{x}_{-i})$$

(generalized pseudo-likelihood puts the variables in groups).

Score matching minimizes the expectation of

$$\begin{aligned} L(x, \theta) &= \frac{1}{2} \|\nabla_x \log p_{\text{model}}(x, \theta) - \nabla_x \log p_{\text{data}}(x)\|_2^2 \\ &= \sum_i \frac{\partial^2}{\partial x_i^2} \log p(x, \theta) + \frac{1}{2} \left(\frac{\partial}{\partial x_i} \log p(x, \theta) \right)^2 \end{aligned}$$

(Z does not depend on x and disappears; p_{data} is not known).

For binary data, *ratio matching* minimizes the average of

$$L(x, \theta) = \sum_i \left(1 + \frac{p(x, \theta)}{p(f_j(x, \theta))} \right)^2$$

where f_i flips the i th bit.

Noise contrastive estimation (NCE) $\log p(x) = \log \tilde{p}_{\theta}(x) + c$ considers the partition function $c = -\log Z$ as another parameter to estimate, not with maximum likelihood, but with a binary classifier, data vs noise (e.g., word2vec). For *self-contrastive estimation*, the noise samples are generated from the model – the model learns to distinguish reality from its own evolving beliefs.

To evaluate or compare models, with the likelihood or the BIC, the whole likelihood, with the partition function, is needed. The partition function can be estimated by *importance sampling*,

$$\begin{aligned} \frac{Z_1}{Z_0} &= \frac{1}{Z_0} \int \tilde{p}_1 = \frac{1}{Z_0} \int p_0 \frac{\tilde{p}_1}{p_0} = \int p_0 \frac{\tilde{p}_1}{\tilde{p}_0} \\ &= \mathbb{E}_{x \sim p_0} \frac{\tilde{p}_1(x)}{\tilde{p}_0(x)} \\ &\approx \frac{1}{N} \sum_{x_i \sim p_0} \frac{\tilde{p}_1(x_i)}{\tilde{p}_0(x_i)}. \end{aligned}$$

If the distributions are very different, *annealed importance sampling* (AIS) adds more distributions between p_0 (tractable) and p_1 (interesting), e.g., weighted geometric averages $p_0^{\eta_i} p_1^{1-\eta_i}$, and computes the successive ratios of partition functions.

19. The **evidence lower bound** (ELBO) is

$$\begin{aligned} \mathcal{L}(v, \theta, q) &= \mathbb{E}_{h \sim q} [\log p(h, v)] + H(q) \\ &= \log p(v) - D_{\text{KL}}(q(h|v) \| p(h|v)) \leq \log p \end{aligned}$$

where v are the observed variables, h the latent variables, q some distribution on h and $D_{\text{KL}} \geq 0$.

MAP estimation is equivalent to variational inference (VI) with q Dirac.

The *mean field approximation* uses a factorized q , $q(h|v) = \prod_i q(h_i|v)$ (it is easy for discrete variables but requires calculus of variations for continuous ones).

20. Learning in a Boltzman machine

$$E(v, h) = - \begin{pmatrix} v \\ h \end{pmatrix}' \begin{pmatrix} R & \frac{1}{2}W \\ \frac{1}{2}W & S \end{pmatrix} \begin{pmatrix} v \\ h \end{pmatrix} - \begin{pmatrix} b \\ c \end{pmatrix}' \begin{pmatrix} v \\ h \end{pmatrix}$$

is local. Conditional distributions for RBM are factorial and easy to compute and sample from.

$$p(h|v) = \prod_j \sigma((2h - 1) \odot (c + W'v))_j$$

$$p(v|h) = \prod_i \sigma((2v - 1) \odot (b + Wh))_i$$

A *deep belief network* is a RBM with additional directed layers; a deep Boltzman machine only has undirected connections.

RBMs can be generalized to continuous variables: with *Gaussian-Bernoulli RBMs*, the mean (or both the mean and the variance) of the Gaussian output depends on the binary latent variables. The *mean-product of Student's T distribution* (mPoT) model replaces the Bernoulli latent variables with Gamma ones.

To compute the gradient in presence of random operations, e.g., ∂_μ or ∂_σ in $y \sim N(\mu, \sigma^2)$, rewrite the model as a transformation of samples from a fixed distribution, e.g.,

$$\varepsilon \sim N(0, 1)$$

$$y = \mu + \sigma \varepsilon$$

and consider the random Gaussian input as other inputs (“reparametrization trick”, “stochastic back-propagation”). For discrete distributions, it is trickier, but doable with reinforcement learning’s REINFORCE algorithm.

Variational autoencoders (VAE) combine a generator with an inference network.

Generative adversarial networks (GAN) combine a generator with a discriminator.

Neural autoregressive networks reuse their features.

Variants of auto-encoders differ in where they add noise.

R in Finance 2018

Bitcoin. Random forests and gradient boosting can help forecast Bitcoin prices from price, volume, users, FX, VIX and search data.

Dynamic model averaging (DMA) combines several models (here, univariate cryptocurrency forecasts, from stock indices, commodities, interest rates, CDS, volatility), with time-varying weights. Implementation in **eDMA**.

Bittrex is the 10th largest bitcoin exchange (4th in terms of number of trades or number of currencies), with a 2% market share it has a REST API and an R package. There are almost 300 cryptocurrencies (on this exchange), but their **cointegration dimension** is at most 4.

The **rbtc** package lets you run a Bitcoin node from R.

Time series models. The finite tick size makes prices discrete: they can be modelled with a **Skellam process** (a difference of Poisson processes) or, more generally, an integer-valued Lévy process. An integer-valued **trawl process** can be sampled as follows:

- Take points at random on $\mathbf{R} \times [0, 1]$ (Lévy basis – it could be a random signed measure, instead, if you are familiar with Lévy processes);
- Progressively move the “trawl” (a shape, e.g., a rectangle, or an exponential) and return the number of points in it.

The non-rectangular trawl makes changes more fleeting.

Avoid the **Hodrick-Prescott** (HP) filter:

- It creates spurious dynamic relations (autocorrelation, predictability), not only in the “trend” component (that is intended and desirable), but also in the “cycle” (noise) one;
- The results at the extremities of the interval are not usable – problematic if we want to use it on a moving or expanding window;

- It is often estimated with a Kalman filter

$$\begin{array}{ll} x_t = y_t + \varepsilon_t & \text{Observation} \\ y_t - 2y_{t-1} + y_{t-2} = \eta_t & \text{Evolution} \end{array}$$

but the estimated smoothing parameter is at odds with common practice.

Instead, just estimate a linear regression

$$y_{t+h} \sim y_t + y_{t-1} + y_{t-2} + y_{t-3}$$

(with $h = 8$ for quarterly data).

The time evolution of the value-at-risk (VaR) can be modeled directly, in an autoregressive way to account for volatility clustering, e.g.,

$$\text{VaR}_t = \beta_0 + \sum_i \beta_i \text{VaR}_{t-i} + \sum_j \gamma_j |x_{t-j}|$$

(or some other function of VaR_{t-i} , x_{t-j} and exogenous variables) and estimated by quantile regression.

The correlated idiosyncratic volatility shock model is yet another multivariate GARCH (factor) model.

A tidyverse for time series may be emerging: **tidyquant** (stock and portfolio analysis), **anomalize** (anomaly detection), **tibbletime** (**collapse_by**, **rollify**, **filter_time**, **as_period**), **timek** (time series machine learning), **sweep**, **furrr** (**future** + **purrr**), **flyingfox** (Quantopian's Zipline Python library via **reticulate**).

The *stationary bootstrap* is a block bootstrap with random block lengths.

Robust statistics. We may want to try to replace some of our location and dispersion estimators with those in the **RobStatTM** package:

- **RobStatTM::MLocDis(x)\$mv** (location and dispersion),
- **RobStatTM::lmrobdetMM**,
- **RobStatTM::lmrobdetDCML** (regression),
- **RobStatTM::MultiRobv(x, type="auto")** (covariance matrix).

Replacing the Fama-French cross-sectional regressions with robust regressions:

- Confirms the relation between B/P, earnings, size and future returns;
- Reveals a negative relation between beta and future returns;
- Suggests interactions (especially with size) are stronger than earlier thought.

Given a robust estimator θ_{rob} , with high breakdown point and good *asymptotic efficiency* $\text{Var}[\text{MLE}] / \text{Var}[\theta_{\text{rob}}]$ but poor finite-sample efficiency, the **distance-constrained maximum likelihood** (DCML) estimator shrinks it towards the maximum likelihood estimator.

$$\begin{array}{lll} \text{Find} & \theta & \\ \text{To minimize} & \text{KL}(\text{data} \| f_\theta) & \text{log-likelihood} \\ \text{Such that} & \text{KL}(f_{\theta_{\text{rob}}} \| f_\theta) \leq \delta & \end{array}$$

Shrinkage estimators of the variance matrix are not robust: instead of shrinking the sample variance matrix towards the identity, shrink the (robust) MCD variance matrix (the variance matrix estimated on the 50% or 75% of the data giving the lowest determinant), just enough for the matrix to be well-conditioned ($\lambda_{\max}/\lambda_{\min} < 1000$). Implementation in **robustbase::covMcd**, **rrcov**, **RiskPortfolios::covEstimation**.

Error estimation. The **influence function** of an estimator T on a distribution F is

$$\text{IF}(r, T, F) = \left. \frac{d[(1-\gamma)F + \gamma\delta_r]}{d\gamma} \right|_{\gamma=0}$$

The variance of the estimator can be estimated as

$$\text{Var}[T(F_n)] \approx \frac{1}{n} \sum \text{IF}^2(r_t, T, F_n)$$

The **Newey-West** standard error estimator gives the standard error of the sample mean in presence of autocorrelation

$$\hat{\sigma}_n[\hat{\mu}_n] = \frac{1}{\sqrt{n}} \left[C_0^2 + 2 \sum_{k \geq 1} \left(1 - \frac{k}{n}\right) C_k \right]$$

where C_k is the lag- k autocovariance (C_0 is the variance); the sum is often truncated to

$$\sum_{k=1}^m \left(1 - \frac{k}{m}\right) C_k,$$

for $m \ll n$. These results can be combined:

$$\text{Var } T(F_n) = E[\text{IF}^2(r_0)] + 2 \sum_{k \geq 1} E[\text{IF}(r_0)\text{IF}(r_k)].$$

Applying this formula to get an approximate finite-sample standard error of performance measures (value-at-risk, expected shortfall, Sharpe ratio) is problematic, but it turns out to be the spectral density at frequency zero,

$$\text{Var } T(F_n) = S_{\text{IF}}(0),$$

which can be estimated from the periodogram, as the intercept of a polynomial regression with exponential noise (the periodogram is exponentially-distributed), with a sparsity penalty (elastic net).

To test if a risk (VaR) model is correct, test if the *probability integral transform* (PIT)

$$P_t = F_t(\text{Loss}_t),$$

i.e., the running quantile, is $U(0, 1)$. Since accuracy in the “bad tail” (losses) is more important, test instead

$$H_0 : \nu(P_t) \sim \nu(U(0, 1)),$$

where ν is monotonic. Implementation in **spectralBacktest**.

The negative effects of errors in mean returns on the mean-variance efficient frontier increase with risk tolerance and number of assets.

Bayesian statistics. Hamiltonian Monte Carlo (HMC) cannot sample from discrete variables, but Stan is flexible and lets you implement the forward (filtering), forward-backward (smoothing) and Viterbi (MAP) algorithms yourself. A **hierarchical hidden Markov model** (HHMM) is a HMM with two types of nodes, emitting and non-emitting, arranged in layers.

An *input-output hidden Markov model* is an HMM whose transition and emission probabilities depend on an input (“control”) signal. Useful features, to forecast prices with a HHMM, include the presence of a local maximum or minimum, trends ($x_{n-4} < x_{n-2} < x_n \wedge x_{n-3} < x_{n-1}$), volume changes ($\log(v_n/v_{n-1})$, $\log(v_{n-1}/v_{n-2})$, $\log(v_n/v_{n-2})$, $\cdot > \alpha$, $\cdot < -\alpha$, $|\cdot| \leq \alpha$).

Stan can fit Gaussian processes.

Jags can estimate vine copulas.

Multilevel Monte Carlo (MLMC) combines Monte Carlo simulations with different timesteps $2^{-k}T$:

$$E[f_n(T)] = E[f_0(T)] + \sum_{k=1}^n E[f_k(T) - f_{k-1}(T)].$$

IT. The **partools** package provides MPI-like distributed computing with a higher-level interface.

The **foreach** package can not only parallelize your code via **multicore** or **parallel**, but also HPC schedulers (LSF, OpenLava, Slurm, with **foreach::registerdoFuture**) or Azure (**registerAzureParallel**).

Postgres lets you define functions (Γ), aggregate functions (Weibull distribution fit, Shapiro-Wilk test, **moments::skewness**, GARCH fit, etc.) and window functions (ARIMA forecast) in R.

The **hdf5r** package replaces the **h5** package presented two years ago [which did not work well].

Besides the obligatory Rcpp tutorial, there was also a Tensorflow one. The ecosystem around Tensorflow is growing. For instance, it is possible to write statistical models in R (rather than Stan/Jags/Bugs) and estimate them by MCMC via TensorFlow.

It is possible to launch CUDA kernels from Rcpp.

Options and trading. Here are a few volatility investing strategies:

- Long vol (VXX) when $\text{SMA}(\text{VIX}/\text{VXV}, 10) > 1$, short vol (XIV/SVXY) otherwise
- Switch between the highest 83-day momentum between XIV/SVXY, ZIV, VXZ, and VXX

- Long XIV/SVXY when $\text{SMA}(\text{VIX} - 10\text{day SPY vol}, 5) > 0$, long VXX otherwise
- Long XIV/SVXY when $\text{VIX}/\text{VXV} < .917$; long VXX when $\text{VIX}/\text{VXV} > 1.083$
- Long XIV/SVXY when $\text{ratio} < \text{SMA}(\text{ratio}, 60)$ and $\text{ratio} < 1$, idem for VXX, where $\text{ratio} = \text{VIX6M} = \text{VIX3M}/\text{VXMT}$.

To trade variance and jump risks around macroeconomic announcements, use long VIX positions and SPX straddles.

The present value of an uncertain stream of cash flows, for an investor with time-separable power utility,

$$\sum_{t \geq 0} \delta^t E \left[\frac{X_t^{1-\gamma}}{1-\gamma} \right]$$

is (Rubinstein’s model, **stochastic discount factor**)

$$\text{PV} = \sum_{t \geq 1} \frac{E[X_t / (1 + r_t^{\text{mkt}})^{\gamma}]}{E[(1 + r_t^{\text{mkt}})^{1-\gamma}]}$$

This can help price options on illiquid assets, such as private equity.

To build an ESG strategy:

- Survey Americans to identify the most important issues (workers, customers, products, environment, community, US jobs, management, shareholders);
- Collect 100 company-level ESG metrics (customer reviews, fines, emissions, etc.);
- Build a portfolio (top half in each industry, market capitalized).

Daily fund flows depend on the Morningstar click rate (raw, trend, change) for some funds, even after controlling for Net asset, Benchmark return, Excess return, Alpha, Market beta, Size beta, Value beta, Momentum beta [but they did not control for multiple testing].

Seasonality. [Several empty talks]

Default models. The **Q-Gaussian** distribution maximizes the Tsallis entropy (the Gaussian maximizes the Shannon entropy); its fatter tails lead to a more realistic Merton distance to default for investment-grade companies.

Bayesian additive regression trees (BART) are forests of regression trees, with a prior on tree structure – monotonicity complicates the definition of the prior and the sampling procedure. Monotonically-constrained BART can help forecast bankruptcies.

The **mvord** package fits models of the form

$$\text{rating} \sim \text{firm} + \text{rater} + \text{time}$$

accounting for correlation between raters and autocorrelation over time.

Graphs. Country modularity, in the graph of non-US companies and directors / analysts / news mentions is higher than sector modularity. Companies sharing directors/analysts/news mentions tend to be more correlated.

Stochastic block models are an alternative to modularity for community detection; they can be generalized to bipartite graphs. Implementation in `dbisbm`.

Text. The `sentometrics` and `quanteda` packages provide lexicon-based sentiment analysis.

To estimate the sentiment (or “tone”) of a document (10k filings) from lists of positive and negative words, one can

- count them;
- weigh them using tf-idf weights;
- weigh them using weights estimated from subsequent market returns.

Abnormal tone is defined by analogy with abnormal returns, as the residuals of

$$\text{tone} \sim \text{market tone} + \text{industry tone}.$$

***Exploring and measuring
non-linear correlations: copulas,
lightspeed transportation and clustering***
G. Marti et al.

Many measures of correlation can be seen as a “distance” between the data copula and some reference copula, e.g., the Fréchet-Hoeffding bounds (comonotonic and counter-monotonic) or the independence copula.

Common divergences (KL, etc.) are not very relevant when dependence is high (given two probability densities, with disjoint supports, they can just tell that the supports are disjoint, not how far apart they are). The **Wasserstein distance** (optimal transport, earth mover’s distance (EMD)) addresses this. Its exact computation is cumbersome, $O(m^3 \log m)$, but its entropic relaxation, the *Sinkhorn distance* (an upper bound of the EMD) can be computed in linear time. The Sinkhorn distance can also be used to compute barycenters of copulas, or to cluster copulas (k -means).

The *target-forget dependence coefficient* of a copula is computed from its Sinkhorn distance to a set of target (e.g., independence) copulas $(C_k^+)_k$, and a set of forget (e.g., Fréchet-Hoeffding) copulas $(C_\ell^-)_\ell$.

$$\text{TFDC}(C) = \frac{\text{Min } d(C_\ell^-, C)}{\text{Min } d(C_\ell^-, C) + \text{Min } d(C_k^+, C)}$$

The *mutual information* $\text{MI}(X, Y)$ is the Kullback-Leibler divergence between the joint distribution (X, Y) and the corresponding independent distribution $p_X p_Y$,

$$\text{MI}(X, Y) = \text{KL}(p_{XY} \| p_X p_Y).$$

***Equitability, mutual information
and the maximal information coefficient***
J.B. Kinney and G.S. Atwal

Mutual information satisfies the *data processing inequality*: $I(X; Z) \leq I(Y; Z)$ if $X \leftrightarrow Y \leftrightarrow Z$ is a

Markov chain (*i.e.*, information is lost, never gained, when transmitted through a noisy channel).

A dependence measure $D(X; Y)$ is *self-equitable* if $D[X; Y] = D[f(X); Y]$ whenever $X \leftrightarrow f(X) \leftrightarrow Y$ is a Markov chain (in particular, if f is bijective).

Mutual information is self-equitable, MIC is not.

***A robust-equitable copula dependence measure
for feature selection***
Y. Chang et al. (2016)

A dependence measure $D(X; Y)$ is *robust equitable* if $D(X; Y) = p$ when (X, Y) has copula $pC + (1 - p)\Pi$, where C is a singular copula and Π the independence copula (self-equitability deals with additive noise rather than mixture noise; both try to be agnostic to the type of relation they detect).

The *robust copula dependence* CD_1 is the L^1 distance between the copula density and the uniform density

$$\text{CD}_\alpha = \iint_{[0,1]^2} |c(u, v) - 1|^\alpha du dv;$$

it can be estimated with a kernel density estimator. It is robust equitable; mutual information and CD_2 are not.

***Copula correlation:
an equitable dependence measure
and extension of Pearson’s correlation***
A.A. Ding and Y. Li

More details on the copula correlation (aka robust copula dependence), with comparisons with other measures of dependence.

***Sinkhorn distances: lightspeed computation
of optimal transportation distances***
M. Cuturi (2013)

The *optimal transport distance* (earth mover’s distance (EMD), Wasserstein distance) between two histograms $r, c \in \Delta_d$, wrt a cost matrix $M \in \mathbf{R}^{d \times d}$, is

$$d(r, c) = \text{Min}_{p \in U(r, c)} \langle P, M \rangle$$

where the transportation polytope $U(r, c)$ is the set of joint probabilities whose margins are r and c ,

$$U(r, c) = \{ P \in \mathbf{R}_+^{d \times d} : P\mathbf{1}_d = r, P'\mathbf{1} = c \}$$

The **Sinkhorn distance** only considers the joint probabilities close to the independence one rc'

$$d_\alpha(r, c) = \text{Min}_{P \in U_\alpha(r, c)} \langle P, M \rangle$$

$$U_\alpha(r, c) = \{ P \in U(r, c) : \text{KL}(P \| rc') \leq \alpha \}.$$

The dual problem (obtained by replacing the hard constraint with a penalty) can be solved efficiently with a fixed point algorithm.

In R: `Barycenter::SinkhornDistance` (buggy).

Fast computation of Wasserstein barycenters

M. Cuturi and A. Doucet (2014)

The Sinkhorn distance (entropic regularization of the Wasserstein distance) makes the computation of Wasserstein barycenters efficient.

The randomized dependence coefficient

D. Lopez-Paz et al.

The Hirschfeld-Gebelein-Rényi **maximum correlation coefficient** is

$$\text{hgr}(X, Y) = \sup_{f, g} \text{Cor}(fX, gY).$$

To estimate it, uniformize X and Y , transform them in several random ways (e.g., $\cos(w'X + b)$) and compute the corresponding *canonical correlation* (i.e., the maximum correlation between a linear combination of the transforms of X and one of those of Y).

Estimating optimal transformations for multiple regression and correlation

L. Breiman and J.H. Friedman (1985)

The *alternating conditional expectation* (ACE) algorithm looks for transformations ϕ, θ of random variables X, Y maximizing the correlation $\text{Cor}(\phi X, \theta Y)$ (not unlike generalized additive models).

While $E[\theta Y - \phi X]^2$ decreases:

$$\phi(X) \leftarrow E[\theta(Y)|X]$$

$$\theta(Y) \leftarrow \frac{E[\phi(X)|Y]}{\|E[\phi(X)|Y]\|}$$

A kernel two-sample test

A. Gretton et al. (2012)

A *reproducing kernel Hilbert space* (RKHS) is Hilbert space of functions $X \rightarrow \mathbf{R}$ (for some unspecified scalar product) such that the evaluation functions

$$\text{ev}_x : \begin{cases} \mathcal{H} & \longrightarrow \mathbf{R} \\ f & \longmapsto f(x) \end{cases}$$

be continuous; they are then (Riesz) of the form $f(x) = \langle f, k(x, \cdot) \rangle$, for some function (“kernel”) k . Conversely, a symmetric positive definite kernel k on X defines a unique RKHS.

For universal RKHS (k continuous and \mathcal{H} dense in \mathcal{C}_b^0 for L^∞), each probability distribution p has a *mean embedding*

$$\mathbb{E}_{x \sim p} [f(x)] = \langle f, \mu_p \rangle,$$

and the **maximum mean discrepancy** (MMD) distance is the distance between those embeddings.

$$\text{MMD}(p, q) = \sup_{\|f\| \leq 1} \mathbb{E}_{x \sim p} f(x) - \mathbb{E}_{y \sim q} f(X) = \|\mu_p - \mu_q\|$$

The plugin estimator of MMD^2 (from the kernel) is biased, but it is easy to obtain an unbiased one, and even

a linear-complexity one

$$\text{MMD}^2 = \frac{1}{m/2} \sum_1^{m/2} h(z_{2i-1}, z_{2i})$$

$$h(z_i, z_j) = k(x_i, x_j) + k(y_1, y_j) - k(x_i, y_j) - k(x_j, y_i);$$

those estimators lead to statistical tests to determine if two samples come from the same distribution.

Optimal copula transport for clustering multivariate time series

G. Marti et al.

Replace d -dimensional time series by their copulas, and use the earth mover’s distance to cluster them.

Define a measure of dependence as the relative distance between the independence copula and one or more target copulas; this also reveals which type of dependence was detected.

A proposal of a methodological framework with experimental guidelines to investigate clustering stability on financial time series

G. Marti et al.

To check the stability of a clustering algorithm for time series, look at how the *adjusted Rand index* (ARI) changes under perturbations:

- Sliding windows of different sizes;
- Odd vs even observations;
- Economic regime (for some regime detection algorithm);
- Whether market returns are in the interquartile range or not;
- Different sampling frequencies;
- Different universes;
- For fixed income: different maturities, or all the maturities together (Hellinger distance between the probability distribution functions $\partial \text{PD} / \partial t$).

On clustering financial time series: a need for distances between dependent random variables

G. Marti et al.

The *hierarchical clustering correlation matrix estimator* is consistent for the *hierarchical correlation block model* (HCBM).

Cluster analysis for portfolio optimization

V. Tola et al.

Original paper on the ultrametric correlation matrix from hierarchical clustering.

Toward a generic representation of random variables for machine learning
G. Marti et al.

The L^2 distance between random variables $d^2(X, Y) = E(X - Y)^2$ mixes dependence and distribution information: it is often unsuitable to cluster iid sequences. Instead, use a convex combination of the *correlation distance* (of the copula (X, Y) , for the dependence side) and of the *Hellinger distance* (between the marginals, for the distribution side).

Copula-based kernel dependency measures
B. Póczos et al. (2012)

The **maximum mean discrepancy** (MMD) between two probability distributions P, Q is

$$M = \sup_{f \in \mathcal{F}} E_{X \sim P}[f(X)] - E_{Y \sim Q}[f(Y)]$$

where \mathcal{F} is the unit ball in a universal reproducing kernel Hilbert space (RKHS) (universal means dense in \mathcal{C}_b^0 , e.g., with the Gaussian or Laplace kernels); M^2 can be estimated as

$$E_{X, X' \sim P}[k(X, X')] - 2 E_{\substack{X \sim P \\ Y \sim Q}}[k(X, Y)] + E_{Y, Y' \sim Q}[k(Y, Y')].$$

The *dependence* I^2 between random variables X_1, \dots, X_d is the MMD distance between their joint copula and the uniform distribution; it can be estimated as

$$\frac{1}{m(m-1)} \sum_{i,j} k(Z_i, Z_j) + k(U_i, U_j) - k(Z_i, U_j) - k(U_i, Z_j)$$

or

$$\frac{1}{m^2} \sum_{ij} k(Z_i, Z_j) + \frac{1}{n^2} \sum k(U_i, U_j) - \frac{2}{mn} \sum k(Z_i, U_j)$$

where $U_i \sim U(0, 1)^d$ and Z_i is the empirical copula of the data X_i .

This dependence measure can be used for *feature selection*:

Find	$S \subset \llbracket 1, d \rrbracket$
To minimize	$ S $
And maximize	$I(X_S \cup Y)$

Optimal transport vs Fisher-Rao distance between copulas for clustering multivariate time series
G. Marti et al.

The Fisher-Rao metric and its tractable approximations (Kullback-Leibler and other divergences – computing geodesics requires solving ODEs) are unsuitable to compute distances between copulas, especially when the dependence is high: the Gaussian copula with correlation 0.99 appears closer to that with correlation 0.50 than to that with correlation 0.9999 – the monotonic copula, $\rho = 1$, does not have a density and is

not on the manifold – it is at infinity. The Wasserstein distance is preferable.

Cluster multivariate time series by replacing them with their copulas.

Autoregressive convolutional neural networks for asynchronous time series
M. Bińkowski et al. (2018)

Irregular time series can be made regular by considering $y_n = (x_{t_n}, t_n - t_{n-1})$; for multivariate asynchronous time series (e.g., quotes for the same asset from different market makers), put all the values together and add a 1-hot encoding of the source.

The significance-offset CNN (SOCNN)

$$x_n = \sum_{m=1}^M W_{.,m} \odot [x_{n-m} + \varepsilon(x_{n-m})] \odot \sigma S_{.,m}(x_{n-1}, \dots, x_{n-m})$$

where ε is dense, shallow, S convolutional and σ the softmax, combines autoregression (for $\sigma = 1$, $\varepsilon = 0$, the recent observations are remembered and used as is) and gated RNN (older observations are summarized, in a nonlinear way).

Hausdorff clustering of financial time series
N. Basalto et al. (2005)

The **Hausdorff distance** gives an alternative to single and complete linkage clustering.

$$\begin{aligned} d(A, B) &= \inf_{a \in A} \sup_{b \in B} d(a, b) \\ d(A, B) &= \sup_{a \in A} \sup_{b \in B} d(a, b) \\ d(A, B) &= \text{Max} \left\{ \sup_{a \in A} \inf_{b \in B} d(a, b), \right. \\ &\quad \left. \sup_{b \in B} \inf_{a \in A} d(a, b) \right\} \end{aligned}$$

One could also switch Sup and Inf (minimax clustering).

Hierarchical clustering with prototypes via minimax linkage
J. Bien and R. Tibshirani (2011)

The *minimax radius* of a cluster C is

$$r(C) = \text{Min}_{x \in C} \text{Max}_{y \in C} d(x, y);$$

the minimizer is a *prototype* of C . *Minimax linkage* hierarchical clustering uses $d(A, B) = r(A \cup B)$.

HCMapper: an interactive visualization tool to compare partition-based flat clustering extracted from pairs of dendrograms
G. Marti et al.

Compare the partitions implied by two dendrograms with a *Sankey diagram* (D3) going from the root of the first one, to the leaves, to the root of the second one, displaying the size of the intersections.

***NetGAN: generating graphs
via random walks***
A. Bojchevski et al. (2018)

Consider random walks of length T on a graph as sequences and train a Wasserstein GAN on them: stop training when the (validation set) link prediction performance drops, or when the edge overlap between the generated graph and the data reaches a user-specified threshold.

***Geometry score: a method for comparing
generative adversarial networks***
V. Khrulkov and I. Oseledets (2018)

To assess the quality of a GAN, compare the data manifold and the generated manifold using:

- The Wasserstein distance between the birth-death diagrams;
- The distance between the persistence landscapes;
- The proportion of time $\beta_1 = i$ [they do not seem to notice this discards the persistence].

***Unsupervised representation learning with deep
convolutional generative adversarial networks***
A. Radford et al. (2016)

To train deep convolutional GANs (DCGAN),

- Replace the pooling layers with strided convolutions;
- Use batch normalization;
- Remove the fully-connected layers;
- Use ReLU in the generator (and tanh for the output) and leaky ReLU in the discriminator.

***StackGAN:
text to photo-realistic image synthesis
with stacked generative adversarial networks***
H. Zhang et al.

To generate high-resolution images from text descriptions using GANs, stack two of them. If there is not enough training text data, add noise to the sentence embedding.

***AlignedReID: surpassing human-level
performance in person re-identification***
X. Zhang et al.

To detect if two pictures (from surveillance cameras, to track visitors in a mall) are of the same person, compute both global and local features, where the local features are from horizontal bands in the image, and are aligned between the two pictures.

***Re-ranking person re-identification
with k -reciprocal encoding***
Z. Zhong et al.

Retrieval systems return a ranking, but do not always use all the information available: in particular, true positives are more similar among themselves. Replace the original distance with a linear combination of the

original distance and the (weighted) Jaccard distance between the set of k -reciprocal neighbours (x and y are k -reciprocal neighbours if each is among the k nearest neighbours of the other), which can be computed on binary vectors, with the 1s replaced with e^{-d} , where d is the distance to the probe.

Deep mutual learning
Y. Zhang et al.

Model distillation first trains a deep neural net on data, then a shallow one to mimic it.

Deep mutual learning uses an ensemble of shallow networks, trained with two losses, a supervised one, and a mimicry one.

Deep learning
A. Ng (Coursera, 2017)

1. With big data, the dev and test sets can be much smaller: 10,000 observations is more than enough, but that can be less than 1% of the data.

High bias is bad performance on the training data; high variance is bad performance on the test set.

Early stopping is a crutch to prevent overfitting: it mixes two objectives, reducing bias (improving in-sample performance) and reducing variance (avoiding overfitting) – other regularization methods (penalties, dropout, etc.) give more control on the bias-variance tradeoff.

Rather than opposing bias and variance, we should oppose “avoidable bias” (or “Bayes error”: the difference between the error and the lowest possible error, estimated, e.g., with the human-level error) and variance.

If the training and dev sets do not come from the same distribution, the difference in performance can come either from an excessive variance or the difference itself. To disentangle those effects, use a “training-dev set” – another dev set, carved out of the training set, to measure variance (i.e., whether the model generalizes to unseen data from the same distribution).

2. Auto-encoders can be used for anomaly detection: for anomalies (inputs from a never-seen class), the reconstruction error is higher.

End-to-end learning needs more data (10 to 100 times more) than traditional multi-step pipelines. Do not use if you have more data for the individual steps than for the whole pipeline.

ResNets can easily learn the identity function (while deep “plain” nets cannot): that is why we can make them as deep as possible. We can also increase their depth by adding new residual layers, initialized as the identity, in the middle.

3. For images, prefer Inception-v4 – VGG16 and VGG19 are larger and have a slightly lower accuracy.

In a CNN, the size progressively decreases, but the number of channels increases.

Average pooling is rarely used, except sometimes at the end, to reduce the size of the final result, e.g., $7 \times 7 \times 1000 \rightarrow 1 \times 1 \times 1000$. Max-pooling is more common.

1×1 convolution (aka “network in network”) is actually a fully-connected network acting on each pixel (the same network for each pixel). (It should not be written 1×1 but $1 \times 1 \times n$, where n is the number of input channels.) There are usually several of them: they are specified by a $1 \times 1 \times n \times m$ tensor, where m is the number of filters, i.e., the number of output channels. Those *bottleneck layers* (1×1 convolutions) are often used to reduce the number of channels before a convolution, to reduce the number of operations (and parameters). For instance, the inception units have a 1×1 convolution before their 5×5 convolutions.

If you do not know if a 1×1 , 3×3 , 5×5 convolution or a maxpooling operation is better, you can do them all, and concatenate the results (inception module: in Keras, `merge([a,b,c,d],mode='concat')`). To reduce the computations, you may want to first reduce the number of layers with a 1×1 convolution. Inception modules also have a maxpool operation (which does not change the number of channels): the 1×1 convolution comes after. The inception network also has a few side outputs, trying to forecast the same output – this helps learning and has a regularizing effect.

To recognize faces with neural nets, feed the neural network pairs of images (faces, extracted from wider images) and have it predict if the two images are of the same person.

To recognize faces, learn a dissimilarity function $d(\text{img}_1, \text{img}_2)$ (siamese network – deepface).

The *triplet loss* (facenet) tries to enforce $d(x_i, x_j) - d(x_i, x_k) + \alpha \leq 0$ (with a margin, α , as for SVMs), using the positive part of the lhs as loss. Choose triplets that are hard to train on; train on 1m to 100m images.

For object localization, have the convnet output: a boolean indicating if an object is present, a 1-hot encoding of the object class, the coordinates of the center of the object bounding box, its width and height (if no object is present, the loss function ignores the predicted class and bbox).

For object detection (there can be several objects), use a sliding window. It can be implemented as a single convolutional neural net (keep the same weights, just change the input size – and rewrite the FC layer as a convolutional one, outputting a $1 \times 1 \times 1$ tensor).

YOLO is similar, with no overlap between the windows, and a localization network (not just a classification one).

For object detection, the ratio of intersection over union (IoU) is a possible loss function.

To avoid detecting the same object in nearby locations, keep the object with the largest object presence probability (non-max suppression), discard the detected ob-

jects with a large overlap (it is the same object), and iterate with the remaining (different) objects; do this independently for each class.

To deal with overlapping objects, predict the presence of several objects with different bbox aspect ratios (anchor boxes): if there are k aspect ratios, the output is k times larger.

Do not run the object detection on the whole region but only on “promising” regions (R-CNN) identified as “blobs” by some segmentation algorithm (classical or CNN – “faster R-CNN”).

To do well in ML competitions use ensembling, and multi-crop at test time (useless in production).

4. The *BLEU* (bilingual evaluation understudy) score, for machine translation, counts the number of 1-, 2- and 3-grams in the computer-generated sentence that are also present in one of the reference translations; it also includes a brevity penalty.

When generating a sequence with an RNN, one needs to select words one by one. The greedy algorithm is suboptimal – it will favour common words. *Beam search* takes the b best words at each step. Use $b = 10$ in production, $b = 100$ to 10,000 for research.

Beam search is biased towards shorter sentences: use the average instead of the sum of the conditional log-probabilities of the successive words (length normalization).

To analyze the error, compare the score of a correct (human-generated) sentence with that of the sentence actually generated, to check if the problem comes from beam search (increase b) or the RNN.

Non-convex multi-objective optimization P.M. Pardalos et al. (2017)

A multiobjective optimization problem

Find	x
To minimize	$f_1(x), \dots, f_n(x)$
Such that	$g(x) \geq 0$

asks for the *Pareto set* (non-dominated solutions – the Pareto *front* is the set of corresponding values). For convex problems, local Pareto optimality implies global optimality, and the solutions are the minimizers of $\sum \alpha_i f_i$ for some α , for various values of α .

Scalarization replaces the objective functions with a single function (this need not give all solutions, and may also produce non-solutions):

- Weighted sum: $\sum w_i f_i(x)$ (for convex problems);
- Weighted sum after transformation into a convex problem;
- Tchebychev: minimize $\text{Max}_i w_i (f_i(x) - u_i)$, where u is a utopian point, $u_i < \text{Min } f_i$; the problem can be reformulated as

Minimize t such that $w_i (f_i(x) - u_i) \leq t$,
 x, t

and one can add a penalty for the Manhattan distance to the utopian point;

- Achievement scalarization: idem, but with an arbitrary point instead of a utopian one;
- Minimize only one objective and use the others as constraints; the constraints may combine several objective functions (normalized normal constraint, normal boundary intersection);
- Pascoletti and Serafini Scalarization

$$\underset{t,x}{\text{Minimize}} t \text{ such that } u + tv - f(x) \geq 0$$

where u and v are arbitrary vectors.

The parameters in those methods can rarely be chosen beforehand: select them adaptively – for instance, with two objectives, and weights (w_1, w_2) as parameters, start with uniformly-distributed weights, and select which interval to refine/subdivide/bisect.

The bi-objective shortest path problem on a graph (with two weightings) can be reduced to the 0-1 knapsack problem: it is NP-complete. The size of an ε -solution is polynomial, but it may be exponential in the number of objectives.

Global optimization methods include Bayesian optimization (under other names: P-algorithm, π -algorithm, efficient global optimization (EGO), kriging) and branch-and-bound (under a Lipschitz assumption, one can find lower bounds of the objectives in each region, and progressively refine promising regions – probabilistic variants use extreme value theory to estimate the minimum in each region).

Generative adversarial nets

I.J. Goodfellow et al.

Generative models can be estimated via an adversarial process, corresponding to a minimax two-player game,

$$\underset{G}{\text{Min}} \underset{D}{\text{Max}} \underset{x \sim \text{Data}}{\mathbb{E}} [\log D(x)] + \underset{z \sim \text{noise}}{\mathbb{E}} [\log(1 - D(G(z)))].$$

Replacing $\log(1 - DGz)$ with $-\log(DGz)$ helps learning early on.

The objective function is related to the Jensen-Shannon metric:

$$\underset{x \sim \text{Data}}{\mathbb{E}} [\log D(x)] - \underset{z \sim \text{noise}}{\mathbb{E}} [\log D(G(z))] \leq 2\text{JS}(\text{Data}, G(\text{noise})) - 2\log 2$$

Image-to-image translation with conditional adversarial networks

P. Isola et al.

The adversarial approach of GANs

can be merged with autoencoders (with skip-connections) for image translation.

Wasserstein GAN

M. Arjovsky et al.

The Wasserstein distance is more relevant than the Kullback-Leibler divergence for distributions supported by low-dimensional manifolds: KL just informs us that the supports are disjoint, while Wasserstein also tells us how far apart they are.

$$\text{TV}(P, Q) = \sup_A |P[A] - Q[A]|$$

$$\text{KL}(P, Q) = \int p \log \frac{p}{q}$$

$$\text{JS}(P, Q) = \text{KL}\left(P, \frac{P+Q}{2}\right) + \text{KL}\left(Q, \frac{P+Q}{2}\right)$$

$$W(P, Q) = \sup_{\gamma} \underset{\substack{\text{pr}_1 \gamma = P \\ \text{pr}_2 \gamma = Q}}{\mathbb{E}} [\|x - y\|]$$

If X and Z are random variables, and $g_\theta(z)$ is continuous in θ , then $W(g_\theta(Z), X)$ is continuous in θ ; if g is locally Lipschitz, then W is differentiable almost everywhere.

The Wasserstein distance is weaker (it has more converging sequences): on compact spaces,

$$\begin{array}{ccccc} \text{KL} & \longrightarrow & \text{JS} & \longrightarrow & W \\ & & \updownarrow & & \updownarrow \\ & & \text{TV} & & \mathcal{D}. \end{array}$$

The Kantorovich-Rubinstein duality

$$W(P, Q) = \sup_{\|f\|_{\text{Lipschitz}} \leq 1} \underset{x \sim P}{\mathbb{E}} [f(x)] - \underset{x \sim Q}{\mathbb{E}} [f(x)]$$

leads to a GAN-like optimization problem

$$\underset{G}{\text{Min}} \underset{D}{\text{Max}} \underset{x \sim \text{Data}}{\mathbb{E}} [D(x)] - \underset{z \sim \text{Noise}}{\mathbb{E}} [D(G(z))]$$

where the discriminator D should be 1-Lipschitz (otherwise, the objective is unbounded); this can be enforced, for instance, by using neural nets with clipped weights.

Contrary to traditional GANs, the gradient remains meaningful: the discriminator can be trained to optimality, and the corresponding Wasserstein distance can help monitor convergence. WGANs do not seem to suffer from mode collapse, but they are unstable when trained with momentum – prefer RMSProp.

The same idea can be used for *integral probability metrics* (IPM):

- Bounded functions give the total variation (TV) distance and energy-based GANs (EBGAN);
- The L^∞ ball in a reproducible kernel Hilbert space $\mathcal{H} = \{k(x, \cdot) : x \in \mathcal{X}\}$ for some kernel $k : \mathcal{X} \times \mathcal{X} \rightarrow \mathbf{R}$ gives the maximum mean discrepancy (MMD) metric and generative moment matching networks (GMMN).

Improved training of Wasserstein GANs I. Gulrajani et al.

Replace the weight clipping with a penalty on the gradient, ensuring its norm is close to 1 (rather than below 1) on straight lines between the data and the generated data,

$$\lambda \mathbb{E}_x (\|\nabla D|_x\| - 1)^2, \quad \lambda = 10.$$

Fully convolutional networks for semantic segmentation J. Long et al.

To turn a classification network into a segmentation one,

- Start with a classifier;
- Replace the fully-connected layers with 1×1 convolutions;
- Add up-sampling and skip-layer connections.

Time series modeling with undecimated fully convolutional neural networks R. Mittelman

Remove the max-pooling and upsampling layers from the FCN, but use “upsampled filters” instead (*i.e.*, replace an FCN filter F with $F \otimes \mathbf{1}_{k \times k}$: it is larger, but has the same number of parameters).

Tiled convolutional neural networks Q.V. Le et al. (2010)

A topological independent component analysis (TICA) network is a 2-layer network whose first layer weights are local and learned, whose second layer is a pooling layer, with square and square root activations respectively, loss function

$$\sum_{t \in \text{Training}} \sum_{i \in \text{Output}} \sqrt{\sum_{k \in \text{Hidden}} \left(\sum_{j \in \text{Input}} w_{kj} x_{jt} \right)^2}$$

and an orthogonality constraint $WW' = I$.

The hidden layer is a sparse representation of the data.

One can obtain an over-complete representation of the data (hidden layer larger than the input) by using local receptive fields (each hidden node only depends on a few input coordinates) and imposing orthogonality only for hidden nodes sharing the same input.

In a *tiled convolutional neural net*, hidden units k steps away share their weights (for a CNN, $k = 1$). They can be pre-trained with TICA, and capture invariances beyond translation (rotation, etc.).

A closed-form solution to photorealistic image stylization Y. Li et al.

For style transfer, start with an autoencoder with unpooling layers

and VGG19 as the encoding part, apply a *whitening and colouring transform* (WCT) to the VGG features

$$\begin{aligned} H_c &\mapsto H = P_s P_c H_c \\ P_c &= E_c \Lambda_c^{-1/2} E_c \\ P_s &= E_s \Lambda_s^{+1/2} E_s \end{aligned}$$

where Λ_c , Λ_s are the eigenvalues of $H_c H_c'$ and $H_s H_s'$ and E_c , E_s their eigenvectors, which makes the correlations of the transformed features HH' match the style ones, $H_s H_s'$, and smooth the result

$$\text{Argmin}_r \sum_{ij} w_{ij} \left\| \frac{r_i}{\sqrt{w'_i \mathbf{1}}} - \frac{r_j}{\sqrt{w'_j \mathbf{1}}} \right\|^2 + \lambda \sum_i \|r_i - y_i\|^2$$

where y is the WCT image, r the final image, and w_{ij} the *matting affinity* of pixels i and j (based on the means and variances of the pixels in a local window) – it is a quadratic optimization problem, with a closed form solution.

Metric learning with adaptive density discrimination O. Rippel et al. (2016)

To help separate the classes in distance metric learning (DML), do not only use a triplet loss, model the distribution of each class in the new space and use a *magnet loss* to pull them apart.

Pixel recurrent neural networks
A. van den Oord et al. (2016)

Recurrent neural networks can be generalized to 2-dimensional structures – for instance, a bidiagonal bi-LSTM combines two grids of LSTMs, one going right and down, the other left and down.

Using natural language processing techniques for stock return predictions
M.L. Chew et al. (2017)

Many studies use a vector embedding and a CNN to forecast post-event price movements [one could also use a bidirectional LSTM with attention, instead of a CNN].

- Use the Stanford NER tool in NLTK to identify company names in news headlines;
- Heuristically map them to tickers (for each company, build a list of possible names, but remove frequent words);
- Infer the structure of the sentence with `textacy` (Spacy) of StanfordPOSTagger;
- Compute Glove embeddings of verb-object pairs;
- Cluster them into 100 event types.

An interpretable and sparse neural network model for nonlinear Granger causality discovery
A. Tank et al. (2017)

Adding a group lasso (or a hierarchical lasso) penalty to the first layer weights of a neural net $x_{i,t} \sim x_{\cdot, < t}$ can help detect (nonlinear) causality and select the number of lags.

Clustering correlated, sparse data streams to estimate a localized housing price
Y. Ren et al.

House prices can be modeled at the census level.

$$\begin{aligned} g_t &: \text{global market trend} \\ x_{it} &: \text{value of census tract } i \\ y_{it\ell} &: \text{value of house } \ell \\ U_\ell &: \text{hedonics (house features)} \\ x_{it} &= g_t + a_i(x_{i,t-1} - g_{t-1}) + \varepsilon_{it} \\ y_{it\ell} &= x_{it} + f_i(U_\ell) + \eta_{it\ell} \\ \varepsilon &\sim N(0, \Sigma), \Sigma \text{ block diagonal} \end{aligned}$$

A unified framework for missing data and cold start prediction for time series data
C. Xie et al.

Matrix factorization (for time series) can be combined with matrix completion (from collaborative filtering):

$$Y_i = LR_i + HU\phi_i + b + \varepsilon_i$$

where R_i are latent time series, ϕ_i features, $U\phi_i$ dimension-reduced features.

Quasi-recurrent neural networks
J. Bradbury et al. (2017)

Model sequential data with *masked convolutions* * (*i.e.*, convolutions using only past data) outputting LSTM elements

$$\begin{aligned} Z &= \tanh(W_z * X) \\ F &= \sigma(W_f * X) \\ O &= \sigma(W_o * X) \end{aligned}$$

combined as $h_t = f_t \odot h_{t-1} + (1 - f_t) \odot z_t$ or

$$\begin{aligned} c_t &= f_t \odot c_{t-1} + (1 - f_t) \odot z_t \\ h_t &= o_t \odot c_t. \end{aligned}$$

Add skip connections (dense convolution), dropout (zoneout), attention.

Lie access neural Turing machine
G. Yang (2016)

In addition to random access, allow translations from one memory cell to another, or the action of some other Lie group (\mathbf{R}^2 , $\text{SO}(2)$, $\mathbf{R}^2 \rtimes \text{SO}(2)$ acting on \mathbf{R}^2).

Learning to optimize
K. Li and J. Malik

Optimization algorithms can be learnt as reinforcement learning policies, with *guided policy search*.

Extrapolation and learning equations
G. Martius and C.H. Lampert (2016)

To learn small, interpretable analytical expressions, amenable to extrapolation, use a neural network whose activation functions are the desired building blocks (the identity, sin, cos, sigmoid – one could also add products and divisions) with a sparsity constraint.

Adversarially learned inference
V. Dumoulin et al. (2017)

Combine generative adversarial networks (GAN, *i.e.*, generator and discriminator) and variational autoencoders (VAE, *i.e.*, inference and generation):

- Encoder, from real data x to latent representation z : $p(x, z) = p(x)p(z|x)$;
- Decoder (generator), from a latent representation z to simulated data x : $p(x, z) = p(z)p(x|z)$, with $p(z) \sim \text{Gaussian}$;
- Discriminator to guess if (z, x) is real or simulated.

Learning to discover sparse graphical models
E. Belilovsky (2017)

Incorporating a prior (e.g., small world) into the graphical lasso can be difficult: instead, use a neural net (CNN, for an arbitrary order on the nodes) to recover the graph from the sample correlation matrix, trained on synthetic data generated by the desired prior.

Deep learning with sets and point clouds
S. Racanbakhsh et al. (2017)

If the input of a layer is a set (if its order is irrelevant). use equivariant transformations, e.g.,

$$\begin{aligned} f(\mathbf{x}) &= \sigma(\lambda \mathbf{x} + \gamma(\mathbf{1}'\mathbf{x})\mathbf{1}) \\ f(\mathbf{x}) &= \sigma(\lambda \mathbf{x} - \gamma(\text{Max } \mathbf{x})\mathbf{1}) \\ f(\mathbf{x}) &= \sigma(\beta + \mathbf{x}\Gamma - \mathbf{1}(\text{Max } \mathbf{x})\Gamma) \end{aligned}$$

Applications include MNIST digit summation (the order of the digits is irrelevant) and point cloud classification, or situations with an existing clustering.

Normalizing the normalizers: comparing and extending network normalization
M. Ren et al. (2017)

Batch normalization, layer normalization (for RNNs) and *divisive normalization* (normalize neurons' activities by their neighbours') are the same operation along different dimensions of a tensor.

Regularizing CNNs with locally constrained decorrelation
P. Rodríguez et al. (2017)

To ensure the features learnt are as diverse as possible, add a penalty $\text{Cor}(\theta_i, \theta_j)^2$ if i and j are neurons in the same layer. To preserve negative correlations, replace Cor^2 with $\text{softplus}(\text{Cor})$ or $\text{softplus}(\lambda(\text{Cor} - 1))$.

Orthogonal weights are also sometimes used (with Xavier scaling) to initialize neural nets. Multibias neural nets have neurons sharing weights but with different biases.

Hierarchical multiscale recurrent neural networks
J. Chung et al. (2017)

LSTM with sparse updates, triggered by a boundary detector.

Geometry of polysemy
J. Mu et al.

Using traditional word embeddings, represent a context (10 words before and after the target word) as a cloud of (20) points. The span of the first $n = 4$ principal components form a subspace, *i.e.*, a point in the Grassmanian $G_{4,300}$. The different senses of a word can be recovered by clustering (the k -means algorithm can be generalized to the Grassmanian) its contexts; each cluster corresponds to a line – a point in $G_{1,300}$.

Exponential machines
A. Novikov et al. (2017)

A d -dimensional tensor \mathcal{A} has **tensor train** (TT) rank at most r if its elements can be written

$$\mathcal{A}_{i_1 \dots i_d} = G_1[i_1] \cdots G_d[i_d]$$

where $G_1[i_1]$ is $1 \times r$, $G_k[i_k]$, for $1 < k < d$, is $r \times r$, and $G_d[i_d]$ is $r \times 1$. Operations on tensor trains are efficient and return other tensor trains.

The linear model

$$\begin{aligned} \text{find} \quad & w, b \\ \text{To minimize} \quad & \sum \ell(\langle x, w \rangle + b, y) + \lambda \|w\|_2^2 \end{aligned}$$

can be generalized to account for interactions

$$\begin{aligned} \text{Find} \quad & \mathcal{W} \\ \text{To minimize} \quad & \sum \ell(\langle \mathcal{X}, \mathcal{W} \rangle, y) + \lambda \|\mathcal{W}\|_2^1 \\ \text{Such that} \quad & \text{TT-rank } \mathcal{W} = r \\ \text{Where} \quad & \mathcal{X}_{i_1 \dots i_d} = \prod_k x_k^{i_k} \end{aligned}$$

and estimated with Riemannian optimization (tensor trains of fixed rank form a Riemannian manifold).

Decoupled neural interfaces using synthetic gradients
M. Jaderberg et al.

To avoid backpropagating the gradients all the way down the computation graph, use neural networks to forecast them from local information.

Why and when can deep (but not shallow) networks avoid the curse of dimensionality: a review
T. Poggio et al. (2017)

Convolutional neural networks (CNNs) work well, not because of weight sharing, but because they are hierarchical compositions of *local* (*i.e.*, low-dimensional) functions.

Improved variational inference with inverse autoregressive flow
D.P. Kingma et al. (2016)

Variational inference looks for a simple distribution q approximating the posterior distribution p minimizing $D_{KL}(q||p)$. *Normalizing flows* allow more flexibility through reparametrization $z_0 \sim q$, $z_t = f_t(z_{t-1})$, where the f_t 's combine a linear transformation and a nonlinearity.

Convolutional neural networks on graphs with fast localized spectral filtering
M. Defferrard et al. (2016)

Convolutional neural nets can be generalized from regular grids to arbitrary networks:

- Consider the Laplacian $L = D - W$ or the normalized Laplacian $L = I - D^{-1/2} W D^{-1/2}$;
- Diagonalize it, $L = U \Lambda U'$;
- Define the Fourier transform as $x \mapsto U'x$ and the convolution as $x * y = U((U'x) \odot (U'y))$;

- Consider filters of the form $x \mapsto g_\theta(L)x$, where $g_\theta(L) = \sum \theta_k L^k$ or $g_\theta(L) = \sum \theta_k T_k(L)$ (Chebychev polynomials).

**Seven neurons memorizing sequences
of alphabetic images
via spike-timing dependent plasticity**

T. Osogami and M. Otsuka

A **dynamic Boltzman machine** (DyBM) is a Boltzman machine unrolled through time.

**Learning dynamic Boltzman machines
with spike-timing dependent plasticity**
T. Osogami and M. Otsuka (2015)

Although a DyBM can be interpreted as an RNN with memory, it can be learnt using only local information (no vanishing gradient problem).

**Nonlinear dynamic Boltzman machines
for time series prediction**

S. Dasgupta and T. Osogami (2016)

A **Gaussian Boltzman machine** is a Boltzman machine (BM) in which the Bernoulli distributions

$$E_j = b_j + \sum_{i \neq j} w_{ij} x_i \quad P[X_j = 1] \propto e^{-E_j}$$

have been replaced with Gaussian distributions

$$\mu_j = b_j + \sum_{i \neq j} w_{ij} x_i \quad X_j \sim N(\mu_j, \sigma_j).$$

A Gaussian dynamic Boltzman machine (DyBM) is an unfolded Gaussian BM. It can be interpreted as a VAR model, with eligibility traces (exponentially weighted moving averages) as additional variables. The input of a Gaussian DyBM can be preprocessed by an echo state RNN (*i.e.*, an RNN with random, rather than learnt, weights).

**Dynamic Boltzman machines
for second order moments
and generalized Gaussian distribution**

R. Raymond et al. (2017)

Gaussian dynamic Boltzman machines can be generalized, by making the variance time-dependent, as in a GARCH model (but using eligibility traces); and/or by replacing the Gaussian distribution, *e.g.*, with $p(x) \propto \exp[-\beta|x - \mu|^\rho]$.

**Training deep and recurrent networks
with Hessian-free optimization**

J. Martens and I. Sutskever (2015)

Hessian-free (HF) optimization (or **truncated Newton**) approximates the objective function with a quadratic

$$h(\theta + \delta) \approx h(\theta) + G'\delta + \frac{1}{2}\delta'H\delta$$

but computes the update $\theta \leftarrow \theta - H^{-1}G$ using a few *conjugate gradient* (CG) steps: there is no need to invert the curvature matrix, or even to compute it.

- Hessian-vector multiplications are directional derivatives of the gradient: they can be computed with forward differentiation.
- Replace the Hessian with the *generalized Gauss-Newton matrix* (GGN), which assumes $f'' = 0$, (*i.e.*, replaces f with its first order approximation); for scalar functions:

$$\begin{aligned} h(\theta) &= L(f(\theta)) \\ h'(\theta) &= f'(\theta)L'(f(\theta)) \\ h''(\theta) &= f''(\theta)L'(f(\theta)) + f'(\theta)L''(f(\theta))f(\theta) \\ &\approx f'(\theta)L''(f(\theta))f(\theta); \end{aligned}$$

for supervised learning:

$$\begin{aligned} h(\theta) &= \frac{1}{|S|} \sum_{(x,y) \in S} L(y, f(x, \theta)) \\ h''(\theta) &\approx \frac{1}{|S|} \sum_{(x,y) \in S} J'H_L J, \quad J = \nabla_z L, \quad H_L = \nabla_{zz} L; \end{aligned}$$

- Use *Tikhonov damping* (L^2 regularization) and make it scale-sensitive by using the diagonal of the Hessian (Levenberg-Marquardt);
- Use *structural damping*, *i.e.*, a penalty, not just to changes in the parameters, but to some intermediate quantities (*e.g.*, hidden activations – just add them to the output of the network and feed them to the loss function);
- Increase or decrease the scale of the penalty by looking at the ratio $\Delta\text{objective}/\Delta\text{penalty}$ (Levenberg-Marquardt heuristic);
- Instead of a penalty, use a *trust region*;
- Use early CG stopping;
- As a last resort, use a line search;
- Initialize CG with the previous direction (slightly scaled down) rather than 0;
- Use a preconditioner: diagonal preconditioners are effective with deep neural nets, because the scale of the gradients can grow/shrink exponentially between layers – but less so for RNNs, because the weights are reused. You may want to blend the diagonal matrix with the identity, $P = (\text{diag}(d) + \kappa I)^\xi$. There is no efficient algorithm to compute the diagonal of the Hessian: use the diagonal of the *empirical Fisher information*

$$\bar{F} = \frac{1}{|S|} \sum_{(x,y) \in S} \nabla L(y, f(x, \theta)) \nabla L(y, f(x, \theta))'$$

$$d = \text{diag} \bar{F} = \frac{1}{|S|} \sum \text{sq} \nabla L(y, f(x, \theta))$$

sq = elementwise square

(but it is biased) or, for an unbiased estimator,

$$d = \mathbb{E}_{v \sim N(0,1)} [\text{sq} J' H_L^{1/2} v]$$

- If possible, estimate the gradient and the Hessian on the same (large) minibatch.

***Sparse portfolios
for high-dimensional financial index tracking***
K. Benidis et al. (2017)

Passive investors try to reproduce the performance of some reference index with a simpler portfolio: fewer and more liquid assets. This can be formulated as an optimization problem:

Find	w	Portfolio weights
To minimize	$\text{TE}[w, b]$	Tracking error
Such that	$w \geq 0, w'1 = 1$	

For a sparse portfolio, one can add an L^0 penalty, but the resulting problem is too difficult to be solved exactly – there are heuristics, but they do not provide good guarantees on the quality of the results. To make it easier to solve, one can relax the constraint. The usual L^1 relaxation does not work here: the L^1 norm is already constrained to be 1: $\|w\|_1 = w'1 = 1$. Instead, one can use a finer relaxation:

$$\rho_{p,\gamma}(\mathbf{w}) = \frac{\log(1 + |\mathbf{w}|/p)}{\log(1 + \gamma/p)};$$

it is not convex, but the optimization problem can be solved by *majorization-minimization* (MM), which reduces non-convex optimization problems to sequences of convex optimization problems. Those optimization problems can be reformulated (again using MM) into a sequence of quadratic programs with a closed form solution – we are left with a simple and very fast iterative algorithm, which no longer requires a solver.

The use of MM to deal with cardinality constraints is more general: for instance, adding a minimum weight constraint (either the weight is zero, or it is above a threshold) leads to a similar algorithm. One can also use other tracking errors, e.g., only pay attention to the downside risk.

To find the minimum of a function f , **majorization-minimization** (MM) looks for a simpler function g such that

$$\begin{aligned} \forall x, y \quad & g(x, y) \geq f(x) \\ \forall y \quad & g(y, y) = g(y) \end{aligned}$$

and iterates $x_{n+1} \leftarrow \text{Argmin}_x g(x, x_n)$.

***Successive convex optimization methods
for risk parity portfolio design***
Y. Feng and D.P Palomar (2015)

Investors usually have to choose between risk parity portfolios and Markowitz-efficient portfolios, but it is possible to combine both loss functions into the same objective, yielding a portfolio close to risk parity, with high returns, with low risk.

***Regularized robust estimation
of mean and covariance matrix
under heavy-tailed distributions***
Y. Sun et al. (2014)

Estimate variance matrices, in the presence of outliers, fat tails and/or insufficient data, with M-estimators (several of them) and a majorization-minimization algorithm.

***Minimal criterion coevolution:
a new approach to open-ended search***
J.C. Brant and K.O. Stanley (2017)

Open-ended evolution (non-objective search) forgoes the objective function and only uses a minimum criterion, which should be satisfied for reproduction. The idea extends to coevolution, e.g., with mazes and maze-solving neural nets, the criteria being that each maze is solved by at least one neural net and each neural net solves at least one maze.

***Stochastic dual coordinate ascent methods
for regularized loss minimization***
S. Shalev-Shwartz and T. Zhang (2013)

Instead of solving the primal problem with (stochastic) gradient descent, solve the dual problem – with (stochastic) coordinate ascent (SDCA).

Submodular risk allocation
S. Ghamami and P. Glasserman (2017)

The problem of choosing which counterparty to use is of the form

$$\text{Minimize}_{A \subset S} F(A) + G(S \setminus A)$$

where S is the set of trades to execute, F and G are the collateral costs for counterparties 1 and 2, and A and $S \setminus A$ the trades sent to them. The costs could be of the form $\sigma(A) = \text{Sd}(\sum_{i \in A} X_i)$, which is submodular if $\text{Var } X$ is close to diagonal.

***A hitchhiker's guide
to automatic differentiation***
P.H.W. Hoffmann (2016)

Non-reversible Metropolis-Hastings J. Bierkens

A Markov chain on a discrete space S , with transition probabilities P , and a probability distribution π on S , satisfy the *detailed balance equation* if $\Gamma = 0$, where $\Gamma(x, y) = \pi(x)P(x, y) - \pi(y)P(y, x)$; the Markov chain is then said to be *reversible* and π is an invariant distribution. But the condition for π to be invariant is more general: $\Gamma \mathbf{1} = 0$ (*global balance*).

A *vorticity matrix* is a skew-symmetric matrix Γ such that $\Gamma \mathbf{1} = 0$. Given a reversible chain k with invariant distribution π and a vorticity matrix Γ ,

$$P(x, y) = k(x, y) + \frac{\Gamma(x, y)}{2\pi(x)}$$

defines a (non-reversible) chain with invariant distribution π (provided $P \geq 0$: since Γ has negative entries, this is not guaranteed).

The *non-reversible Metropolis-Hastings* (NRMH) chain

$$\begin{aligned} R(x, y) &= \frac{\Gamma(x, y) + \pi(y)Q(y, x)}{\pi(x)Q(x, y)} \\ A(x, y) &= \text{Max}\{1, R(x, y)\} \\ P(x, y) &= Q(x, y)A(x, y) \text{ if } x \neq y \end{aligned}$$

provided $Q(x, y) = 0 \Leftrightarrow Q(y, x) = 0$ and $\Gamma(x, y) \geq -\pi(y)Q(y, x)$, can be generalized to continuous spaces.

Non-reversible chains have better theoretical properties (lower variance, fewer large deviations).

The Langevin diffusion $dX = \nabla \log \pi dt + \sqrt{2}dW$ (for instance, the OU diffusion, $dX = -V^{-1}Xdt + \sqrt{2}dW$, which samples from $N(0, V)$) can be made non-reversible

$$dX = (I + S)\nabla \log \pi + \sqrt{2}dW,$$

where S is skew-symmetric; the MH acceptance step to correct the discretization error can be replaced by a NRMH step.

DeepWalk: online learning of social representations B. Perozzi et al. (2014)

Embed the vertices of a graph in \mathbf{R}^n (e.g., for automated text layout, or community discovery) as you would words (with skipgrams), considering random walks (of vertices) as “sentences” (or words).

Modeling dependence with C- and D-vine copulas: the R package CDVine E.C. Brechmann and U. Schepsmeier (2013)

A multivariate distribution $f(x_1, x_2, x_3)$ can be decom-

posed as

$$\begin{aligned} f(x_1, x_2, x_3) &= f(x_1)f(x_2|x_1)f(x_3|x_1, x_2) \\ f(x_2|x_1) &= \frac{f(x_1, x_2)}{f(x_1)} \\ &= \frac{c_{12}(F_1(x_1), F_2(x_2))f(x_1)f(x_2)}{f(x_1)} \\ &= f(x_2)c_{12}(F_1(x_1), f_2(x_2)) \\ f(x_3|x_1, x_2) &= \frac{f(x_2, x_3|x_1)}{f(x_2|x_1)} \\ &= \frac{c_{23|1}(F(x_2|x_1), F(x_3|x_1))f(x_2|x_1)f(x_3|x_1)}{f(x_2|x_1)} \\ &= c_{23|1}(F(x_2|x_1), F(x_3|x_1))f(x_3|x_1) \\ &= c_{23|1}(F(x_2|x_1), F(x_3|x_1))f(x_3)c_{13}(F(x_1), F(x_3)) \\ f_{123} &= f_1f_2f_3c_{12}c_{13}c_{23|1} \end{aligned}$$

where $F(x_2|x_1)$ and $F(x_3|x_1)$ are known from c_{12} and c_{13} , and we assume that the copula density $c_{23|1}$ does not depend on x_1 .

There are many such decompositions. The $d(d-1)/2$ factors in those formulas can be arranged into $d-1$ trees – a **vine**. Special cases include stars (C-vines) and chains (D-vines), both defined by an ordering of the variables.

The **CDVine** package provides functions for BB copulas (which allow both upper and lower tail dependence, contrary to most archimedean copulas), bivariate copula analysis (**BiCop*** for contourplot, Kendall's plot, χ -plot, λ function, independence tests, gof tests, estimators (MLE, method of moments using Kendall's τ)), and C- and D-vine estimators (but you need to provide the variable order and the copula family).

Maximum likelihood estimation of mixed C-vines with applications to exchange rates
C. Czado et al. (2012)

To select the variable ordering in a C-vine copula, start with the most correlated variable,

$$i^* = \underset{i}{\operatorname{Argmax}} \sum_j |\tau_{ij}|,$$

renumber them so that $i^* = 1$, estimate the corresponding copulas C_{ij} , transform the variables $v_{j|1} = F(u_1|u_j)$, where $F(u|v) = \partial C_{uv}/\partial v$ and iterate.

Social media mining: an introduction
R. Zafarani et al. (2014)

2. The *Steiner tree problem*, finding the smallest tree, in a graph, containing a given subset of nodes, is NP-hard.

Signed graphs can model friend-foe relations; signed directed graphs are used in social status theory.

3. There are many node *centrality* measures:

- Eigenvector: $c_i = \lambda^{-1} \sum a_{ij}c_j$, *i.e.*, c is an eigenvector for eigenvalue λ (from the Perron-Frobenius theorem, the largest eigenvalue gives positive centralities);
- Katz and PageRank are variants of eigenvector centrality;
- Betweenness: number of shortest paths a node is on;
- Closeness: (harmonic) average distance to the other nodes.

There are a few more node metrics:

- Clustering: proportion of triangles (for signed graphs, one can distinguish between balanced and unbalanced triangles);
- Reciprocity (for directed graphs).

There are many node similarity measures:

- Number of nodes in common, $|N_x \cap N_y|$;
- Jaccard similarity, $\frac{|N_x \cap N_y|}{|N_x \cup N_y|}$;
- Cosine similarity, $\frac{|N_x \cap N_y|}{\sqrt{|N_x||N_y|}}$;
- Regular similarity, $\sigma_{ij} = \alpha \sum_{k\ell} A_{ik}A_{i\ell}\sigma_{k\ell}$;
- Adamic-Adar, $\sum_{z \in N_x \cap N_y} \frac{1}{\log |N_z|}$;
- Preferential attachment, $|N_x||N_y|$;
- Katz (weighted average path length);
- Hitting time (average time a random walk takes to reach y from x), commute time;
- Rooted PageRank;
- SimRank, $\sigma_{xy} = \lambda \frac{1}{|N_x||N_y|} \sum_{x' \in N_x} \sum_{y' \in N_y} \sigma_{x'y'}$.

4. Network models try to reproduce the following stylized facts:

- Power law degree distribution (*scale-free* network);
- High clustering coefficient;

- Low average path length (*small world*).

Random graphs models, $G(n, p)$ (n nodes, edge probability p) and $G(n, k)$ (n nodes, k edges) show a phase transition (apparition of a giant component) when the average degree reaches 1. The degree distribution is binomial (asymptotically Poisson – not a power law) and the clustering coefficient, p , is low. The average path length is $\log \# \text{nodes} / \log \langle \text{degree} \rangle$.

The *small world* model starts with a regular (ring) lattice and rewrites each edge (replaces one extremity at random) with probability β . The degree distribution is still incorrect, but the clustering coefficient and the average path length are fine.

The *preferential attachment* (Barabási-Albert) model adds one node at a time, connects it to m nodes, chosen with probabilities proportional to their degrees. The resulting graph is scale-free, *i.e.*, its degree distribution is a power law, but its exponent is always the same (3); the average path length is small enough, but the clustering coefficient is too low.

The *stochastic block model* was not mentioned.

5. The *weighted vote relational neighbour* (wvRN) classifier is similar to k -NN:

$$P[y_i = 1] = \frac{1}{|N_i|} \sum_{j \in N_i} P[y_j = 1]$$

(since not all y_i 's are observed, iterate to find a fixed point).

To evaluate the result of a clustering algorithm:

- Cohesiveness: $\sum_{i \in \text{Clusters}} \sum_{j \in C_i} \|x_j - c_i\|^2$
- Separateness: $\sum_i \|c_i - c\|^2$
- Silhouette: $\frac{1}{n} \sum_x \frac{b(x) - a(x)}{\max\{b(x), a(x)\}}$, where $a(x)$ is the average distance to the other elements of the cluster and $b(x)$ the minimum average distance to the elements of another cluster.

6. Communities could be defined as *cliques*, (but they are rare in real networks), k -plexes (subgraph with n nodes, each of degree at least $n - k$) or k -cliques (subgraphs in which all shortest paths have length at most k).

The clique percolation method (CPM) uses cliques as seeds: communities are the connected components of the clique graph, whose vertices are cliques of size k and with edges when cliques share $k - 1$ nodes.

Classical clustering algorithms can be used with node similarity.

Minimum cuts tend to generate singletons. Instead, one can look for partitions $P = (P_1, \dots, P_k)$ minimiz-

ing

$$\text{RatioCut}(P) = \frac{1}{k} \sum \frac{\text{Cut}(P_i, \bar{P}_i)}{|P_i|}$$

$$\text{or NormalizedCut}(P) = \frac{1}{k} \sum \frac{\text{Cut}(P_i, \bar{P}_i)}{\text{vol}(P_i)}$$

where the volume is the sum of the degrees. Those problems are NP-hard, but can be relaxed (spectral clustering).

The *modularity* of a community is the difference between the number of edges inside it and the expected number of edges for a random graph with similar degrees,

$$\text{Modularity}(P) = \sum_i \sum_{j,k \in P_i} A_{jk} - \frac{d_j d_k}{2m}.$$

The *Girvan-Newman* divisive hierarchical communities are obtained by progressively removing edges with the largest edge betweenness.

Evolving networks have a few more stylized facts:

- Segmentation into giant component, stars and singletons;
- Densification: the number of edges increases faster than the number of nodes, $|E_t| \propto |V_t|^\alpha$, $\alpha > 1$ (often, $\alpha \approx 1.6$);
- Diameter shrinkage.

To find evolving communities, consider a single optimization problem, for the communities of G_t for all t 's, with a penalty to keep the communities of G_t and G_{t+1} close.

7. The information cascade model (ICM) models information diffusion on a known network, in a sender-centric fashion: at each time step, each activated node (potential client who has already heard of our product) activates nearby nodes (talks to them and succeeds if his conviction p_{ij} exceeds their threshold t_j). Choosing the seed nodes to maximize the speed of cascades is a submodular optimization problem.

The diffusion of innovation (on a complete or unknown network) can be modeled as

$$A' = (\alpha + \beta A)(\text{Population} - A)$$

(where A is the number of adopters, α the external influence and β the internal influence) or with epidemic models (SIRS – SI, SIR, SIS are obtained with $\lambda = \gamma = 0$, $\lambda = 0$ and $\lambda = \gamma$, $R = 0$)

$$\begin{aligned} S' &= \lambda R - \beta IS \\ I' &= \beta IS - \gamma I \\ R' &= \gamma I - \lambda R \\ N &= S + I + R \end{aligned}$$

8. *Assortativity* measures the propensity of similar nodes to be linked. For categorical features, it can be assessed by modularity; for continuous ones, by covariance or correlation.

It can be explained by *influence* (the presence of links changes node attributes) or *homophily* (feature similarity creates edges).

Influence can be measured by centrality, or the size of the cascade (in the ICM or SIR model), e.g., the number of nodes affected, the average number of hops, or the rate at which the population is infected. Specific examples include the number of in-links, the inverse of the number of outlinks (novelty), the number of comments, the length for blogposts, or the number of followers (popular but imprecise), retweets and mentions for Twitter.

Contrary to sender-centric cascade (epidemic) models, influence (or threshold) models are receiver-centric.

In the *linear threshold model* (LTM, e.g., Schelling's model of racial segregation), node i becomes active if $\sum_{j \in N_i} w_{ji} \geq \theta_i$.

The *linear influence model* (LIM)

$$|P_t| = \sum_{u \in P_t} I(u, t - t_u) \quad \text{population influenced}$$

$$I(u, t - t_u) = c_u(t - t_u)^{-\alpha_u} \quad \text{influence function}$$

$$|P_t| = \sum_{u,t} A_{ut} I_{ut}, \quad I \geq 0$$

can be solved with nonnegative least squares.

Several tests disentangle influence and homophily:

- Shuffle test: compare the **social correlation** (the slope in the logistic regression activation = $\alpha + \beta \times \# \text{ active friends} + \varepsilon$) before and after shuffling the activation times;
- Edge reversal test: the social correlation should not change when reversing the edges;
- Randomization test: look at the assortativity gain

$$\begin{aligned} \text{Gain}_{\text{influence}}(t) &= A(G_t, X_{t+1}) - A(G_t, X_t) \\ \text{Gain}_{\text{homophily}}(t) &= A(G_{t+1}, X_t) - A(G_t, X_t). \end{aligned}$$

9. Recommendation engines can average the scores for similar items and/or users, but most rely on matrix factorizations, finding embeddings U (for users) and I (items) such that $\text{similarity}(i, j) \approx \cos(U_i, I_j)$, sometimes with a penalty $\text{sim}(i, j) \|U_i - U_j\|^2$ to ensure nearby nodes have nearby feature vectors.

10. *Link prediction* can be based on node similarity. User migration can be forecasted from user activity, network size and rank (in-degree).

Error correcting codes F. Lemmermeyer (2005)

Given a finite set A (alphabet, e.g., $\{0, 1\}$), a *code* is a subset $C \subset A^n$.

A *linear code* is a linear subspace of \mathbf{F}_q^n .

The Hamming [7, 4] code, in \mathbf{F}_2^7 , adds 3 parity bits to a 4-bit message.

A code of type $[n, k, d]_q$ is a subset of \mathbf{F}_q^n of size q^k , with minimum distance d .

The *minimum distance* of a code is the minimum Hamming distance between any two codewords. The minimum distance of a linear code is the minimum number of non-zero bits in a codeword (the minimum weight). A code with minimum distance d can detect $d-1$ errors and correct $\lfloor (d-1)/2 \rfloor$.

[The linear algebra notation for linear codes often uses row vectors.] A *generator matrix* of a linear code C is a matrix G whose rows form a basis of C ; it can be used to encode messages,

$$\begin{cases} \mathbf{F}_q^k & \longrightarrow \mathbf{F}_q^n \\ x & \longmapsto xG. \end{cases}$$

A *parity matrix* of C is a generator matrix H of C^\perp ; it can be used to detect the presence of errors:

$$C = \{c \in \mathbf{F}_q^n : cH' = 0\}.$$

Codewords are elements c whose *syndrome* cH' is zero.

The Hamming code $\text{Ham}(r)$ is defined by a parity matrix whose columns are the nonzero vectors in \mathbf{F}_2^r ; it has type $[2^r - 1, 2^r - 1 - r, 3]_2$.

For a code $C \subset \mathbf{F}_q^n$ with minimum distance $2t + 1$, the *sphere packing bound* is

$$|C| \sum_{i=0}^t \binom{n}{i} (q-1)^i \leq q^n.$$

For a *perfect code*, it is an equality. The perfect codes are Hamming ($t = 1$), repetition codes of odd length $n = 2t + 1$ and the binary Golay code G_{23} .

For linear codes of type $[n, k, d]$, the *singleton bound* is $d \leq n - k + 1$.

If the generator matrix is in standard form, $G = (I|A)$, a corresponding parity check matrix is $H = (-A'|I)$.

To decode a message c encoded with a general linear code $C \subset \mathbf{F}_q^n$, notice that two words x, y are in the same coset $v + C$ iff they have the same syndrome. The *coset leader* e of a coset $v + C$ is the word in it with minimal weight: subtracting it from the encoded message corrects the errors (for efficient decoding, one can store a mapping table from syndromes to coset leaders).

The *Plotkin* product of two codes $C_1, C_2 \subset \mathbf{F}_2^n$ of the same length is

$$C_1 * C_2 = \{(u, u + v) : u \in C_1, v \in C_2\}.$$

Cyclic linear codes are linear codes stable by cyclic permutations

$$(c_1 c_1 \cdots c_{n-1}) \longmapsto (c_{n-1} c_0 c_1 \cdots c_{n-2});$$

they correspond to ideals of $\mathbf{F}_q[X]/(X^n - 1)$. Those ideals are principal and generated by the divisors g of $X^n - 1$. If $X^n - 1 = gh$, then h is a parity check polynomial. To decode a message, compute its euclidean division by h : the syndrome polynomial $s(X)$ is the remainder. The error is the word of minimum weight among the cyclic shifts $X^i s(X) \bmod g(X)$.

If r consecutive powers of an n th root of unity are roots of $g(X)$, then $d \geq r + 1$.

Golay's G_{23} code, of type $[23, 12, 7]_2$, corresponds to

$$X^{11} + X^9 + X^7 + X^6 + X^5 + X + 1 \mid X^{23} - 1.$$

A tutorial on conformal prediction G. Shafer and V. Vovk (2013)

Conformal prediction regions are defined by $y \in R_\varepsilon$ if

$$p_y = \frac{\#\{I : \alpha_i > \alpha_n\}}{n} > \varepsilon$$

where $\alpha_i = d(\{z_1, \dots, z_n\} \setminus \{z_i\}, z_i)$, $z_k = (x_k, y_k)$ for $k < n$, $z_n = (x_n, y)$, d is some *non-conformity measure* and $\{\dots\}$ denotes multisets.

They are valid, *i.e.*, they contain the true value the advertized proportion of the time, provided the sequence of random variables is *exchangeable*.

The bags of observations can be seen as an *online compression model*, with summarizing and updating operators,

$$\begin{aligned} \{z_1, \dots, z_n\} &\longmapsto \{z_1, \dots, z_n\} \\ \{z_1, \dots, z_n\}, z_{n+1} &\longmapsto \{z_1, \dots, z_n, z_{n+1}\}. \end{aligned}$$

Relaxations of exchangeability include within-label exchangeability or the online Gaussian linear model.

Advances in financial machine learning M. Lopez de Prado (2018)

2. Financial data is often irregularly-spaced and should be transformed into tabular format, often as *bars*, *i.e.*, summaries (open, high, low, close, VWAP) over intervals: time bars, tick bars (every 1000 ticks), volume bars (number of shares), dollar bars (value traded), tick/volume/dollar imbalance bars (cumulated order imbalance),

$$b_t = \begin{cases} b_{t-1} & \text{if } \Delta \text{price} = 0 \\ \text{sign}(\Delta \text{price}) & \end{cases}$$

tick/volume/dollar runs bars (length of the longest run in b_t).

[The book tends to use ratio returns instead of log-returns (ratio returns are skewed and have extreme positive values) and cumulated products instead of cumulated sums of logarithms (this is numerically problematic).]

3. Instead of forecasting the returns, or their sign, or whether they will exceed some threshold, h bars ahead (with dollar bars, otherwise h should vary), use a *triple barrier*: forecast whether the price will go above or below (stop-loss) a threshold before time h – there are three outcomes: profit-taking, stop-loss and time-loss.

Consider using a *cascade* of models: a first model with high recall, followed by another with high precision (e.g., separately predicting the sign of the returns and whether the time barrier will be hit) [he calls that “met-labeling”].

4. Using bars leads to overlaps: weigh the observations accordingly.

5. Returns may not be the only way of turning log-prices into stationary time series, as required by many statistical procedures: *fractional integration*, which accounts for long memory, may be a better choice.

6,7. Use ensemble methods, cross-validation (with no overlap, and perhaps even an embargo).

8. Feature importance can be assessed by mean decrease impurity (in-sample) or mean decrease accuracy (out-of-sample). These are single-feature importance measures: to limit the substitution effect, try to orthogonalize the features.

9. [The discussion of hyperparameter tuning only mentions grid and random search, not low-discrepancy sequences or Bayesian optimization.]

10. Size your position to account for the possibility that the signal will strengthen further using, e.g., another model to estimate the probability of a correct forecast.

11. Backtesting can be dangerous: compute the *probability of backtest overfitting*.

12. While k -fold cross-validation suffers from look-ahead bias, it should not be completely discarded: a model able to predict the future from the past but not the past from the future would be suspicious.

Account for multiple testing with FWER or FDR.

13. Backtesting on synthetic data, and comparing the strategy with a random one, can help check if the model overfits.

14. Backtest statistics should include time (different regimes should be present), capacity, leverage, frequency of bets, average holding period, annual turnover, correlation to the underlying (to check if the strategy is just long or short); usual performance measures, P&L from hits, from misses; Herfindahl index of the time between bets, size of the tails (e.g., $\langle r_+ \rangle$,

$\langle r_- \rangle$); Sharpe ratio variants (correction for short time series, skewness, kurtosis, multiple testing); attribution.

15. The *strategy risk* is the sensitivity of the Sharpe ratio of a strategy (say, paying π with probability p and $-\pi$ with probability $1 - p$, with n bets per year) to the hit ratio p , or by how much the hit ratio should drop to wipe out the profit.

17. Structural breaks can be detected with CUSUM tests, looking if the cumulated normalized residuals of $y \sim x$ are consistent with a constant slope, or Dickey-Fuller-like tests.

- To test for explosive behaviour in $y_t = \rho y_{t-1} + \varepsilon_t$, i.e., $\rho = 1$ if $t \leq t_0$ and $\rho > 1$ if $t > t_0$, test for a non-zero slope in $\Delta y_t \sim y_{t-1} \mathbf{1}_{t > t_0}$;
- The ADF test uses more lags $\Delta y_t \sim y_{t-1} \mathbf{1}_{t > t_0} + \sum_{\ell} \Delta y_{t-\ell}$;
- The supremum ADF test uses $\sup_{t_0} \text{ADF}_{t_0, t}$, but there are quantile and “conditional” (cf. CVaR) variants.

Sub- and super-martingale tests test $H_0 : \beta = 0$ versus $H_1 : \beta \neq 0$ on

$$y = \alpha + \gamma t + \beta t^2 + \varepsilon$$

$$\log y = \alpha + \gamma t + \beta t^2 + \varepsilon$$

$$\log y = \alpha + \beta t + \varepsilon$$

$$\log y = \alpha + \beta \log t + \varepsilon$$

and use $\sup_{t_0} |\hat{\beta}/\sigma_{\beta}|$.

19. There have been three generations of microstructure features: first-generation models assume the mid-price is a random walk, or use high and low values to estimate volatility, spread or imbalance; second-generation models focus on illiquidity,

Kyle	$\Delta \text{price} \sim \text{signed volume}$
Amihud	$ \Delta \log \text{price} \sim \text{volume}$
Hasbrouk	$\Delta \log \text{price} \sim \pm \sqrt{\text{volume}}$;

third-generation models (PIN, VPIN) focus on trades.

Other microstructural features include the distribution of order sizes, cancellation rates, limit orders, market orders, presence of TWAP traders, options markets (option quotes contain little information, but option trades are informative), serial correlation of the signed order flow.

Microstructural information can be defined by building a model to forecast a market maker’s profit from those features and looking at its performance (e.g., cdf of the log-likelihood).

22. To process big data, scientists tend to use HPC clusters rather than the cloud: the cloud has distributed storage, relies on virtualization (flexible, but with a performance impact), and is less scalable (because of IO and network virtualization) and more expensive than HPC.

Convergence
of the stochastic six-vertex model to the ASEP
A. Aggarwal

In the asymmetric simple exclusion process (ASEP) model, particles are initially placed on the integers (not all of them) and move left or right, if the new position is not occupied, at times given by random exponential clocks with rates $0 \leq L < R$.

The *six-vertex model* is a probability distribution on the set of paths in the first quadrant $\mathbf{Z}_{\geq 0}^2$ starting from a set of points on the x or y axis, obtained by extending the paths from $T_n = [x + y \leq n]$ to T_{n+1} with probabilities

A numerical study of the F-model
with domain-wall boundaries
R. Keesman and J. Lamers

The six-vertex model on a square lattice demands exactly two ingoing and two outgoing edges at each vertex.

Modified profile likelihood inference
and interval forecast
of the burst of financial bubbles
V. Filimonov et al. (2016)

The LPPL model can be justified by a geometric random walk with jumps

$$\frac{dp}{p} = \mu_t dt + \sigma_t dW - \kappa dJ$$

where the hazard rate of the jumps J grows exponentially with log-periodic oscillations

$$h(t) = \alpha(t_c - t)^{m-1} [1 + \beta \cos(\omega \log(t_c - t) - \phi')].$$

If the excess return μ_t is proportional to the hazard rate, then the expected log-price is

$$E[\log p] = A + B(t_c - t)^m + C(t - t_c)^m \cos(\omega \log(t_c - t) - \phi).$$

We expect

$$0.1 \leq m \leq 0.9, \quad 6 \leq \omega \leq 13, \quad B < 0, \quad D = \frac{m|B|}{\omega|C|} \geq 0.8.$$

In the likelihood L , one can separate the critical time t_c from the nuisance parameters η ,

$$\hat{t} = \underset{t}{\operatorname{Argmax}} \underset{\eta}{\operatorname{Max}} L(t, \eta)$$

where $L_p(t) = \operatorname{Max}_{\eta}(t, \eta)$ is the **profile likelihood**. The likelihood can sometimes be factored into *marginal* and *conditional* likelihoods, $L(t, \eta) = L(t)L(\eta)$, but not here.

The profile likelihood ignores the uncertainty on the nuisance parameters. The *modified profile likelihood* adds a penalty using the Fisher information matrix of the nuisance parameters.

t : parameter of interest

η : nuisance parameters

$L(t, \eta)$: likelihood

$\ell(t, \eta) = \log L(t, \eta)$ log-likelihood

$\ell_p(t) = \operatorname{Max}_{\eta} \ell(t, \eta)$ profile log-likelihood

$\hat{\eta}_t = \operatorname{Argmax}_{\eta} \ell(t, \eta)$

$\hat{t}, \hat{\eta} = \operatorname{Argmax}_{t, \eta} \ell(t, \eta)$

$I(\hat{\eta}_t) = - \frac{\partial^2 \ell}{\partial \eta \partial \eta'} \Big|_{\eta = \hat{\eta}_t}$ Fisher information

$|A| = |\det A|$

$\ell_m(t) = -\frac{1}{2} \log |I(\hat{\eta}_t)| + \log J(t) + \ell_p(t)$

$J(t)$: Jacobian term, to make the modified profile likelihood invariant to a reparametrization of the nuisance parameters (difficult to evaluate)

$J(t) \approx \frac{|I(\hat{\eta}_t)|}{|\Sigma(t, \hat{\eta}_t; \hat{t}, \hat{\eta})|}$

$\Sigma(t_1, \eta_1; t_2, \eta_2) = E_2 \left[\frac{\partial \ell}{\partial \eta} \Big|_{t_1, \eta_1} \frac{\partial \ell}{\partial \eta'} \Big|_{t_2, \eta_2} \right]$

$\frac{\partial \ell}{\partial \eta}$: score function

E_2 : expectation wrt the distribution of the error term $\varepsilon(t_2, \eta_2)$

The *multiscale modified profile likelihood* plots those confidence intervals in the $t_2 - t_1$ vs $t_c - t_2$ space, highlighting when the constraints are satisfied.

Dissection of Bitcoin's
multiscale bubble history
J.C. Gerlach et al. (2018)

To identify Bitcoin bubbles ex post:

- Look for “drawups”, successions of positive returns interrupted by negative returns no larger than ε , immediately followed by a similarly-defined drawdown, with $\varepsilon = \varepsilon_0 \sigma$, where σ is the volatility over the past w days, and keep dates identified as a peak by 95% of the parameters $(\varepsilon, w) \in [0.1, 5] \times [10, 60]$ (“epsilon drawdown method”);
- Define the begining of the bubbles by fitting an LPPL model with various starting points, and keeping that with the lowest root mean square error, detrended by removing the effect of the estimation period $t_2 - t_1$ (“Lagrange regularization”);

- Define the end of the post-bubble correction as the minimum before the next bubble.

For real-time bubble prediction, fit the LPPL model on different window sizes and cluster the $(t_2 - t_1, t_c - t_1)$, with k -means and the silhouette to choose the number of clusters, to have one or several scenarios.

***Blockchain: data malls,
coin economies and keyless payments***
Z. Kakushadze and R.P. Russo (2018)

The Iota data marketplace is a decentralized data lake whose coin allows users to buy and sell data from each other. Augur is a decentralized prediction market based on Ethereum, using a “reputation” token. Golem is a network to rent spare computing power. MicroRaiden provides off-blockchain micropayments on Ethereum. The Everipedia (a Wikipedia competitor) token is mined by editors by making valuable contributions.

Data provenance, keyless payments (sending BTC to an email address, in a decentralized way) and voting are other applications.

***Cryptocurrency portfolio management
with deep reinforcement learning***
Z. Jiang and J. Liang

End-to-end portfolio construction to find the weights maximizing the after-cost returns, on 12 (liquid) cryptocurrencies, from the prices on 50 30-minute periods, with a convolutional network (CONV+FC). [There is no “reinforcement learning”; the convolution kernels are 12×4 , *i.e.*, they also convolve in the “asset” direction.]

***Are Bitcoin bubbles predictable?
Combining a generalized Metcalfe’s law
and the LPPLS model***
S. Wheatley et al. (2018)

Metcalfe’s law states that the value of a network is proportional to the square of its number of nodes. The Bitcoin market value is proportional to some power (1.7) of the number of users (or the number of transactions, from bitcoininfocharts.com, smoothed): deviations from this generalized Metcalfe’s law is a bubble signal; it can be combined with the LPPL model.

***Classification of crypto-coins and tokens
from the dynamics
of their power law capitalization distributions***
K. Wu et al. (2018)

The distribution of the market capitalization of coins (resp. tokens), from coinmarketcap.com, is well-described by a Pareto (power law) distribution with exponent 0.6 (resp. 1.1). This can be explained by modeling the market capitalization of each coin with independent geometric Brownian motions (with the same parameters), with new coins created by a Poisson process with exponentially growing intensity, and existing coins dying with a constant hazard rate.

***Pricing options
with exponential Levy neural network***
J. Huh (2018)

For Fourier-transform-based option pricing, model the Lévy density

$$\frac{d\nu}{dx}(x) = e^{-x} \mathcal{F}^{-1}[h(w)](x)$$

with a 1-hidden-layer neural net h whose hidden nodes are in two groups, whose outputs are multiplied.

***Generating virtual scenarios
of multivariate financial data
for quantitative trading applications***
J. Franco-Pedroso et al. (2018)

Simulated returns from traditional models are not realistic (Gaussian returns) and/or not scalable (multivariate GARCH, *e.g.*, BEKK). To reproduce “multivariate stylized facts” (kurtosis, skewness, volatility clustering, increased correlation in periods of high volatility, number of “trends”, distribution of the “trend ratios” μ/σ), take a more empirical approach:

- Split the data into up- and down-trends for the market index;
- In each of those trends, estimate the variance matrix on a moving window;
- Sample Gaussian returns from those distributions [I suspect they reject the samples disagreeing with the trend].

***Forecasting directional changes
in financial markets***
A. Bakhach et al (2015)

An upward or downward trend can be defined as a price change beyond a threshold θ ; trends go from one extreme to another; a confirmation point is the first point, after an extreme, exceeding the threshold. The overshoot is the difference between an extreme and the previous confirmation point (rescaled by θ). One can predict of the overshoot of the current trend will exceed some threshold d using decision trees and three variables: the Aroon up and down indicators, *i.e.*, the number of up (or down) trends ago the maximum (or minimum) extremum (or confirmation point) was (among the past $n = 20$ up/down trends) and the difference between the last two confirmation points.

***The role of the dynamic conditional
quartic beta and the capital markets***
G. Corvasce

Define a (cross-sectional, time-varying) *quartic beta* from the quartic loss $\sum (y_i - \beta x_i)^4$.

**Imaging time series
to improve classification and imputation
Z. Wang and T. Oates (2015)**

Convert a time series to an image, using a *Gramian angular field*:

- Rescale x to $[-1, 1]$;
- Let $\phi_t = \arccos x_t$;
- Consider $\cos(\phi_t + \phi_s)$ or $\sin(\phi_t - \phi_s)$

or a *Markov transition field*

- Bin the observations, $y = \text{discretize}(x)$;
- Compute the transition matrix P ;
- Spread it out to preserve the temporal dependence

$$M_{t \rightarrow s} = P_{y_t \rightarrow y_s}$$

and use a (tiled) CNN.

**Deep reinforcement learning bootcamp
P. Abbeel et al. (2017)**

1. Planning or optimal control is the search of the optimal policy on a *known* Markov decision problem (MDP).

Value iteration iterates the Bellman equation

$$\begin{aligned} V_0(s) &= 0 \\ V_{k+1}(s) &= \max_a \mathbb{E}_{s'} [R(s, a, s') + \gamma V_k(s')] \\ &= \max_a \sum_{s'} P(s'|a, s) [R(s, a, s') + \gamma V_k(s')] \end{aligned}$$

Q-value iteration is similar, but computes $Q(s, a)$, the expected value, if we start in state s , take action a , and act optimally thereafter.

$$Q_{k+1}(s, a) = \sum_{s'} P(s'|a, s) [R(s, a, s') + \gamma \max_{a'} Q(s', a')]$$

These are just systems of equations but, because of the maximum, they are not linear. If the policy π is fixed, however, it is just a linear system, which can be solved iteratively or directly (**policy evaluation**).

$$V^\pi(s) = \sum_{s'} P(s'|a, s) [R(s, a, s') + \gamma V^\pi(s')]$$

Policy iteration alternates two steps:

- Compute the value V^π of the policy π_k ;
- Improve the policy by taking the best 1-step action

$$\pi_{k+1}(s) = \underset{a}{\text{Argmax}} P(s'|a, s) [R(s, a, s') + \gamma V^\pi(s')]$$

2. If the MDP is not known, we can act at random and estimate the expected Q -value (**tabular Q-learning**).

$$\begin{aligned} Q(s, a) &\leftarrow (1 - \alpha)Q(s, a) + \alpha \cdot \text{target} \\ \text{target} &= R(s, a, s') + \gamma \max_{a'} Q(s', a') \end{aligned}$$

This is *off-policy* learning: the first term comes from the policy actually followed (e.g., ϵ -greedy), the second

from the optimal policy found so far. The learning rate α should satisfy $\sum \alpha_t = \infty$, $\sum \alpha_t^2 < \infty$.

Approximate Q-learning replaces the table $Q(s, a)$ with a function (e.g., a linear combination of hand-selected features), and a gradient update

$$\theta \leftarrow \theta - \frac{1}{2} \alpha \nabla_\theta (Q_\theta(s, a) - \text{target})^2.$$

3. Deep Q networks (DQN) use a neural network to model Q_θ , but

- The target is not stationary;
- The data is not iid;

To address those concerns:

- Use batches (*experience replay*);
- Use an older set of weights for the target (*target network*);
- Use Huber loss instead of square loss;
- Use RMSProp instead of standard SGD;
- Anneal the exploration rate.

Neural fitted Q-iteration is a batch version of DQN: generate a lot of ϵ -greedy episodes; fit the resulting target for a while; iterate.

Double DQN uses two sets of weights, to select the best action, and to estimate it (otherwise $\max_a Q_\theta(s, a)$ is biased upwards)

Prioritized experience replay uses the Bellman error as transition weights.

$$\left| r + \gamma \max_{a'} Q_{\theta_1}(s', a) - Q_{\theta_2}(s, a') \right|$$

In a *duelling DQN*, the neural network adds structure to the Q -value and separately forecasts state value and advantage, $Q(s, a) = V(s) + A(s, a)$.

Noisy nets add noise to the parameters for better exploration.

4. Policy gradient methods directly look for an optimal stochastic policy $\pi_\theta(s)$ (a deterministic policy is a combinatorial object, more difficult to optimize). This is on-policy (less exploration) and less sample-efficient, but can deal with large action spaces (with Q -learning, $\text{Argmax}_a Q(s, a)$ can be difficult to compute).

Consider a whole episode and let

$$\tau = (s_0, u_0, s_1, u_1, \dots, s_N, u_N)$$

be a state-action sequence. We want to maximize the

expected utility $U(\theta) = \sum P_\theta(\tau)R(\tau)$.

$$\begin{aligned}\nabla_\theta U &= \sum \nabla_\theta P_\theta(\tau)R(\tau) \\ &= \sum P_\theta(\tau) \frac{\nabla_\theta P_\theta(\tau)}{P_\theta(\tau)} R(\tau) \\ &= \sum P_\theta(\tau) \nabla_\theta \log P_\theta(\tau) R(\tau) \\ &= \mathbb{E}[\nabla_\theta \log P_\theta(\tau) R(\tau)] \\ &\approx \frac{1}{m} \sum_i \nabla_\theta \log P_\theta(\tau_i) R(\tau_i)\end{aligned}$$

$$\begin{aligned}\nabla_\theta \log P_\theta(\tau) &= \nabla_\theta \log \prod_t P(s_{t+1}|s_t, a_t) \pi_\theta(s_t|s_t) \\ &= \sum_t \nabla_\theta \log P(s_{t+1}|s_t, a_t) + \nabla_\theta \log \pi_\theta(a_t, s_t) \\ &= \sum_t \nabla_\theta \log \pi_\theta(a_t|s_t)\end{aligned}$$

This can also be derived using *importance sampling*:

$$\begin{aligned}U(\theta) &= \mathbb{E}_{\tau \sim \theta} [R(\tau)] \\ &= \mathbb{E}_{\tau \sim \theta_{\text{old}}} \left[\frac{p_\theta(\tau)}{p_{\theta_{\text{old}}}(\tau)} R(\tau) \right] \\ \nabla U(\theta)|_{\theta=\theta_{\text{old}}} &= \mathbb{E}_{\tau \sim \theta_{\text{old}}} \left[\frac{\nabla_\theta p_\theta(\tau)|_{\theta=\theta_{\text{old}}}}{p_{\theta_{\text{old}}}(\tau)} R(\tau) \right] \\ &= \mathbb{E}_{\tau \sim \theta_{\text{old}}} [\nabla_\theta \log P_\theta(\tau)|_{\theta=\theta_{\text{old}}} R(\tau)]\end{aligned}$$

To reduce variance, one can add a baseline

$$\begin{aligned}\nabla U(\theta) &\approx \frac{1}{m} \sum_i \nabla_\theta \log P_\theta(\tau_i) R(\tau_i) \\ &\approx \frac{1}{m} \sum_i \nabla_\theta \log P_\theta(\tau_i) (R(\tau_i) - b)\end{aligned}$$

and discard terms that do not depend on the current action

$$\begin{aligned}\nabla U(\theta) &\approx \frac{1}{m} \sum_i \sum_t \nabla_\theta \log \pi_\theta(a_{it}, s_{it}) (R(\tau_i) - b) \\ &= \frac{1}{m} \sum_i \sum_t \nabla_\theta \log \pi_\theta(a_{it}, s_{it}) \left(\sum_{k \geq t} R(s_{ik}, a_{ik}) - b \right).\end{aligned}$$

The difference $A_{it} = \sum_{k \geq t} R(s_{ik}, a_{ik}) - b$ is the **advantage**.

Here are possible choices for the baseline:

- Constant: $b = \mathbb{E}[R(\tau)] \approx \frac{1}{m} \sum R(\tau_i)$;
- Optimal constant,

$$b = \frac{\sum (\nabla \log p(\tau_i))^2 R(\tau_i)}{\sum (\nabla \log p(\tau_i))^2};$$

- Time-dependent:

$$b = \mathbb{E}[R(\tau_{\geq t})] \approx \frac{1}{m} \sum_i \sum_{k \geq t} R(s_{ik}, a_{ik});$$

- State-dependent (**actor-critic** – in particular, if the current state is hopeless, regardless of the actions taken, there is no valuable information and the gradient is zero):

$$b(s_t) = \mathbb{E}[r_t + r_{t+1} + \dots] = V^\pi(s_t).$$

To estimate the value function $V^\pi(s)$, we can use supervised learning, e.g.,

- Monte-Carlo: minimize

$$\left[V_\phi^\pi(s_{it}) - \sum_{k \geq t} R(s_{ik}, u_{ik}) \right]^2$$

(we end up with two neural nets: one for the policy, one for the value function);

- Temporal difference (TD): use the Bellman equation for V^π

$$\begin{aligned}\phi_{i+1} &= \underset{\phi}{\text{Argmin}} \sum \left\| R + \gamma V_{\phi_i}^\pi(s_{t+1}) - V_\phi^\pi(s_t) \right\|_2^2 + \\ &\quad \lambda \|\phi - \phi_i\|^2\end{aligned}$$

(there are now two hyperparameters, γ and λ).

To reduce the variance:

- Discount more;
- Use function approximation:

$$\begin{aligned}Q^\pi(s, u) &= \mathbb{E}[r_0 + \gamma r_1 + \gamma^2 r_2 + \dots] &= Q_0 \\ &= \mathbb{E}[r_0 + \gamma V^\pi(s_1)] &= Q_1 \\ &= \mathbb{E}[r_0 + \gamma r_1 + \gamma^2 V^\pi(s_2)] &= Q_2 \\ &= \mathbb{E}[r_0 + \gamma r_1 + \dots + \gamma^4 r_4 + \gamma^5 V^\pi(s_5)].\end{aligned}$$

The **Async advantage actor critic** (A3C) uses Q_5 ; the *generalized advantage estimation* (GAE) averages all of those:

$$Q^\pi = (1 - \lambda) \sum_{n \geq 0} \lambda^n Q_n^\pi.$$

5. Notice that the policy gradient step is also the gradient step of some optimization problem: we can replace that step with a few iterations of an optimization algorithm solving that problem, with a constraint or penalty to limit the step size.

More precisely, the gradient $E_t[\nabla_\theta \log \pi(a|s)A]$ could come from the surrogate loss $E_t[\log \pi(a|s)A]$ or to the importance sampling loss

$$E_t \left[\frac{\pi_\theta(a|s)}{\pi_{\theta_{\text{old}}}(a|s)} A \right].$$

Trust region policy optimization (TRPO) uses a constraint to define the “trust region” (the region where we trust our approximation to be close enough)

$$E[\text{KL}(\pi_{\theta_{\text{old}}}(\cdot|s), \pi_\theta(\cdot|s))] \leq \delta.$$

In practice, use a linear approximation of the objective, a quadratic approximation of the constraint (the Kullback-Leibert divergence becomes the Fisher information matrix – it is a **natural gradient**) and solve

using the conjugate gradient (Hessian-free optimization).

Proximal policy optimization (PPO) uses a penalty instead of a constraint – but adjusting the level of the penalty is harder than adjusting the size of the trust region – a constant value does not work.

Those methods do not work well with CNNs, RNNs and complicated architectures.

Variants include:

- KFAC: Natural policy gradient blockwise approximation of the Fisher information matrix;
- ACKTR: A2C + KFAC natural gradient;
- PPO with clipped objective.

6. Practical advice:

- Use several baselines: cross-entropy, policy gradient, Q-learning SARSA;
- Use more samples per batch;
- Check the sensitivity to all parameters – the method should be robust;
- Try different random seeds;
- Standardize: $\text{clip}((x - \mu)/\sigma, -10, 10)$;
- Use $\text{KL}(\pi_{\text{old}}, \pi_{\text{new}})$ as diagnostic; spikes indicate a drop in performance.

7. When computing the gradient of an expectation, the parameter can be in the distribution, or in the integrand, or in both.

$$\begin{aligned}\nabla_{\theta} \mathbb{E}_{s \sim p_{\theta}} [f(X)] &= \mathbb{E} [f(x) \nabla_{\theta} \log p_{\theta}(x)] \\ \nabla_{\theta} \mathbb{E}_{x \sim N(0,1)} [f_{\theta}(x)] &= \mathbb{E} [\nabla_{\theta} f_{\theta}(x)]\end{aligned}$$

A **stochastic computation graph** is a DAG some of whose nodes are stochastic, *i.e.*, of the form “sample x from p_{input} ” instead of “ $x = f(\text{input})$ ”; we want the gradient of the expectation of the final output.

Examples include dropout or hard attention.

8. The **cross-entropy method** (CEM, aka CMA-ES) works well for Tetris (for a small number of parameters: 22). It is a generalization of the finite difference method, obtained with a 2-element population, defined with mirrored (antithetic) noise.

In practice, transform the reward $R(\tau)$ to its percentile or to an indicator variable for the best $k\%$ policies.

Derivative-free methods are not sample-efficient, but very easy to parallelize.

9. **Model-based reinforcement learning** is sample-efficient, and can even be used on real (physical) robots: model $p(s'|s, a)$ using Gaussian processes, neural nets of Gaussian model mixtures; optimize $\pi_{\theta}(a|s)$; iterate a few times (otherwise the distribution of states can be very different).

The global (DP, NN, GMM) can be used as a prior, with a local (Bayesian linear) model in the neighbourhood of the current trajectory, using a constraint

$$\text{KL}(p(\tau) \parallel p_{\text{old}}(\tau)) < \varepsilon.$$

For high-dimensional data (e.g., the goal could be specified by an image, with no explicit reward), learn in latent space.

10a. If an agent has *rational preferences* (*i.e.*, it cannot be taken advantage of), its preferences can be summarized by a **utility** function, and its behaviour described by *expected utility maximization* (von Neuman and Morgenstern theorem).

Humans are not rational (Allais’s paradox).

10b. **Inverse reinforcement learning** (IRL) infers a reward function from demonstrations – but it is not uniquely defined, and the demonstrations are not truly optimal. Do not learn a single reward function, but a distribution of reward functions – the maximum entropy one (the partition function is problematic, but the corresponding gradient descent algorithm can be seen as a generative adversarial network (GAN)).

11. The main challenges in RL are sample efficiency and exploration (we are still relying on random actions).

Distributional RL (C51) does not learn a value *function* but value *distributions*.

Unsupervised RL deals with sparse rewards by learning more about the environment through auxiliary prediction and control tasks (e.g., predicting that some pixels will change colours, or inducing those changes – for images, use CNN features instead of pixels).

Imagination-augmented agents learn an imperfect model, and use samples from that model as additional trajectories to learn from.

Hierarchical RL improves exploration by learning subtasks and combining them to reach the desired goal.

Feudal networks use two agents, a manager, who decides on the subtasks (and is rewarded if they help get close to the goal), and a worker, who tries to perform the subtasks (and is not aware of the ultimate goal).

For real robots, train the agent in a simulated environment, and fine-tune it in the physical world. **One-shot imitation learning** can then learn a new task from a single example.

12. Current reinforcement learning focuses on a single task, in contrast to machine learning, where generalization matters.

To improve generalization, train on different physical robots.

If the problem has some structure, if you can decompose the task into different “modules”, have separate neural nets learn them, and only combine them at the end (we already saw that with duelling DQNs).

Given a single demonstration, decompose it into intermediate steps (e.g., the latent representation from a CNN), and use them as intermediate goals. *Translation* from the demonstration context to the current context (e.g., the position of the objects) may be needed.

Model-based RL learns about the physical world and can use that knowledge to forecast the outcome of an action and act towards a new goal.

Multi-task learning is a form of regularization and data augmentation – some aspects of the world, useful to plan a task, may be easier to learn when performing another task.

Model-agnostic meta learning looks for a policy that can easily be adjusted to new tasks by policy gradient – for instance, a robot that could be steered in any direction after just one gradient step (*one-shot learning*).

13. The programming exercises use Chainer.

Can't decide? Undecide! C. Goodman-Strauss (2010)

Turing machines can be encoded in seemingly innocuous mathematical objects – the undecidability of the stopping problem leads to more concrete undecidable problems:

- Given a finite collection of tiles and a “seed” pattern, can we tile the whole plane?
- Collatz-like functions, in particular **Fractran** programs – given a list of fractions and a starting integer n , multiply it with the first fraction p/q in the list so that np/q is integer; continue with that integer – for instance

$$\frac{3}{11} \quad \frac{847}{45} \quad \frac{143}{6} \quad \frac{7}{3} \quad \frac{10}{91} \quad \frac{3}{7} \quad \frac{36}{325} \quad \frac{1}{2} \quad \frac{36}{6}$$

generates all prime powers of 10, in order;

- Post’s tag production systems: start with a sequence of zeroes and ones, remove the first three digits and add 00 or 1101 at the end, depending on whether the first digit was 0 or 1;
- SAT (with statements such as “the k th cell contains a at time t ”, “the machine is reading cell k at time t in state s ”, etc.
- Conway’s game of life;
- Wolfram’s rule 110.

Facets of entropy R.W. Yeung (2012)

The entropy function of a collection of discrete random variables $(X_i)_{1 \leq i \leq n}$ is

$$H : \begin{cases} \mathcal{P}([1, n]) & \rightarrow \mathbf{R} \\ \alpha & \mapsto H(X_\alpha) \end{cases}$$

where $H(X_\alpha)$ is the joint entropy of $(X_i)_{i \in \alpha}$. It satisfies the polymatroidal axioms

$$\begin{aligned} H(\emptyset) &= 0 \\ \alpha \subset \beta &\implies H(\alpha) \leq H(\beta) \\ H(\alpha) + H(\beta) &\geq H(\alpha \cap \beta) + H(\alpha \cup \beta). \end{aligned}$$

In addition to entropy, the *Shannon information mea-*

sures are

$$\begin{aligned} H(X|Y) &= H(X, Y) - H(Y) \\ I(X; Y) &= H(X) + H(Y) - H(X, Y) \\ I(X; Y|Z) &= H(X, Z) + H(Y, Z) - H(Z, Y, Z) - H(Z). \end{aligned}$$

Joint entropy and mutual information behave like set intersection and union.

$H(X)$	A
$H(Y)$	B
$H(X, Y)$	$A \cap B$
$I(X; Y)$	$A \cup B$

The polymatroidal axioms are equivalent to the basic inequalities:

$$\begin{aligned} \text{entropy} &\geq 0 \\ \text{conditional entropy} &\geq 0 \\ \text{mutual information} &\geq 0 \\ \text{conditional mutual information} &\geq 0 \end{aligned}$$

Those inequalities are not sufficient to describe entropy functions:

$$\begin{aligned} \mathcal{H}_n &= \{H : \mathcal{P}([1, n]) \rightarrow \mathbf{R}\} \\ \Gamma_n^* &= \{H \in \mathcal{H}_n : H \text{ is entropic}\} \\ \Gamma_n &= \{H \in \mathcal{H}_n : H \text{ polymatroidal}\} \\ \Gamma_n^* &\subset \Gamma_n \\ \Gamma_2^* &= \Gamma_2 \\ \Gamma_3^* &\subsetneq \Gamma_3 \text{ but } \overline{\Gamma_3^*} = \Gamma_3 \end{aligned}$$

For $n \geq 3$, Γ_n^* is neither closed nor convex, but $\overline{\Gamma_n^*}$ is a cone; for $n \geq 4$, there are many more non-Shannon-type inequalities: $\overline{\Gamma_4^*} \subsetneq \Gamma_4$.

Nonlinear time series analysis with R R. Huffaker et al. (2017)

Given a dynamical system, *i.e.*, a system of differential equations, we can study its orbits – they are sometimes chaotic, in the sense that

- Nearby trajectories diverge exponentially fast (chaos);
- The trajectories tend to accumulate around an “attractor” with non-integral dimension (strangeness).

For continuous (autonomous) systems, chaotic behaviour is only possible in dimension at least 3, but discrete systems (e.g., the *Poincaré map* of a continuous system, *i.e.*, the intersections of its trajectories with a plane) in dimension 1 or 2 can be chaotic.

Conversely, given just one coordinate of one of those trajectories, observed with noise, is it possible to reconstruct the other coordinates, the whole attractor, and the original dynamical system? This is the goal of nonlinear time series analysis.

The *embedding* of a univariate time series $(x_t)_{t \geq 0}$ with delay τ and dimension m is the multivariate time series $(x_t, x_{t+\tau}, \dots, x_{t+(m-1)\tau})_{t \geq 0}$. Under reasonable assumptions, it can be used to describe the dynamics of the system: one coordinate is indeed enough (Takens).

To estimate the delay τ , use the first minimum of the *automutual information* (AMI – but there is no theoretical justification, and even no guarantee that a minimum exists).

To estimate the embedding dimension, look at the proportion of *false near neighbours* (FNN), *i.e.*, the proportion of points close, in phase space, at time t , but not at time $t+1$ – sign that some information has been left out. PCA can also be used.

For this (and for the Lyapunov exponent), we want the points to be close in phase space, but not because they are close in time – they should be somehow “intependent”. The *Theiler window* specifies a minimum time separation. To estimate it, plot the proportion of FNN as a function of both space and time separation, or use the first zero of the autocorrelation function (ACF).

The dimension of the attractor can be defined using box counting

$$\lim_{\varepsilon \rightarrow 0} \frac{\log N(\varepsilon)}{\log(1/\varepsilon)}$$

where $N(\varepsilon)$ is the number of balls (or boxes) of size ε needed to cover the set or the *correlation dimension*

$$D_2 = \lim_{\varepsilon \rightarrow 0} \frac{\log C(\varepsilon)}{\log \varepsilon}$$

$$C(\varepsilon) = \lim_{n \rightarrow +\infty} \frac{1}{n^2} \# [|y_i - y_j| \leq \varepsilon]$$

(this is a different notion: it gives more weight to areas visited more often). The embedding dimension should be at least $2D + 1$.

The *recurrence plot* shows the distance (in phase space) between the observation at time t and that at time s ; it can be thresholded to give a binary image, and reduced to a few numeric quantities: emphrecurrent quantitative analysis (RQA) looks, among other things, at the proportion of points in vertical or diagonal segments.

Singular spectrum analysis (SSA) can help separate signal from noise – but it is manual, and some of the components have to be grouped.

To test for stationarity, use Schreiber’s nonlinear cross-prediction stationarity test (divide the time series into non-overlapping segments; fit a nonlinear model on each, *e.g.*, k -NN on an embedding; measure the performance of model i on segment $j \neq i$ versus that on segment i).

A linear system is a differential equation of the form $\dot{y} = Ay$. With real eigenvalues, there can be a stable, unstable or saddle point; with complex eigenvalues, it can be a stable or unstable focus equilibrium, or a centre point. If you see exponentially damped or

exploding trajectories, use a linear model.

To test for nonlinearity, use the BDS test, or the *Hellinger distance* $S_p(k)$ between $f_{X_t, X_{t+k}}$ and $f_{X_t} f_{X_{t+k}}$ (which can be seen as a “nonlinear correlation”) or the moving block bootstrap (in a time series of 0s and 1s, estimate \hat{p} and check if its variance is $\sqrt{\hat{p}(1-\hat{p})/n}$ as it would for an iid sequence).

Non-linearity can also be assessed using *surrogate data*, *i.e.*, time series with the same “linear properties”, *e.g.*,

- ARMA surrogates: Fourier-transform the time series, randomize the phases, transform it back;
- Amplitude-adjusted Fourier transforms (AAFT) surrogates: idem, but transform the output to recover the same distribution;
- PPS surrogates (for aperiodic oscillations): (first coordinate of a) random walk on the reconstructed shadow attractor

and looking at some statistic, *e.g.*, correlation dimension, maximum Lyapunov exponent, nonlinear prediction error or permutation entropy.

Granger causality only works for stochastic systems. For deterministic ones, try to predict future values of y using x ’s attractor (convergent cross-mapping, CMM): if $x(t_a), x(t_b), \dots$ are neighbours of $x(t_0)$, then $y(t_a), y(t_b), \dots$ should be close to $y(t_0)$, and increasingly so as more data arrives. Delayed cross-mapping check how the forecast skill changes with the lag between x and y .

To detect changepoints, compute the SSA decomposition before and after a possible changepoint, compute the scalar product (*i.e.*, correlation) between the first eigenvectors, and compare with surrogate data to have a p -value.

To detect changepoints, one can also estimate the distribution of values on a moving window: it will usually have one peak, but may have two (or be a mixture distribution) during transition periods

Phenomenological modeling estimates the coefficients of an ODE from data, *e.g.*, with regression, assuming the coefficients are polynomial, approximating the derivatives with high (4th) order centered finite differences, with the lasso or adaptive lasso ($|\beta|^\nu$ penalty, $0 < \nu < 1$) to deal with multicollinearity.

Implementations in `tseriesChaos` (`mutual`, `d2`, `false.nearest`, `lyap_k`), `nonlinearTseries` (RQA), `tseriesEntropy` (`Srho.test.ts`, `surrogateAR`, `Trho.test.AR`, `Trho.test.SA`), `Rssa`, `fractal` (`surrogate`), `multispatialCCM`, `MESS`, `extRemes`.

**A differential equation for modeling
Nesterov’s accelerated gradient method:**

Nesterov momentum

$$\begin{aligned}x_k &= y_{k-1} - s \nabla f(y_{k-1}) \\ y_k &= x_k + \frac{k-1}{k+2}(x_k - x_{k-1})\end{aligned}$$

by a can be modeled by an ODE

$$\ddot{x} + \frac{3}{t}\dot{x} + \nabla f(x) = 0.$$

The $O(1/t^2)$ convergence rate is guaranteed if the damping term $\frac{3}{t}\dot{x}$ is sufficiently large: 3 is the smallest constant guaranteeing it but, for large t , the system is over-damped. This suggests resetting t whenever $\langle \dot{x}, \ddot{x} \rangle = 0$ or, for Nesterov momentum, resetting k whenever Δx starts decreasing.

Learning gradient descent: better generalization and longer horizons K. Lv et al. (2017)

The optimization algorithm can be added to the model, to have the computer choose the best stochastic gradient descent variant. For instance, one can use the gradient as input and the updates as output of a coordinate-wise LSTM cell whose latent variables are the first and second moments of the previous gradients (momentum and AdaDelta’s normalizing factors). To help make the algorithm scale-invariant:

- Randomly scale the functions to minimize at training time;
- Add a random convex function, $g(x) = \frac{1}{n} \sum (x_i - v_i)^2$ to make the objective better-behaved;
- Do not feed the raw gradient and momentum to the LSTM, but rescale them with the AdaDelta factor.

Fighting biases with dynamic boosting A.V. Dorogush et al.

Boosting uses the same model to build the data and to compute the gradient: this data reuse introduces bias in the gradient. CatBoost avoids it.

Oblivious decision trees use the same criterion across an entire level of the tree.

Escaping from saddle points – online stochastic gradient for tensor decomposition R. Ge et al.

Even for non-convex functions, SGD converges to a local minimum in a polynomial number of iterations.

Failures of gradient-based deep learning S. Shalev-Shwartz et al

Gradient-based optimization fails when:

- The gradient is too flat and/nor not informative enough about the position of the minimum;

- The sample gradient has a low signal-to-noise ratio;
- The condition number is high.

Possible solutions include:

- Preconditioning;
- Intermediate losses in end-to-end architectures;
- “Forward-only update rule”: if a derivative is zero, in intermediate computations, replace it with 1.

An overview of gradient descent optimization algorithms S. Ruder

A tutorial on Bayesian optimization of expensive cost functions, with applications to active user modeling and hierarchical reinforcement learning R. Brochu et al. (2010)

Illustrated introduction to Bayesian optimization followed by non-trivial examples:

- Bayesian modeling of preferences

$$\begin{aligned}P[X \succ Y] &= \Phi(f(X) - f(Y)) \\ f &\sim \text{GP}\end{aligned}$$

- (the Bradley–Terry model assumes f is linear and uses a logit instead of the probit Φ);
- Hierarchical reinforcement learning.

Batched high-dimensional Bayesian optimization via structural kernel learning Z. Wang et al. (2017)

Bayesian optimization can scale to high-dimensional functions by assuming a latent additive structure, and learning it with Gibbs sampling (Dirichlet prior for the mixing proportions: $\theta \sim \text{Dir}(\alpha)$, $z_j \sim \text{Multi}(\theta)$). Function evaluations can be batched using a determinantal point process (DPP) and processed in parallel.

Distribution-free predictive inference for regression J. Lei et al. (2017)

Conformal inference provides distribution-free, finite-sample prediction sets. With a naive approach, fitting the model on $(x_1, y_1), \dots, (x_n, y_n)$ and using the quantiles of the residuals to form a prediction interval $\hat{\mu}(x_{n+1}) \pm q_\alpha$, the prediction intervals are too small.

Instead, fit the model on $(x_n, y_1) \dots, (x_n, y_n), (x_{n+1}, y)$, for all values of y : the prediction set is the set of y ’s in their $\hat{\mu}(x_{n+1}) \pm q_{y,\alpha}$ interval.

To reduce the computations, do not refit the model for all values of y , but split the data into equal-sized parts, use the first to fit the model, and the second to estimate the residual quantiles. Using N splits, each at level α/N , and taking the intersection of the corresponding intervals, reduces randomness but enlarges the interval – the Bonferroni effect dominates. The

Jackknife (using quantiles of the leave-out-one residuals) relies on a similar idea, but is more fragile, unless we impose strong conditions on the estimator.

**Multivariate quantiles
and multivariate L-moments
A. Decurving (2014)**

Univariate **L-moments** can be defined from order statistics:

$$\begin{aligned}\lambda_1 &= E[X] \\ \lambda_2 &= \frac{1}{2}E[X_{(2)} - X_{(1)}] \\ \lambda_3 &= \frac{1}{3}E[X_{(3)} - 2X_{(2)} + X_{(1)}] \\ &\dots \\ \lambda_r &= \frac{1}{r} \sum (-1)^r \binom{r-1}{k} E[X_{r-k:k}]\end{aligned}$$

or by projecting the quantile function Q on the shifted Legendre polynomials (an orthogonal basis of $L^2([0, 1]; \mathbf{R})$ for the scalar product $\langle f, g \rangle = \int_0^1 fg$ – Legendre polynomials use $\int_{-1}^1 fg$).

Multivariate L-moments can be defined using:

- The monotone transport between the distribution of interest and $\text{Unif}[0, 1]^d$ to define the quantiles, $Q(F(u)) = T(u)$;
- The basis of products of univariate Legendre polynomials.

Other target distributions (the min-copula, a standard Gaussian) and other transports (e.g., Rosenblatt), or other orthogonal polynomials (Hermite) can be used.

The **monotone transport** from μ to ν is the only measurable map T such that $T_{\#}\mu = \nu$ and $T = \nabla\phi$, for some convex function ϕ (it is guaranteed to exist if $\mu = \text{Unif}[0, 1]^d$ or, more generally, if it gives zero measure to sets of Hausdorff measure at most $d - 1$) [Brenier’s theorem].

The **Rosenblatt transport** is

$$T(x_1, \dots, x_d) = \begin{pmatrix} F_{X_1}(x_1) \\ F_{X_2|X_1=x_1}(x_2) \\ F_{X_3|X_1=x_1, X_2=x_2}(x_3) \\ \vdots \end{pmatrix}.$$

The **power Voronoi diagram** is defined using the “distance”

$$d(x_i, u) = \|u - x_i\|^2 + w_i.$$

The convex piecewise linear function

$$\phi_h(u) = \text{Max}_i u \cdot x_i + h_i,$$

for $h_i = -\frac{1}{2}(\|x_i\|^2 + w_i)$ has constant gradient x_i on each Voronoi cell. The monotone transport between μ and the empirical distribution of a sample x_1, \dots, x_n is $T = \nabla\phi_h$ with

$$h = \text{Argmin} \int \phi_h(u) du - \frac{1}{n} \sum h_i$$

(which can be computed by Newton’s method).

**Forecaster’s dilemma:
extreme events and forecast evaluation
S. Lerch et al.**

Forecasts are often only evaluated when an extreme event occurs (earthquake, financial crisis, etc.): this encourages forecasters to always predict disaster – whenever they will be examined, they will be right. There is no fix for point forecasts, but probability forecasts are more flexible. The joint distribution of forecast F and observation Y can be decomposed as

$$[F, Y] = [F][Y|F] = \text{sharpness} \times \text{calibration}.$$

The quality of a forecast distribution F for an observation y can be measured by the logarithmic score

$$\text{LogS}(F, y) = -\log f(y)$$

or by the continuously ranked probability score

$$\text{CRPS}(F, y) = \int_{-\infty}^{+\infty} (F(y) - \mathbf{1}_{y \leq z})^2 dz.$$

There are weighted variants:

$$\text{CL}(F, y) = -w(y) \log \frac{f(y)}{\int w f}$$

$$\text{twCRPS}(F, y) = \int w(z) (F(z) - \mathbf{1}_{y \leq z})^2 dz.$$

**The Cramér distance
as a solution to biased Wasserstein gradients
M.G. Bellemare et al.**

In machine learning, the Kullback-Leibler divergence (relative entropy) is often used to measure the “distance” between the data and the fitted model. Instead, one can use the *Wasserstein metric*, which does not only consider probabilities, but also proximities.

It is scale-invariant

$$d(cX, cY) \leq |c|^\beta d(X, Y)$$

and sum-invariant

$$d(A + X, A + Y) = d(X, Y)$$

but does not have unbiased sample gradients

$$\nabla_\theta d(P, Q_\theta) \neq \mathbb{E}_{x_1, \dots, x_m \sim p} \nabla_\theta d\left(\sum \delta_{x_i}, Q_\theta\right).$$

Prefer the **Cramér distance**

$$d_2(P, Q) = \left(\int (F_P(x) - F_Q(x))^2 dx \right)^{\frac{1}{2}},$$

which is scale-invariant, sum-invariant, and has unbiased sample gradients.

A note on the evaluation of generative models
L. Theis et al. (2016)

The *Jensen-Shanon divergence* (JSD) is a symmetrized KL divergence:

$$\text{JSD}(p, q) = \frac{1}{2} \text{KL}\left(p \parallel \frac{p+q}{2}\right) + \frac{1}{2} \text{KL}\left(q \parallel \frac{p+q}{2}\right)$$

The *maximum mean discrepancy* (MMD) is

$$\text{MMD}(p, q) = \mathbb{E}_{\substack{x, x' \sim p \\ y, y' \sim q}} [k(x, x') - 2k(x, y) + k(y, y')]^{1/2}.$$

Random projection through multiple optical scattering: approximating kernels at the speed of light
A. Saade et al.

Analogue, optical devices can efficiently compute random projections.

Alpha-beta divergences discover micro and macro structures in data
K. Narayan et al. (2015)

The Kullback-Leibler divergence

$$D(P\|Q) = \sum_{i \neq j} P_{ij} \log \frac{P_{ij}}{Q_{ij}}$$

minimized by t-SNE can be replaced by the α - β -divergence

$$D(P\|Q) = \frac{1}{\alpha\beta} \sum_{i \neq j} -P_{ij}^\alpha Q_{ij}^\beta + \frac{\alpha}{\alpha+\beta} P_{ij}^{\alpha+\beta} + \frac{\beta}{\alpha+\beta} Q_{ij}^{\alpha+\beta}.$$

Different values of (α, β) focus on macro-structures, micro-structures or hard-to-classify observations ($\alpha \approx 1, \beta \approx 0, \alpha + \beta \approx 1$).

Entropic graph-based posterior regularization
M.W. Libbrecht et al. (2015)

To encourage variables associated to nodes in a graph to have similar posterior distributions when those nodes are linked, add a penalty for their KL divergence. More precisely, *posterior regularization* introduces an auxiliary joint distribution q , adds a regularizer to it, and a penalty to make it close to the posterior p ,

$$\text{Penalty}(p) = \max_q -D(q\|p) + \text{Penalty}(q).$$

Persistence topology of syntax
A. Port et al.

Persistence homology shows that language evolution cannot be summarized by a tree, but often needs a more general phylogenetic *network* – for Indo-European, the first homology generator comes from ancient Greek.

Spin class models of syntax and language evolution
K. Siva et al.

Spin model to model and forecast the evolution of a weighted graph with binary feature vectors at each node.

Graph grammars, insertion Lie algebras and quantum field theory
M. Marcolli and A. Port

Graph grammars generalize context-free and context-sensitive grammars, and model parallelism: the production rules replace a subgraph (a single, non-terminal node, in the case of context-free grammars) with a new graph.

Prevalence and recoverability of syntactic parameters in sparse distributed memories
J.J. Park et al.

A *Kanerva network* (or *sparse distributed memory*) learns a mapping $\mathbf{F}_2^N \rightarrow \{\pm 1\}$ from a dataset $(x_i, y_i)_i$ as follows:

- Pick k points $\hat{x}_1, \dots, \hat{x}_k \in \mathbf{F}_2^N$, each associated with a count variable $\hat{y}_1, \dots, \hat{y}_k$, initialized at 0;
- For each observation (x_i, y_i) , find the points within distance d of x_i , and increment/decrement their counts.

Here, they are used to check which language features (SVO order, etc. – from the SSWL (now TerraLing) or WALS databases) can be recovered. They can also learn the identity map $\mathbf{F}_2^N \rightarrow \{\pm 1\}^N$, *i.e.*, learn a dataset.

Implementation in `msbrogli/sdm`.

Submodularity in data subset selection and active learning
K. Wei et al. (2015)

To select a small sample of data on which to train a classifier with minimal performance loss, consider the data log-likelihood,

$$\ell(S) = \sum_{i \in V} \log p(x_i, y_i | \theta(s))$$

i.e., the likelihood of the whole data V when the model is estimated on a subset $S \subset V$. For the naive Bayes or the nearest neighbour classifiers, this is a difference of submodular functions but, under the constraints $|S| = k$ and S balanced (same label distribution as V), it reduces to a modular function, which can be approximately maximized with the lazy greedy algorithm.

***Langevin diffusions and
the Metropolis-adjusted Langevin algorithm***
T. Xifara et al.

Given a diffusion $dX_t = \mu(X_t)dt + \sigma(X_t)dW_t$, the probability density function $p(x, y)$ satisfies the Fokker-Plank equation

$$\frac{\partial p}{\partial t} = -\frac{\partial(\mu p)}{\partial x} + \frac{1}{2} \frac{\partial(\sigma^2 p)}{\partial x^2}$$

or

$$\frac{\partial p}{\partial t} = -\mathbf{1}' \nabla_x (\mu p) + \frac{1}{2} \mathbf{1}' \nabla_x^2 (\sigma \sigma' p) \mathbf{1}$$

in dimension n . One can therefore build a diffusion with a prescribed stationary distribution, e.g.,

$$dX_t = \frac{1}{2} \nabla \log \pi dt + dW_t$$

or

$$dX_t = \frac{1}{2} A \nabla \log \pi dt + \Gamma dt + \sqrt{A} dW_t$$

(with $\Gamma(x) = 0$ if $A(x)$ does not depend on x).

***FairTest: discovering unwarranted
associations in data-driven applications***
F. Tramèr et al.

Unwarranted associations are statistically significant associations, in a subpopulation, between a protected attribute and an output, with no accompanying explanatory factor. Examples include

- Unintended side effects (e.g., discounted prices if there is a competitor nearly exclude low-income areas);
- Large errors affecting a subpopulation (e.g., future health prediction for the elderly).

***The dual-sparse topic model: mining focused
topics and focused terms in short text***
T. Lin et al. (2014)

Spike-and-slab prior for sparse topic mixtures and sparse word usage.

***A unified model
for unsupervised opinion spamming detection
incorporating text generality***
Y. Xu et al.

Hierarchical Bayesian model for spam detection, combining text, user and item features, estimated with Gibbs-EM, *i.e.*, alternating between collapsed Gibbs sampling and variational inference gradient descent.

***Bayesian post-selection inference
in the linear model***
S. Panigrahi et al.

In *selective inference* (adaptive data analysis), the analyst looks at the data before deciding which question to ask. This can be modeled by *conditioning* on selection, *i.e.*, by using a *truncated* log-likelihood, for a sequence

model (k largest statistics, BY correction) or a (generalized) linear model (through a convex approximation of the truncated likelihood).

***Learning the nonlinear geometry of
high-dimensional data: models and algorithms***
T. Wu and W.U. Bajwa (2015)

Union-of-subspace (UoS) models have trouble when the subspaces are close: constrain the subspaces to be close, using a distance on the Grassmanian, e.g., $d(S_1, S_2) = \|D_1 - P_{S_2} D_1\|_F$ where D_i is an orthonormal basis of S_i and P_{S_2} is the projection on S_2 – it can also be defined from the *principal angles* θ^k as $d(S_1, S_2) = \sqrt{s - \sum \cos^2 \theta_{12}^k}$, where s is the subspace dimension (for nonlinear data, use a kernel).

***Scalable Gaussian processes for characterizing
multidimensional change surfaces***
W. Herlands et al. (2015)

Mixture models

$$f(x) = \sum p_i f_i(x), \quad \mathbf{p} = \text{softmax}(\mathbf{w}(x)),$$

with a Gaussian process prior on \mathbf{w} , can be seen as generalizations of changepoint models.

Deterministic independent component analysis
R. Huang et al.

Variants of the HKICA algorithm (FastICA, *i.e.*, finding directions maximizing some measure of non-Gaussianity, only has theoretical guarantees in the noiseless case):

- Sample $\phi, \psi \sim N(0, I)$;
- Compute $m_p(\eta) = E[(\eta' X)^p]$, $f = \frac{1}{12}(m_4 - 3m_2^2)$, $\nabla^2 \hat{f}$;
- Compute the eigenvectors of $(\nabla^2 \hat{f} \phi)(\nabla^2 \hat{f} \psi)^{-1}$, $A = (\mu_1 | \dots | \mu_d)$;
- We then have $\mathbf{x} \approx A\mathbf{s} + \text{Gaussian noise}$.

On restricted nonnegative matrix factorization
D. Chistikov et al. (2016)

The *nonnegative rank* of an $n \times m$ nonnegative matrix M is the smallest d for which we can find nonnegative $n \times d$ and $d \times m$ matrices W and H such that $M = WH$. If M is rational, W and H need not be so, *i.e.*, $\text{rank}_+^{\mathbf{Q}} > \text{rank}_+^{\mathbf{R}}$ in general (in dimensions beyond 3). The *restricted NMF* requires $\text{rank } M = \text{rank } W$, defining a *restricted nonnegative rank*.

***Distributional rank aggregation
and an axiomatic analysis***
A. Prasad et al. (2015)

Rank aggregation is the problem of combining several rankings (e.g., from search engines) into one. Distributional rank aggregation only uses the distribution (histogram) of the rankings. The normative axioms of “social welfare theory”, non-dictatorship, universality,

transversality, Pareto efficiency and independence to irrelevant alternatives (Arrow's impossibility theorem) can be relaxed and satisfied.

Parallel resampling in the particle filter
L.M. Murray et al. (2015)

The propagation and weighting steps of sequential Monte Carlo (SMC, particle filters) are easy to parallelize, but the resampling step is less so – try:

- Rejection sampling, if an upper bound on the weights is known:

$$j \sim \text{Unif}[1, N] \text{ while } \text{Unif}(0, 1) > w_1/w_{\max};$$

- Metropolis: run N identical Markov chains in parallel, for B steps, sampling from $\text{Multinom}(\mathbf{w})$ – only the weight ratios w_i/w_j are needed.

Scalable nearest neighbor algorithms for high-dimensional data
M. Muja and D.G. Lowe (2014)

The FLANN library for approximate nearest neighbour search automatically selects the algorithm among:

- *Randomized k -d forests*: multiple k -d trees searched in parallel, in which the split dimension is chosen randomly from the top 5 with highest variances – non-axis-aligned variants exist but do not perform significantly better;
- *Priority search k -means trees*: find k clusters and process each cluster recursively until they reach a minimum size – it is just another way of hierarchically partitioning the space.

Six myths of polynomial interpolation quadrature
L.N. Trefethen

Equispaced interpolation may diverge (Runge phenomenon) but *Chebyshev interpolation*, i.e., interpolation on $[-1, 1]$ at $x_k = \cos(j\pi/n)$, converges for Lipschitz continuous functions.

It can be numerically evaluated with the *barycentric*

formula

$$\begin{aligned}\ell_j(x) &= \prod_{i \neq j} \frac{x - x_i}{x_j - x_i} \\ \ell(x) &= \prod (x - x_i) \\ \ell'(x_j) &= \prod_{i \neq j} (x_i - x_j) \\ \ell_j(x) &= \frac{\ell(x)}{x - x_j} \frac{1}{\ell'(x_j)} = \frac{\ell(x)}{x - x_j} w_j \\ g(x) &= \sum \ell_j(x) y_j = \ell(x) \sum \frac{w_j}{x - x_j} y_j \\ 1 &= \ell(x) \sum \frac{w_j}{x - x_j} \\ g(x) &= \frac{g(x)}{1} = \frac{\sum \frac{w_j}{x - x_j} y_i}{\sum \frac{w_j}{x - x_j}}\end{aligned}$$

The monomials x^k are well-suited to find roots on the circle; for roots on $[-1, 1]$, prefer Chebyshev polynomials.

Fixed points of belief propagation an analysis via polynomial continuation
C. Knoll et al.

Homotopy continuation is a way of numerically finding the solutions of a system of equations, by following a homotopy from an easy-to-solve system to the desired one. In the case of a polynomial system, the *polyhedral homotopy method* finds all the solutions (it scales better than Gröbner bases).

Non-free implementation in Hom4PS-3.

Transfinite game values in infinite chess
C.D.A. Evans and J.D. Hamkins

A position has value (at most) n if there is a strategy leading to a check-mate in (at most) n moves, whatever the opponent does.

A position with value ω , the first infinite ordinal, is a position with Black to play resulting in a mate-in- n position for White, with n as large as Black wants.

A position with value $\omega + n$ is n moves away from a position with value ω .

A position with value $n\omega$ is a position in which Black can announce n times “I will make an announcement in k_i moves” or, for the last one, “I will lose in k_n moves”, with the k_i 's as large as desired.

In a position with value $k\omega$, Black can play to be in a position with value $k\omega$, with k as large as desired.

A position in infinite chess with game value ω^4
C.D.A. Evans et al.

What is a Leavitt path algebra?

G. Abrams

Given a monoid M , it is possible to find a ring R so that $(\text{Mod } R, \oplus) \simeq M$.

Highly comparative time-series analysis: the empirical structure of time series and their methods

B.F. Fulcher et al. (2013)

The `hctsa` Matlab library (GPL) provides 1000 time series features for classification, clustering and biclustering, to be used with the UCR time series dataset for nearest neighbour search.

FATS: Feature analysis for time series

I. Nun et al. (2015)

The FATS Python library computes 30 time series features (to classify astronomy time series).

Feature-based time series analysis

B.D. Fulcher (2017)

Look at global features:

- Distribution of the values (μ , σ , etc.);
- Stationarity, e.g., $\text{StatAv} = \frac{\text{sd}(\bar{x}_{1:w}, \bar{x}_{w+1:2w}, \dots)}{\text{sd}(x)}$
- ACF, Fourier and wavelet coefficients;
- Nonlinear time series analysis: Lyapunov coefficients, correlation dimension, correlation entropy;
- Entropy: approximate entropy, sample entropy, permutation entropy;
- Scaling (fractality): Hurst exponent (DFA);
- Time series models: parameters and goodness-of-fit statistics, properties of the residuals;

and subsequence features:

- If the time series are aligned, consider $\text{Mean}(x_{i:j})$, $\text{Sd}(x_{i:j})$, $\text{Slope}(x_{i:j})$ – these are families of features: select them greedily, using the entropy gain (as in decision trees);
- *Shapelets* are small patterns that may appear in a time series,

$$\min_i d(x_{i-w:i+w}, \text{shapelet})$$

selected by genetic algorithms – you can also look at their position or the number of occurrences.

Automatic time series phenotyping using massive feature extraction

B.D. Fulcher and N.S. Jones (2016)

Normalize the time series with a “robust sigmoid”,

$$x \leftarrow \left(1 + \exp - \frac{x - \text{median}}{1.35 \times \text{IQR}} \right)^{-1}$$

Large-scale unusual time series detection

R.J. Hyndman et al. (2015)

A few more time series features:

- Lumpiness: variance of the variances in 24-observation blocks;
- Spikiness: variance of the l.o.o. variances of the STL residuals;
- Level and variance change: maximum change in mean or variance in consecutive 24-observation blocks;
- KL score: maximum Kulback-Leibler divergence between kernel density estimates of consecutive 48-observation blocks;
- Flat spots: maximum run length of the (10-value) quantized time series.

Some features are not defined: peak, trough, curvature.

Forecastable component analysis

G.M. Goerg (2013)

Find orthogonal directions, maximizing *forecastability*, measured by $\Omega = 1 - H / \log 2\pi$, where H is the **spectral entropy**, *i.e.*, the entropy of the spectral density (the spectrum, rescaled to be a probability density on \mathbf{S}^1). Implementation in `ForeCA::Omega`.

A scalable method for time series clustering

X. Wang et al. (2004)

Cluster time series using the following features:

- Trend = $1 - \frac{\text{Var}(\text{detrended})}{\text{Var}(\text{raw})}$
- Seasonality = $1 - \frac{\text{Var}(\text{deseasoned})}{\text{Var}(\text{raw})}$
- Periodicity: position of the first peak in the ACF, if it is positive, and significantly higher than the previous trough;
- Serial correlation: Box-Pierce statistic;
- Non-linearity: Teräsvirta test statistic;
- Skewness, kurtosis, Hurst exponent, maximum Lyapunov exponent.

All those features have values in $[0, +\infty)$: rescale them parametrically

$$q \mapsto \frac{e^{aq} - 1}{b + e^{aq}}$$

so that quantiles 10% and 90% correspond to time series with and without the features (respectively an example from the literature, and white noise).

TSclust: an R package for time series clustering

P. Montero and J.A. Vilar (2014)

The TSclust package defines the following dissimilarity measures:

- L^p distance;
- Dynamic time warp (DTW) distance,

$$d(x, y) = \min_r \sum_{(i,j) \in r} |x_i - y_j|;$$

- Fréchet distance,

$$d(x, y) = \min_r \max_{(i,j) \in r} |x_i - y_j|;$$

- Correlation:

$$\sqrt{2(1 - \text{Cor}(x, y))}, \quad \left(\frac{1 - \text{Cor}(x, y)}{1 + \text{Cor}(x, y)} \right)^{\beta/2};$$

- L^2 distance between the ACF, with constant or exponentially decaying weights;
- L^2 distance between the periodograms, the normalized periodograms, the integrated periodograms (Cramér–von Mises distance between the spectral densities);
- Distance between the wavelet coefficients, the $AR(\infty)$ coefficients or the cepstral coefficients;
- Statistics from ARMA tests checking if the two time series come from the same model;
- Distance between the SAX representations (obtained by aggregating, and then quantizing with quantiles);
- Divergence between the distributions of the permutations induced by an m -dimensional embedding;
- Normalized compression distance and variants:

$$\frac{C(xy) - \min\{C(x), C(y)\}}{\max\{C(x), C(y)\}}, \quad \frac{C(xy)}{C(x)C(y)};$$

- Distance between the k -step-ahead forecast distributions, from a *sieve bootstrap* (i.e., bootstrap on the residuals of an AR or similar model).

Those measures can be corrected, for correlation or complexity, by multiplying by

$$\frac{1}{1 + \exp k \text{Cor}(\Delta x, \Delta y)} \quad \text{or} \quad \frac{\max\{\text{CE}(x), \text{CE}(y)\}}{\min\{\text{CE}(x), \text{CE}(y)\}},$$

where $\text{CE}(x) = \|\Delta x\|_2^2$.

***pdc: an R package
for complexity-based clustering of time series***
A.M. Brandmaier (2015)

To cluster time series, use an m -dimensional embedding, replace the m -dimensional vectors with the corresponding permutation (their ranks), and use the *Hellinger distance* (a metric approximation of the KL divergence) between the permutation distributions as a dissimilarity measure. Choose the embedding dimension m and the delay τ to minimize the (average) normalized *permutation entropy*

$$-\frac{1}{m!} \sum_{\sigma \in \mathfrak{S}_m} p_\sigma \log p_\sigma.$$

***Visualising forecasting algorithm performance
using time series instance spaces***
Y. Kang et al. (2016)

Time series features (spectral entropy, trend and seasonality strength from the STL decomposition, period (if known), ACF, optimal Box-Cox transformation to make the time series linear) can be used to

- Check how diverse the M3 dataset (in the MComp package) is;
- Add synthetic time series in its gaps, using a genetic algorithm;
- Visualize which forecasting algorithms perform well with which type of time series.

***JIDT: an information-theoretic toolkit
for studying the dynamics of complex systems***
J.T. Lizier (2014)

The JIDT Java library provides several information-theoretic measures for time series, centered on *transfer entropy*, and several estimators.

Entropy rate	$H(X_{n+1} X_n)$
Active information storage	$I(X_n; X_{n+1})$
Transfer entropy	$I(Y_{n+1}; X_{n+1} X_n)$
Conditional TE	$I(Y_{n+1}; X_{n+1} X_n, Z_n)$

(you can replace X_n with (X_n, \dots, X_{n+k-1})).

Multiscale entropy analysis
M. Costa et al. (2000)

Compute the average of the datapoints on non-overlapping windows of size τ , and then the sample entropy; plot the sample entropy versus τ – for $1/f$ noise, it is flat.

***Introducing nonlinear time series analysis
in undergraduate courses***
M. Perc (2004)

Nonlinear time series analysis studies stationary, deterministic time series, from data alone, i.e., without knowledge of the underlying dynamical system.

The dynamical system can often be recovered from the *Takens embedding*, i.e., the cloud of points $(x_t, x_{t+\tau}, \dots, x_{t+(m-1)\tau}) \in \mathbf{R}^m$. To choose the delay τ , check when the ACF decreases to $1/e$, or when the AMI (auto-mutual information) reaches its first minimum – though there is no reason such a minimum should exist. To choose the embedding dimension m , notice that two points close in the embedding should remain close at the next time step – if not, i.e., if

$$\|p_t - p_s\| \leq \sigma \quad \text{but} \quad \frac{|x_{t+m\tau} - x_{s+m\tau}|}{\|p_t - p_s\|} > 10,$$

they are *false nearest neighbours* (FNN) – we are missing some information about them. Plot the proportion of FNN as a function of m to help select m .

To test for stationarity, split the time series into non-overlapping segments and compare the mean and standard deviation on each segment, or look at the *cross-prediction error* δ_{ij} when forecasting the next observation in segment j with a k -NN model fitted on segment i .

To recover the dynamical system,

- Split the embedding space into boxes;
- Whenever a trajectory crosses a box, compute its average direction, as a unit vector;
- Average the vectors in each (non-empty) box – if the directions are consistent, the average will still have unit norm.

The *Lyapunov exponent* measures how fast nearby trajectories diverge; it can be estimated by choosing a point p_s close to p_t and averaging

$$\frac{1}{\nu} \log \frac{\|p_{t+\nu} - p_{s+\nu}\|}{\|p_t - p_s\|}$$

with $\nu = m\tau$, and replacing the point p_s at each step, trying to keep the same direction.

Nonlinear time series analysis revisited **E. Bradley and H. Kantz (2015)**

Nonlinear time series analysis reconstructs the state space of a dynamical system, from data alone, to compute fractal dimension, Lyapunov exponents (instability), Kolmogorov-Sinai entropy (unpredictability), etc. – but noise and the finiteness of the data call for caution.

- The fraction of pairs of data points at distance at most ε (the *correlation sum*) scales as ε^{D_2} , where D_2 is the *fractal (Renyi) dimension*.
- The time series should be long enough: as a rule of thumb, $N > 42^{D_2}$.
- To test if the values are significantly different from a null model, use *surrogate time series*: Fourier transform the data, randomize the phases, transform back, map onto the original values (only keeping the rank), and somehow recover the correlations.
- Permutation entropy.
- Recurrence plots and *recurrence quantitative analysis* (RQA): proportion of black points in the plot, in diagonals, in vertical lines, length distribution of those lines.
- Network characteristics: interpret the recurrence matrix as a graph and look at some of its metrics: centrality, shortest paths, clustering coefficients, etc.

Distinguishing noise from chaos is difficult.

Complex network approach for recurrence analysis of time series **N. Marwan et al. (2009)**

The following five RQA features

- Maximum diagonal length;
- Laminicity: proportion of points in vertical lines;
- Link density (for the network whose adjacency matrix is the recurrence plot);
- Clustering coefficient;
- Average minimum path length

can identify different regimes of the logistic map $x_{n+1} \leftarrow \alpha s_n(1 - x_n)$ as α varies, or (when estimated on a moving window) the different regimes of a real-world time series.

Characterizing the structural diversity of complex networks across domains **K. Ikehara and A. Clauset (2016)**

To compare networks, look at scale-invariant features: clustering coefficient, degree assortativity and network motifs (compared with a random graph with the same degree distribution).

Time series classification with COTE: the collective of transformation-based ensembles **A. Bagnall et al. (2014)**

Classify time series using ensemble methods (random forests or **rotation forests** – random forests with a PCA on a random subset of the variables at each node), on data transformed into the time (shapelets), frequency (periodogram) or autocorrelation (ACF, PACF, AR coefficients) domains.

The **shapelet features** are the distances to smaller time series s (“shapelets”),

$$d(s, x) = \min_{\substack{y \subset x \\ \text{len}(x) = \text{len}(s)}} d(s, y);$$

those smaller time series are taken from subsequences of the training data, pruned to retain only the most discriminating ones (small distances to one class, large distance to the others) and to avoid redundancy.

Forecasting at scale **S.J. Taylor and B. Letham**

To forecast time series, Facebook uses a GAM-like model, with trend, seasonality (Fourier) and (irregular) holiday components – curve fitting is easier than time series modeling. The trend is either piecewise linear (with a large number of potential changepoints, but a Laplace prior keeps them sparse), or a logistic growth model, with changepoints accounting for changes in market size (e.g., using the population from the World Bank).

R/Python implementation, via Stan, in `fbprophet`.

Distributed and parallel time series feature extraction for industrial big data applications **M. Christ et al. (2017)**

Select time series features (from `hctsa`) using tests for feature \perp outcome (Fisher, Kolmogorov-Smirnov or Kendall rank, depending on whether the variables are binary or continuous) and the Benjamini-Yekutieli (BY) procedure to control the false discovery rate (FDR).

The all-relevant feature selection using random forest **M.B. Kursu and W.R. Rudnicki (2010)**

To find all the relevant features (instead of just a non-redundant set), add a “shadow” variable for each feature, by shuffling its values, fit a random forest, and

mark as relevant the features more important than the best random one; remove them, and iterate until nothing left is relevant.

R implementation in Boruta.

Surrogate time series

T. Schreiber and A. Schmitz (1999)

To test if a time series is linear, e.g.,

- H_0 : iid;
- H_0 : ARMA (“Gaussian linear”);
- H_0 : Nonlinear transformation of an ARMA process;

(these are *composite* null hypotheses), look at statistics such as *time reversibility* $E[(X_n - X_{n-\tau})^3]$ or the non-linear prediction error (nlpe). The p -value can be computed with simulations. The bootstrap would estimate an ARMA model on the data and generate new data from the fitted model. **Constrained randomization** generates data with the same ARMA estimates, *i.e.*, with the same ACF. For instance, one can Gaussianize the data, compute its FFT, randomize the phase, transform back, and restore the distribution, but this tends to give a flatter power spectrum. Instead, start with a shuffled time series and iterate:

- Force the spectrum to be correct, by rescaling it to the correct amplitudes, keeping the phases;
- Force the distribution to be correct (resampling).

Conserving the Fourier amplitudes preserves the periodic ACF, not the ACF: to limit the problem, measure the corresponding artefacts and remove a few observations at the beginning or the end to minimize them. Alternatively, use simulated annealing to find a permutation of the original time series with a small discrepancy between the ACFs (not exactly the minimum discrepancy: that would be the original time series).

A large set of audio features for sound description (similarity and classification) in the Cuidado project **G. Peeters (2004)**

Audio features include:

- Spectral shape (linear or exponential fit; properties of the spectral density);
- ACF, zero crossing rate;
- Length of the ADSR (envelope) phases;
- Fundamental frequency, inharmonicity (weighted average distance between successive spectral peaks and multiples of the fundamental), harmonic deviation (deviation of the harmonics from the spectral envelope), odd/even harmonic ratio, tristimulus (relative energy in harmonics 1, 2–4 and 5+).

Time-varying market beta: does the estimation methodology matter? **B. Nieto et al. (2014)**

Comparison of several time-varying beta estimators (prefer Kalman or GARCH):

- Regression on a moving window, with constant or decreasing weights;
- Multivariate GARCH

$$\text{BEKK: } H_{t+1} = C'C + A'\varepsilon_t\varepsilon_t'A + B'H_tB$$

$$\text{DCC: } H_t = D_t R_t D_t$$

(where D_t is a diagonal GARCH model) and asymmetric variants;

- Kalman filters

$$\text{random walk: } \beta_{t+1} = \beta_t + \text{noise}$$

$$\text{random observations: } \beta_t = \beta_0 + \text{noise}$$

Arbitrated ensemble for time series forecasting **V. Cerqueira et al.**

To combine time series forecasts, model how each model performs for different types of inputs and how this performance changes with time (the metamodel forecasts the model error).

Graph-theoretic properties of the darkweb **V. Griffith et al.**

The Darkweb is only loosely connected: most sites have no outgoing links. Data from the tor2web proxy onion.link, crawled with scrapinghub.com (commercial), starting from directoryvi6plzm.onion and ahmia.fi/onions.

A divide-and-conquer framework for distributed graph clustering **W. Yang and H. Xu (2015)**

The generalized stochastic block model divides the nodes into clusters and outliers; the edge probability is p for nodes inside the same cluster and $q < p$ otherwise (edges between clusters or involving an outlier). It can be fitted, in parallel, with a divide-and-conquer approach:

- Randomly partition the nodes into groups;
- Find clusters in each of those subgraphs;
- Build a “fused” graph, whose nodes are the subgraph clusters, and with an edge between two clusters if the edge density exceeds some threshold t ($q < t < p$);
- Find clusters in the fused graph.

Real-time community detection in large social networks on a laptop **B. Chanberlain et al.**

The **minhash** of a subset $A \subset \llbracket 1, n \rrbracket$ is $h_\sigma(A) = \text{Min}\{\sigma(a), a \in A\}$ for a (fixed) random permutation $\sigma \in \mathfrak{S}_n$. The *Jaccard similarity* can be approximated with minhashes:

$$J(A, B) = \frac{|A \cap B|}{|A \cup B|} = \mathbb{P}_{\sigma \in \mathfrak{S}_n} [h_\sigma(A) = h_\sigma(B)].$$

Given a large graph, the neighbours of a node can be compressed (lossily) using minhash signatures (e.g., 1000 hash functions for 1,000,000 nodes), and locality-sensitive hashing (LSH) can be used to find approximate nearest neighbours: with the Jaccard similarity,

they form a weighted graph, on which we can compute (local) communities. The Jaccard similarity also helps solve coverage problems (“find the smallest number of athletes that have influence over half of Twitter”) – $|A \cup B| = |A| + |B| - |A \cap B|$ links the number of neighbours of a community and of a node and their Jaccard similarity.

Querrying k -truss community in large and dynamic graphs
X. Huang et al. (2014)

The k -truss of a graph G is the largest subgraph in which each edge is in at least $k - 2$ triangles.

A k -truss community is a maximal k -truss subgraph in which any two edges are reachable through a series of adjacent triangles.

After putting the k -truss subgraphs in a suitable index, one can retrieve the k -truss community of a vertex in linear time.

Bayesian dynamic modeling and analysis of streaming network data
X. Chen and K. Irie (2015)

To model the flow of visitors on a graph (website), consider a non-Gaussian state space model

i : node

t : time

n_{it} : number of occupants of node i at time t

x_{ijt} : flow from i to j between $t - 1$ and t

$x_{0it} \sim \text{Pois} \phi_{it}$ new visitors

$x_{i,t} \sim \text{Mult}(n_{i,t-1}, \theta_{i,t})$ movement between nodes

ϕ_{it} : arrival rate

θ_{ijt} : transition probabilities

$$\theta_{ijt} = \frac{\phi_{ijt}}{\sum \phi_{i,t}}$$

$$\phi_{ijt} = \mu_t \alpha_{ij} \beta_{jt} \gamma_{ijt}$$

β_{jt} : attractivity of node j at time t

Unpaired image-to-image translation using cycle-consistent adversarial networks
J.Y. Zhu et al.

CycleGAN translates (unpaired) images between two domains (paintings and photographs, horses and zebras, summer and winter, aerial photographs and maps, etc.) by learning two mappings

$$\mathcal{X} \xrightleftharpoons[B]{G} \mathcal{Y}$$

with an adversarial loss to make the distribution of $G(\mathcal{X})$ indistinguishable from that of \mathcal{Y} , and to ensure $F \circ G \simeq \text{id}$ (cycle-consistency).

InfoGAN: interpretable representation learning by information maximizing generative adversarial nets
X. Chen et al.

To make the latent space of GANs more interpretable (in an ICA-like way), split the noise into an incompressible part z and a “code” c , and solve the minimax problem

$$\begin{aligned} \min_G \max_D V_{\text{GAN}}(D, G) - \lambda I(c; G(z, c)) \\ V_{\text{GAN}}(D, G) = \mathbb{E}_{x \sim \text{Data}} [\log D(x)] + \\ \mathbb{E}_{(c, z) \sim \text{Noise}} [\log(1 - DG(c, z))] \end{aligned}$$

after replacing the mutual information with a (variational) lower bound.

Adversarial feature learning
J. Donahue et al. (2017)

The BiGAN has an encoder, converting the data to features, and its discriminator uses both the data and the latent representation.

Texture networks: feed-forward synthesis of textures and stylized images
D. Ulyanov et al (2016)

To generate a texture (target), find a CNN f generating similar VGG features, *i.e.*, minimizing

$$\| \text{VGG } f(\text{noise}) - \text{VGG target} \|.$$

For style transfer, use

$$\| \text{VGG } f(\text{noise}, \text{content}) - \text{VGG target} \|,$$

where the target is fixed.

Rethinking the inception architecture for computer vision
C. Szegedy et al.

X-CNN: cross-modal convolutional neural networks for sparse datasets
P. Veličković et al.

Process the input layers separately, mix them, and merge them.

Multiplicative LSTM for sequence modelling
B. Krause et al.

Tensor RNNs have character-specific hidden-to-hidden weights

$$h(t) = W_{hh}^{x_t} h_{t-1} + W_{hx} x_t.$$

Multiplicative RNNs use a sparse description of those weight matrices

$$W_{hh}^{x_t} = W_{hm} \cdot \text{diag}(W_{mx} x_t) \cdot W_{mh}.$$

This idea can be combined with LSTMs (which already contain a multiplication).

Google's multilingual neural machine translation system: enabling zero-shot translation
M. Johnson et al.

The same network can translate into many languages: just add a token, at the beginning of the sentence, specifying the target language.

Skip-thought vectors
R. Kiros et al.

Compute sentence embeddings by reconstructing the surrounding sentences, using a seq2seq RNN with GRU units, trained on the BookCorpus dataset.

AudioSet: an ontology and human-labeled dataset for audio events
J.F. Gemmeke et al.

AudioSet is the audio equivalent of ImageNet: 600 classes, 2 million 10-second samples, from YouTube.

Unsupervised machine translation using monolingual corpora only
G. Lample et al.

Learn embedding of two languages into the same latent space, initialized with a bilingual lexicon (only words – no sentences), and learn to reconstruct a sentence from language A from a noisy version of its embedding. Add an adversarial regularization, with a discriminator to recognize the language from the latent space.

The translation loop is an example of noise.

Neural architecture search with reinforcement learning
B. Zoph and Q.V. Le (2017)

Reinforcement learning can help improve existing network architectures (number of layers, dimension, filter size, stride, etc.) and devise new LSTM-like cells.

Self-critical sequence training for image captioning
S.J. Rennie et al.

Reinforcement learning deals with non-differentiable rewards: it maximizes the *expected* reward wrt a baseline to reduce minibatch variance. Those ideas can be used for the non-differentiable evaluation metrics commonly used in natural language processing (BLEU, etc.) instead of cross-entropy.

Learning options in reinforcement learning
M. Stolle and D. Precup

Use frequently-visited states as subgoals for your reinforcement learning system to easily adapt to different goals.

Effect of reward function choices in risk-averse reinforcement learning
S. Ma and J.Y. Yu

Given a Markov decision process (MDP), one can maximize the value-at-risk (VaR) or the expected shortfall (ES, CVaR) instead of the expected discounted reward.

Hyperband: a novel bandit-based approach to hyperparameter optimization
L. Li et al. (2016)

To tune hyperparameters, *successive halving* uniformly allocates resources (number of training sets, number of features, iterations) to n random configurations, evaluates their performance, throws away the bottom half, and continues, improving the precision on the performance of the remaining configuration, until there is only one left. For a given time budget B , Hyperband tried different trade-offs between n and B/n .

Learning concept embedding with combined human-machine expertise
M.W. Wilber

Add triplet constraints $d_{ij} \leq d_{ik}$ to t-SNE (from MechanicalTurk).

***The high-dimensional geometry
of binary neural networks***
A.G. Anderson and C.P. Berg

In high dimensions, binarization approximately preserves directions and batch-normalized weight-activation dot products – but keep continuous weights for the first layer: it is very different.

***Exploring loss function topology
with cyclical learning rates***
L.N. Smith and N. Topin (2017)

Repeatedly increasing and decreasing the learning rate (e.g., $0.1 \rightarrow 1 \rightarrow 0.1$) allows the optimization to find several different minima, often better than a constant learning rate.

***Generating focused molecule libraries for drug
discovery with recurrent neural networks***
M.H.S. Segler et al.

Fit a recurrent neural net (3 stacked LSTM layers, 1024 dimensions, dropout=0.2) on the Smiles description of 1,000,000 molecules (a 1-dimensional, textual description of molecules) and use it to generate new molecules for further (in silico) testing.

***Kernel approximation methods
for speech recognition***
A. May et al.

Random features approximate the kernel trick. They can be selected iteratively: generate random features, fit the model, keep the best features; start again with a new set of random features.

The following loss functions do not penalize incorrect forecasts as much as cross-entropy:

$$\begin{aligned} & - \sum_{i,y} (\mathbf{1}_{y=y_i} + \beta p(y|x_i)) \log p(y|x_i) && \text{entropy-penalized} \\ & - \sum_i \log(p(y_i|x_i) + \lambda) && \text{capped} \\ & - \sum_{1 \leq i \leq k} \log p(y_i|x_i) && \text{top-}k. \end{aligned}$$

***World literature according to Wikipedia:
introduction to a DBpedia-based framework***
C. Hube et al. (2017)

DBpedia extracts data from Wikipedia infoboxes, using hand-written (crowd-sourced) rules. The data is not as clean as we would like: for instance, there is no single, reliable way of identifying “writers”.

***PathNet: evolution channels gradient descent
in super neural networks***
C. Fernando et al.

To learn different tasks on the same network (“evolutionary dropout”): pick a random set of paths through

the network, train the corresponding subnet, for the first task; freeze the corresponding weights; proceed to the second task.

***Deep forest: towards an alternative
to deep neural networks***
Z.H. Zhou and J. Feng (2017)

Deep models need not be limited to neural nets: use a random forest for a classification problem; concatenate its input and its output (class probabilities) and feed them to another random forest; iterate a few times. Those layers could be convolution-like, taking patches of an image or sequence as input.

***Batch renormalization:
towards reducing minibatch dependence
in batch-normalized models***
S. Ioffe

When using batch normalization with small or non-iid batches, add a (non-learned) affine transform to account for the difference in mean and variance between the minibatch and the population.

***PixelNet: representation of the pixels,
by the pixels, and for the pixels***
A. Bansal

For pixel-level predictions (semantic segmentation, edge detection, surface normal extraction), use a spatially-invariant (convolutional) model, with multi-scale features (“hypercolumns”, *i.e.*, connections from earlier, more detailed layers) and only sample a few (2000) pixels per image (to reduce the dependence, which could harm stochastic gradient descent).

***Cosine normalization: using cosine similarity
instead of dot product in neural networks***
L. Chunjie et al.

Replace the dot product $x \mapsto w \cdot x$ in neural networks with the cosine similarity (*i.e.*, correlation)

$$x \mapsto \frac{w \cdot x}{\|w\| \|x\|}.$$

***Neural audio synthesis of musical nodes
with WaveNet autoencoders***
J. Engel et al.

The NSynth dataset contains 300,000 4-second notes, from 1000 instruments, from commercial sample libraries, with different pitches and velocities.

***Learning character-level compositionality
with visual features***
F. Liu et al.

For alphabetical languages, character-level models can understand word morphology and deal with unknown words. For more complex writing systems (Chinese,

Japanese, Korean), convert the characters to 36×36 images and feed them to a CNN + GRU-CNN.

Tacotron: towards end-to-end speech synthesis
Y. Wang et al.

End-to-end speech synthesis by combining convolution (n -grams), batch normalization, residual connections, highway networks, bidirectional GRUs and attention to produce spectrogram frames.

A study of complex deep learning networks on high-performance, neuromorphic and quantum computers
T.E. Potok et al.

Adiabatic quantum computers can fit (non-restricted, *i.e.*, non-bipartite) Boltzmann machines – networks with intra-layer connections are becoming tractable.

Neuromorphic computers (spiking neural nets, SNN), built with memristors, may make computations more efficient.

Opening the black box of deep neural networks via information
R. Schwartz-Ziv and N. Tishby

Representing a learning (deep) neural net in the *information plane* ($I(\text{input}; \text{hidden})$, $I(\text{hidden}; \text{output})$) where the mutual information $I(X, Y) = \text{KL}(p_{x,y} \| p_x p_y)$ measures the information the input variable X has on the output Y , reveals two phases:

- Compressing the information, *i.e.*, increasing $I(\text{hidden}; \text{output})$ while preserving $I(\text{input}; \text{hidden})$;
- Discarding irrelevant information, *i.e.*, decreasing $I(\text{input}; \text{hidden})$, which helps generalization.

Database learning: towards a database that becomes smarter every time
Y. Park et al.

The answer to each database query can help fine-tune a probabilistic model of the data, used to speed up future queries and/or provide faster approximate results.

Active convolution: learning the shape of convolution for image classification
Y. Jeon and J. Kim

Active convolution units have no fixed shape and allow for fractional pixel coordinates.

A simple neural network module for relational learning
A. Santoro et al.

Relation networks (RN) are built from modules of the form

$$x \mapsto f_{\phi} \left(\sum_{ij} g_{\theta}(x_i, x_j) \right)$$

where f and g are multi-layer perceptrons (but it is the same g_{θ} for all pairs).

Fast algorithms for convolutional neural networks
A. Lavin and S. Gray

The *Winograd minimal filtering algorithm* computes 1- or 2-dimensional filters with the minimal number of multiplications – for the small filters used on CNNs, it is faster than the FFT.

HyperNetworks
D. Ha et al.

Hypernetworks are networks generating the weights of another network; they can be trained end-to-end with backpropagation. They can generate non-shared LSTM (or CNN) weights.

Deep feature interpolation for image content changes
P. Upchurch et al.

Deep neural networks can describe images with features in a linear (not curved) space: linear interpolation in a direction (age, gender, glasses, smile, etc.) produces high-resolution image transforms.

Fitted learning: models with awareness of their limits
N. Kardan and K.O. Stanley

For classification problems, use k neurons for each class in the output layers (instead of 1), train to set their values to 1, but use their *product* at test time – this limits overly-confident generalizations.

Unsupervised learning for physical interaction through video prediction
C. Finn et al.

Predict motion, at the pixel level, assuming that pixels do not move large distances, and that pixels are only transformed in a small number of ways (pixels belonging to the same object move in the same way).

Residual networks behave like ensembles of relatively shallow networks
A. Veit et al.

**Aggregated residual transformations
for deep neural networks**
S. Xie

Input convex neural networks
B. Amos et al.

Neural nets can be constrained to be convex functions of their input, by requiring the weights to be positive

(skip connections are useful for the network to remain expressive), or of part of the input,

$$z_{i+1} \sim z_i \odot u_i + z_i \odot y + u_i$$

by requiring part of the input (the $z \odot u$ term) to be positive.

Such networks can be used in optimization problems,

$$\underset{y}{\text{Argmin}} f(x, y; \theta).$$

**Wide and deep learning
for recommender systems**
H.T. Cheng et al.

Self-normalizing neural networks
G. Klambauer

No batch normalization is needed for the activation function

$$\text{selu}(x) = \lambda \begin{cases} x & \text{if } x > 0 \\ \alpha(e^x - 1) & \text{if } x \leq 0. \end{cases}$$

**Aggregated residual transformations
for deep neural networks**
S. Xie et al.

Put the non-linearity (purple) before or after aggregating.

Memory networks
J. Weston et al. (2015)

Add (classical) memory cells to a neural network: at each time step, the neural network decides which cells to update and how, using their contents together with the new data.

DeepCoder: learning to write programs
M. Balog et al.

Inductive program synthesis (IPS) for a simple array manipulation language (only linear control flow: head, last, take, drop, access, min, max, rev, sort, sum; map, filter, count, zip, scan; $(+1)$, (-1) , $(\times 2)$, $(/2)$, $(\times -1)$, $(^2)$, (> 0) , (< 0) , odd, even). The neural network is only used to guide more traditional approaches: stochastic local search, depth-first search, etc.

mixup: beyond empirical risk minimization
H. Zhang et al.

To help the network generalize better to examples slightly outside the training distribution, augment the data with convex combinations $(1 - \lambda)(x_1, y_1) + \lambda(x_2, y_2)$ (use one-hot-encoding for y).

Coherent line drawing
H. Kang et al.

The *edge tangent flow* of an image I is computed iteratively:

$$t_x \leftarrow \nabla I(x)^\perp$$

$$t_x \leftarrow \frac{1}{k} \sum_{\|x-y\| \leq r} \sigma(\|\nabla I(x)\| - \|\nabla I(y)\|)(t_x \cdot t_y) t_y.$$

Applying a difference of Gaussians (DoG) in the direction orthogonal to the edge flow gives a nice line drawing.

Simplex noise demystified
S. Gustavson (2005)

Simplex noise is similar to Perlin noise, but replaces hypercubes with simplices, which facilitates interpolation.

SATGraf: visualizing the evolution of SAT formula structures in solvers
Z. Newsham et al. (2014)

To visualize how SAT solvers transform a boolean formula, look at the *clause-variable incidence graph* – its community structure is related to the running time.

Network risk and financial crisis
Y.A. Chen (2015)

Build a parametric portfolio from the Katz centrality

$$\mathbf{x} = \gamma \mathbf{A} \mathbf{x} + \beta \mathbf{1}$$

of the weighted network defined by the variance of residual returns.

Compute the beta of each stock wrt that portfolio; decompose the idiosyncratic volatility into “network volatility” and a remainder.

Media network and return predictability
L. Guo and Y. Tao (2017)

The connection score of two stocks i, j , is

$$CS_{ij} = \sum_k \text{tone}_{ik} \times \text{tone}_{jk}$$

where the sum is over all news mentioning both i and j and the tone is in $[-1, 1]$.

The media connection index

$$\frac{\sum_{i \neq j} CS_{ij}}{\sum_{ij} CS_{ij}}$$

can be used as a risk measure.

Deep stock representation learning: from candlestick charts to investment decisions
G. Hu et al.

Feed candlestick charts (*i.e.*, images), for the FTSE 100 stocks, to a convolutional autoencoder; cluster them using the resulting latent representation, with a community detection algorithm (no need to specify the number of clusters); invest in the stocks with the largest Sharpe ratio in the cluster.

Local explosion modelling by noncausal processes
C. Gouriéroux and J.M. Zakoian (2016)

Non-causal AR(1) processes can model bubbles growing and bursting; aggregating them allows for different rates of increase (*e.g.*, a continuous distribution); one can also add a (causal, Gaussian) AR(1).

The myths and limits of passive hedge fund replication
N. Amenc et al. (2007)

There are two approaches to replicate hedge funds (neither works well):

- Compute the exposure of hedge fund returns to a set of pre-selected factors;
- Build an option, on a reference asset (anything, *e.g.*, S&P 500) and choose the payoff function giving the desired payoff distribution (“moment matching”). The price of that option can be used as a measure of performance. This “replicating” strategy has comparable returns, but not at the same times. The first moment is not captured: the returns are lower. [There is a bivariate, copula-based variant but it only models (portfolio, underlying), not (portfolio, fund).]

Possible improvements to capture nonlinearities, dynamic trading, non-stationarity and time series properties include:

- Heuristic dynamic (rule-based) strategies;
- Instrumental variables for time- and state-dependence;
- Future factor loading forecasts;
- Time-varying models (Kalman filter, particle filter, Markov switching);
- Ad hoc options portfolios (*e.g.*, ATM and OTM puts and calls on S&P 500);
- Statistical techniques to estimate the options (and underlyings) needed.

An alternative approach to alternative beta
T. Toncalli and J. Teïletche (2007)

Use the Kalman filter to estimate time-dependent factor exposures. It also decomposes the returns (for one period) into traditional (*i.e.*, average) beta, alternative (difference with the average) beta and alpha (residual, intercept).

Tracking problems, hedge fund replication and alternative beta
T. Roncalli and G. Weisang (2008)

The Kalman filter provides (Gaussian, linear) factor exposures. The unscented Kalman filter (UKF) allows for non-Gaussian innovations. One can add non-linear assets to the list of factors; if they depend on a parameter (say, a strike), it can be modeled as a random walk, as part of the hidden state, but the model becomes nonlinear – use a particle filter (PF, sequential Monte Carlo, SMC). Hedge fund performance can be decomposed into: traditional beta, alternative beta, lag (alternative beta one period ahead), alternative alpha (the rest – this includes illiquid assets).

Regular(ized) hedge fund clones
D. Giamouridis and S. Paterlini (2009)

Use the lasso for factor-based hedge fund replication [the resulting weights are biased towards zero].

***Can hedge fund returns be replicated?
The linear case***
J. Hasanhodzic and W. Lo

Replicate individual hedge funds using in-sample or 24-month rolling window regressions against USD, AA bonds, BAA—treasury, S&P 500, commodities (GSCI) and VIX monthly changes, with no intercept, weights summing to 1, and using leverage to match the target’s volatility. The clones have lower autocorrelation (a proxy for illiquidity).

***Hedge fund replication:
putting the pieces together***
V. Weber and F. Peres (2013)

Do not only use static factors, but also dynamic ones (carry, momentum). Correct hedge fund returns for illiquidity:

$$\hat{R}_t = \frac{R_t - \alpha R_{t-1}}{1 - \alpha} \quad (\text{Gettner})$$

R_t = observed returns
 α = $\text{Cor}(R_t, R_{t-1})$.

***Send in the clones?
Hedge fund replication using futures contracts***
N.P.B. Bollen and G.S. Fisher (2012)

Replicating hedge fund indices [many people invest in funds of funds] with futures (USD, 10-year, gold, oil, S&P 500) using 1 to 4 year rolling window regressions gives poor performance and shows no sign of market timing, $r \sim \sum f_i + \sum 1_{f_i > 0} f_i$; the clone-target correlation is high, but mostly due to market exposure.

***Hedge fund replication:
a model combination approach***
M.S. O’Doherty et al. (2016)

Instead of directly estimating a linear replication model, estimate separate replication models, using domestic equities (S&P 500, S&P Midcap 400), international equities (FTSEE 100, Nikkei 225), currencies (GBP, CHF, JPY) and commodities (gold, corn, oil) and average using “log-scale” weights (BMA).

A primer on alternative risk premia
R. Hamdan et al. (2016)

Five concerns with the five-factor model
D. Blitz et al.

The two factors added to the Fama-French model (market, size, value, profitability, investment) are not robust, lack an economic rationale, and still ignore momentum.

***Bayesian Poisson Tucker decomposition
for learning the structure
of international relations***
A. Schein et al. (2016)

Model international relations (country i takes action a on country j at time t) using country-community, action-topic and time-regime factor matrices:

$$y_{i \rightarrow j}^t \sim \text{Poisson} \left(\sum_c \theta_{ic} \sum_d \theta_{jd} \sum_k \phi_{ak} \sum_r \psi_{tr} \lambda_{c \rightarrow d}^r \right)$$

with Gamma priors, estimated with MCMC.

A gentle introduction to value at risk
L. Ballotta and G. Fusai (2017)

The idiosyncratic momentum anomaly
D. Blitz et al. (2017)

Use idiosyncratic momentum (rather than total momentum) to forecast future returns.

***Deep learning for forecasting stock returns
in the cross-section***
M. Abe and H. Nakayama (2018)

Deep neural networks, with 1 to 6 fully-connected hidden layers, 50% dropout, tanh activations, to forecast (uniformized) 1-month ahead stock returns for MSCI Japan, from 25 (uniformized) investment factors, both current and past values (3, 6, 9 and 12 months), trained for 100 epochs on universe-sized minibatches, on a 10-year window.

***Proofs are programs:
19th century logic and 21st century computing***
P. Wadler (2000)

Frege’s logic considers judgments (e.g., $\vdash A$), axioms (e.g., $\vdash A \rightarrow A$) and deduction rules, e.g.,

$$\frac{\vdash B \rightarrow A \quad \vdash B}{\vdash A}.$$

Gentzen’s logic adds assumptions to the judgments (e.g., $B_1, \dots, B_n \vdash A$ instead of $\vdash A$) and to the deduction rules, e.g.,

$$\frac{\Gamma \vdash B \rightarrow A \quad \Delta \vdash B}{\Gamma, \Delta \vdash A}.$$

While this may look more complex (in particular, the three if-then notions: \rightarrow for propositions, \vdash for judgments and \div in the inference rules), the deduction rules end up simpler and more intuitive.

Typed λ -calculus has typing judgments (e.g.,

$$x_1 : B_1, \dots, x_n : B_n \vdash t : A,$$

meaning that if the x_i ’s have types B_i , then t has type A) and the same deduction rules as Gentzen’s system, e.g.,

$$\frac{\Gamma \vdash t : B \rightarrow A \quad \Delta \vdash u : B}{\Gamma, \Delta \vdash t(u) : A}.$$

(Unless we explicitly add recursion, all functions terminate and the calculus is not Turing-complete.) Term reduction corresponds to proof simplification (Curry-Howard correspondance).

***Physics, topology, logic and computation:
a Rosetta stone***

J.C. Baez and M.M. Stay (2009)

Variants of monoidal categories

- braided: $\swarrow \searrow$
- symmetric: $\swarrow \searrow = \searrow \swarrow$
- cartesian: $\otimes = \times$
- closed: $\otimes \dashv \underline{\text{Hom}}$
- compact: $\underline{\text{Hom}}(X, Y) = X^* \otimes Y$
- dagger (with a functor $\dagger : \mathfrak{C} \rightarrow \mathfrak{C}^{\text{op}}$, the identity on $\text{Ob } \mathfrak{C}$, with $f^{\dagger\dagger} = f$)

appear in many domains, e.g.,

- cobordisms
- tangles in \mathbf{R}^n
- finite-dimensional Hilbert spaces (the inner product gives a dagger structure)
- finite-dimensional representations of a Lie (resp. quantum) group form a compact symmetric (braided) monoidal category.

Propositional calculus forms a monoidal category with propositions as objects, a single morphism $X \rightarrow Y$ whenever $X \Rightarrow Y$, and $\otimes = \wedge$, $\underline{\text{Hom}}(X, Y) = X \Rightarrow Y$. It is a **Heyting algebra**, *i.e.*, a preorder \mathfrak{C} such that \mathfrak{C} and \mathfrak{C}^{op} be cartesian closed.

Linear logic replaces $\wedge, \Rightarrow, \top$ with \otimes, \multimap and I and only requires a symmetric monoidal category, not a cartesian closed one: there are no natural morphisms $X \rightarrow X \otimes X$ or $X \rightarrow I$, *i.e.*, we cannot duplicate or delete information (as in quantum physics or chemistry).

Alternatively, one can consider propositions as objects and proofs as morphisms, where the proofs are obtained from inference rules, *i.e.*, natural or *dinatural* transformations, most of which come from the monoidal/braided/cartesian structure.

In **λ -calculus**, everything is a function. For instance, **Church numerals** are

$$\begin{aligned} 0 &= \lambda f \mapsto \lambda x \mapsto x & f &\mapsto \text{id} \\ 1 &= \lambda f \mapsto \lambda x \mapsto f(x) & f &\mapsto f \\ 2 &= \lambda f \mapsto \lambda x \mapsto f(f(x)) & f &\mapsto f^2 \end{aligned}$$

and addition and multiplication are

$$\begin{aligned} \text{times} &= \lambda a \lambda b \lambda f \lambda x \ a(b(f)) \\ \text{plus} &= \lambda a \lambda b \lambda f \lambda x \ a(f)(b(f)(x)). \end{aligned}$$

(I write $\lambda x \mapsto t$ or $\lambda x \ t$ instead of $(\lambda x.t)$ and dispense with many of the parentheses.)

Typed λ -calculus, where every term has a type, forms a cartesian closed category with types as objects and equivalence classes of terms as morphisms (if we

do not focus on *what* is computed but *how* it is computed, we get a 2-category, with terms as morphisms and equivalence classes to rewrites as 2-morphisms).

Linear type theories correspond to symmetric monoidal categories. They can also be described by **combinators**. The usual ones

$$\begin{aligned} I &= \lambda x \mapsto x \\ K &= \lambda x \mapsto \lambda y \mapsto x \\ S &= \lambda x \mapsto \lambda y \mapsto \lambda z \mapsto x(z)(y(z)) \end{aligned}$$

cannot do because K forgets information and S duplicates it. Each term t is equivalent to $\text{cp}(t) \text{vp}(t)$, where $\text{cp}(t)$ is the combinator part and $\text{vp}(t)$ the variable part.

Internal set theory
E. Nelson (2002)

There are two ways of presenting non-standard analysis: either explicitly, by constructing the hyperreals, or by tweaking the ZFC axioms (*internal set theory*):

- The subset axiom, to define $\{x \in X : A(x)\}$, is only valid for internal formulas A (those which do not use the “standard” predicate);
- Transfer: $\forall^{\text{st}} t_1 \dots \forall^{\text{st}} t_n (\forall^{\text{st}} x A \Leftrightarrow \forall x A)$, for any internal formula A ;
- Idealization: $\forall^{\text{stfin}} X \exists y \forall x \in X A \Leftrightarrow \exists y \forall^{\text{st}} x \in X A$ (for A internal);
- Standardization:

$$\forall^{\text{st}} X \exists^{\text{st}} Y \forall^{\text{st}} z (z \in Y \Leftrightarrow z \in X \wedge A(z))$$

for any formula A (internal or external), which allows us to define $^S\{z \in X : A(z)\}$ the standard set whose standard elements are the standard elements z of X such that $A(z)$.

The “standard” predicate is no longer limited to real numbers, but applies to sets, functions, topological spaces, points in topological spaces, etc.

Includes exercises. Check *Radically elementary probability theory*, by the same author, on probability theory with non-standard finite probability spaces.

Division by three
P.G. Doyle and J.H. Conway (1994)

Proving $A \times 3 \approx B \times 3 \implies A \approx B$ does not require the axiom of choice.

***Developing bug-free machine learning systems
with formal mathematics***
S. Selsam et al. (2017)

The **lean** theorem prover tries to combine program verification (à la Coq) and formal mathematics (à la Mizar). Here, it is used for a provably correct gradient descent implementation.

**The ring of algebraic functions
on persistence bar codes
A. Adcock et al. (2013)**

To turn a barcode $[x_1, y_1], \dots, [x_n, y_n]$ into features, for machine learning, use multisymmetric polynomials $p_{ab} = \sum_i x_i^a y_i^b$, for instance

$$\begin{aligned} & \sum x_i(y_i - x_i) \\ & \sum (y_{\max} - y_i)(y_i - x_i) \\ & \sum x_i^2(y_i - x_i)^4 \\ & \sum (y_{\max} - y_i)^2(y_i - x_i)^4. \end{aligned}$$

Barcodes form an affine (semi)algebraic ind-variety, with ring of algebraic functions $\Lambda_2 = \varinjlim k[x_1, y_1, \dots, x_n, y_n]^{\mathfrak{S}_n}$ (multisymmetric polynomials), quotiented by an ideal $D = \varinjlim D_n$ corresponding to the identification of intervals of length zero. Λ_2 is freely generated by the multisymmetric power sums $p_{ab} = \sum_i x_i^a y_i^b$, and D by the $p_{a+1,b} - p_{a,b+1}$.

An alternative is to use the bottleneck or Wasserstein distance.

**Persistent homology
H. Edelsbrunner and D. Morozov
(Handbook of discrete
and computational geometry, 2017)**

The implementation details are not that complicated.

**High-dimensional topological data analysis
F. Chazal (Handbook of discrete
and computational geometry, 2017)**

1. A subset $X \subset \mathbf{R}^n$ can be represented by its distance function

$$\phi : \begin{cases} \mathbf{R}^n & \rightarrow \mathbf{R}_+ \\ x & \mapsto d(x, X) \end{cases}$$

(it is proper and $x \mapsto \|x\|^2 - \phi(x)^2$ is convex). To increase the robustness to outliers, consider measures instead of subsets, e.g., $\mu = \sum_{x \in X} \delta_x$ if X is discrete, and the functions

$$\delta_{\mu, \ell} : \begin{cases} \mathbf{R}^n & \rightarrow \mathbf{R}_+ \\ x & \mapsto \inf\{r > 0 : \mu(B(x, r)) > \ell\} \end{cases}$$

They are not smooth, but the **distance to measure** $d_{\mu m}^2$ is

$$d_{\mu m}^2 : \begin{cases} \mathbf{R}^n & \rightarrow \mathbf{R}_+ \\ x & \mapsto \frac{1}{m} \int_0^m \delta_{\mu, \ell}(x)^2 d\ell \end{cases}$$

(it is the average of the squared distances from x to its k nearest neighbours). If two measures μ and ν are close (for the Wasserstein distance), then the sublevel sets of their distance-to-measure functions are homotopy equivalent (**reconstruction** theorem).

2. For many tasks, full reconstruction is not needed and a few homotopy or **homology** invariants suffice.

In particular, the **nerve** of an open cover $X = \bigcup_i U_i$ all of whose finite intersections are contractible is homotopy equivalent to X (nerve theorem).

3. **Persistent homology** keeps track, not only of the dimensions of the homology groups (Betti numbers) of $\bigcup_{x \in X} B(x, \varepsilon)$ as ε increases, but also of individual connected components, cycles and cavities – the result, the $(\text{birth}_i, \text{death}_i)$ pairs, forms the **persistence diagram**. The **bottleneck distance** between two persistence diagrams D and D' is the smallest $\delta > 0$ for which we can match all points of D at distance at least δ from the diagonal with a point of D' at distance at most δ . It is bounded by twice the Gromov-Hausdorff distance.

4. The **Mapper** algorithm visualizes a dataset $X \subset \mathbf{R}^n$ and a function $f : X \rightarrow \mathbf{R}$ by choosing an open cover $\bigcup I_i$ of $f(X) \subset \mathbf{R}$ by intervals, clustering the points in each $f^{-1}(I_i)$ into a (finite) cover, and plotting the 1-skeleton of the corresponding cover of X .

**Topological analysis of financial time series:
landscapes of crashes
M. Gidea and Y. Katz (2017)**

The **persistence landscape** is obtained from the (birth, death) persistence diagram by flipping it 45°, associating a piecewise function to each birth-death pair, and considering the sequence of functions given by the k th largest values. While persistence diagrams form a (non-complete) metric space for the Wasserstein distance, persistence landscapes form a Banach space for the L^p norm. (Measure theory on an infinite dimensional Banach space is a little more complicated: for instance, the notions of weak (Pettis) and strong (Bochner) integrability differ.)

The L^1 or L^2 norm of the persistence landscape of the daily returns of a few indices (S&P 500, DJIA, Nasdaq, Russel 2000) on a 50-day window may help forecast crises.

**Statistical topological data analysis
using persistence landscapes
P. Bubenik (2015)**

Initial paper on persistence landscapes.

**A persistence landscapes toolbox
for topological statistics
P. Bubenik and P. Dłotka**

Standalone, file-based C++ implementation (computing persistence landscapes, their averages, their L^p distances). Also check the TDA R package.

Topology-based data analysis identifies a subgroup of breast cancers with a unique mutational profile and excellent survival
M. Nicolau et al. (2011)

The **mapper** algorithm takes a cloud of points \mathcal{X} and a (Morse) function $f : \mathcal{X} \rightarrow \mathbf{R}$ (e.g., a random projection, a measure of density, a distance to a baseline, an eccentricity measure), applies a clustering algorithm to the points in each $f_a = f^{-1}([a - \varepsilon, a + \varepsilon])$, and builds a graph with those clusters as nodes and edges between $x \in f_a$ and $y \in f_b$ if $x \cap y \neq \emptyset$ (partial clustering, discrete Morse theory). In R, check **TDAmapper**.

It is another way of “filtering” a cloud of points into a graph, keeping most of its features (loops, appendages, etc.).

Topological methods for the analysis of high dimensional datasets and 3D object recognition
G. Singh et al.

In the Mapper algorithm, using several Morse functions defines a simplicial complex instead of a graph – and letting ε vary leads to persistence homology.

The Topology Toolkit
J. Tierny et al.

Topological data analysis (TDA) is not a single algorithm (Mapper, or persistence homology, depending in who you ask), but a smogasbord of techniques. TTK is a library (C++, BSD, accessible from Python) and graphical toolkit (built on Paraview) using low-dimensional TDA (mostly discrete Morse theory) to visualize scientific data (PDE solutions and other scalar fields).

The data is given as a Morse function $f : \mathcal{M} \rightarrow \mathbf{R}$, i.e., a scalar field (or several of them); in contrast with high-dimensional TDA, the PL manifold \mathcal{M} is often uninteresting (\mathbf{R}^2 or \mathbf{R}^3).

TDA studies the transitions of the Betti numbers $\beta_k f^{-1}\{x\}$ or $\beta_k f^{-1}]-\infty, x]$ or $\beta_k f^{-1}[x, +\infty[$ as x varies.

A point is *critical* if one of

$$\begin{aligned} \text{Link}^+(p) &= \{q \in \text{Neigh}(p) : f(q) > f(p)\} \\ \text{Link}^-(p) &= \{q \in \text{Neigh}(p) : f(q) < f(p)\} \end{aligned}$$

is not simply connected. Critical points can be paired into birth-death pairs, defining a *persistence diagram*. To simplify f , one can prune short-lived pairs (those whose persistence, $f(\text{death}) - f(\text{birth})$ is small). The *persistence curve* is the plot of the number of critical points with persistence at least x , as x increases.

The *Reeb graph* segments \mathcal{M} into regions where $\pi_0 f^{-1}c$ does not change.

The *Morse complex* is defined by the attraction bassins of f .

Subsampling methods for persistent homology
F. Chazal et al. (2015)

Compute the persistence landscape on several subsamples and average them.

Equilibrated adaptive learning rates for non-convex optimization
Y.N. Dauphin et al.

In the presence of different curvatures, in particular around a saddle point, gradient descent oscillates a lot. **Preconditioning** uses a change of variables,

$$\begin{aligned} \theta &= D^{-1/2} \hat{\theta} \\ \hat{f}(\hat{\theta}) &= f(D^{-1/2} \hat{\theta}) = f(\theta) \\ \nabla \hat{f} &= D^{-1/2} \nabla \\ \nabla^2 \hat{f} &= D^{-1/2'} (\nabla^2 f) D^{-1/2} \\ \theta_{t+1} &\leftarrow \theta_t - \eta D^{-1} \nabla f(\theta_t). \end{aligned}$$

The *absolute Hessian* (defined from the eigen-decomposition of the Hessian, by taking the absolute value of the eigenvalues) gives a perfect conditioner (the curvature is the same in all directions), $D = |H|$, but it is computationally expensive.

The *Jacobi conditioner* is the diagonal of the Hessian. It could be estimated as

$$\text{diag } H = \mathbb{E}_{v \sim \text{Unif}(\{\pm 1\}^n)} [v \odot H v].$$

AdaGrad, AdaDelta, RMSProp are other diagonal conditioners.

The *equilibrium conditioner* is the diagonal of the absolute Hessian; it can be defined as the L^2 norm of the rows of the Hessian; it can be estimated as

$$\|H_{i\cdot}\|^2 = \mathbb{E}_{v_i \sim N(0,1)} [(Hv)^2].$$

A smart stochastic algorithm for nonconvex optimization with applications to robust machine learning
A. Aravkin and D. Davis

Machine learning minimizes $\sum_{1 \leq i \leq n} f_i(x)$. Trimmed machine learning minimizes $\sum_{1 \leq i \leq k} f_{(i)}(x)$, where $f_{(i)}(x)$ are the order statistics of $(f_i(x))_i$.

The problem can be formulated as

$$\begin{aligned} \text{Find} \quad & w \in \mathbf{R}^n, x \in \mathcal{H} \\ \text{To minimize} \quad & \frac{1}{n} \sum_i w_i f_i(x) + r_1(w) + r_2(x) \\ \text{Where} \quad & r_1 = \mathbf{1}_{\Delta_h} \\ & \Delta_h = \{w \in [0, 1]^n : w' \mathbf{1} \leq h\}. \end{aligned}$$

and solved by proximal alternating minimization ($w \leftarrow \text{prox}_{r_1}(\dots)$, $x \leftarrow \text{prox}_{r_2}(\dots)$). With mini-batches, use variance reduction (SVRG).

Model calibration with neural networks
A. Hernandez (2016)

Given enough training data, optimization can be replaced with a trained neural net.

Pymanopt: a Python toolbox for optimization on manifolds using automatic differentiation
J. Townsend et al. (2016)

Automatic differentiation can also compute (first and second) derivatives on Riemannian manifolds.

Learning to learn for global optimization of black box functions
Y. Chet et al.

A recurrent neural network (RNN: LSTM or differentiable computer) can learn to reproduce what a Bayesian blackbox optimizer does (it uses its memory to store information about the previous function evaluations). It is much faster than GP-based algorithms, and competitive in case of model mis-specification.

Understanding deep learning requires rethinking generalization
C. Zhang et al.

We still do not know why deep neural networks work well: VC dimension, Rademacher complexity, uniform stability, explicit/implicit regularization, model capacity fail to explain why they generalize so well in some cases (real data) but not others.

A tutorial on Bayesian optimization of expensive cost functions, with applications to active user modeling and hierarchical reinforcement learning
E. Brochu et al. (2010)

An entropy search portfolio for Bayesian optimization
B. Shahriari et al.

Use a portfolio of acquisition functions and follow that giving the largest decrease in the uncertainty of the location of the minimizer (or sample accordingly).

A theoretical analysis of optimization by Gaussian continuation
H. Mobahi and J.W. Fisher (2015)

Optimization by continuation [or mollifying] starts to optimize an easy simplification (e.g., a convex relaxation) of the problem, and progressively transforms it into the actual task.

The irace package: iterated racing for automatic algorithm configuration
M. López-Ibáñez et al.

Implementation of the iterated F-race algorithm, with a few extensions (other statistical tests, restarts, etc.).

Guaranteed non-convex optimization: submodular maximization over continuous domains
A.A. Bian et al. (2016)

The notion of *submodularity* can be generalized to continuous domains: for $f : \mathbf{R}^n \rightarrow \mathbf{R}$, the following conditions are equivalent.

- (i) $f(x) + f(y) \geq f(x \wedge y) + f(x \vee y)$, where \wedge and \vee are the coordinate-wise min and max;
- (ii) $\forall x \forall i \neq j \frac{\partial^2 f}{\partial x_i \partial x_j} \leq 0$;
- (iii) $f(\lambda e_i + a) - f(a) \geq f(\lambda e_i + b) - f(b)$, whenever $a \leq b$, $a_i = b_i$, $\lambda \geq 0$, where e_i is the i th basis vector.

Best subset selection via a modern optimization lens
D. Bertsimas et al. (2015)

Best subset selection for linear regression can be done exactly for $p \leq 30$ (**leaps**), with the lasso, or with *non-convex penalized regression*; the minimax concave penalty (MCP), implemented in **Sparsenet**, is quadratic for β small and then constant; the smoothly clipped absolute deviation (SCAD) penalty is linear, then quadratic, then constant.

Progress in mixed integer programming makes solving the exact problem reasonable for $p = 100$, $n = 1000$.

Hard thresholding computes $H_k(x) = \underset{\|\beta\|_0 \leq k}{\text{Argmin}} \|\beta - c\|_2^2$.

If g is Lipschitz and convex,

$$g(\eta) \leq g(\beta) + \frac{L}{2} \|\eta - \beta\|_2^2 + \langle \nabla g(\beta), \eta - \beta \rangle.$$

To solve

$$\underset{\beta}{\text{Minimize}} g(\beta) \text{ subject to } \|\beta\|_0 \leq k$$

for g lipschitz and convex, iterate

$$\beta_{m+1} \leftarrow H_k\left(\beta_m - \frac{1}{L} \nabla g(\beta_m)\right)$$

(discrete projected gradient) until $\|\Delta\beta\|_2 \leq \varepsilon$; then solve the continuous problem for the corresponding non-zero coordinates.

A line search $\beta_{m+1} = (1 - \lambda)\beta_m + \lambda H$ gives better empirical performance.

Subgroup discovery
M. Atzmueller (2005)

Subgroup discovery (SD) is a frequent-itemset-based supervised clustering technique: after extracting frequent association rules for the target variable, select a small number of them with good quality (measured by some statistical test: χ^2 , gof, etc.) so that they hardly overlap and have good coverage.

***Anytime discovery of a diverse set of patterns
with Monte Carlo Tree search***
G. Bosc et al.

Pattern mining is a form of structured learning (progressively build patterns, one element at a time): Monte Carlo Tree Search (MCTS) produces more diverse rules than greedy approaches.

***On b-bit min-wise hashing for large-scale
regression and classification with sparse data***
R.D. Shah and N. Meinshausen (2016)

Large-scale datasets (large p , large n , but sparse) can be tackled with random projections ($X \mapsto XA$, A random) or sketches ($X \mapsto AX$). *b-bit min-wise hashing* reduces a large sparse binary matrix X as follows:

- Pick a random permutation of the columns;
- In each row, find the index (in the permuted matrix) of the first non-zero value;
- Use the last b bits of those indices as b new columns in the compressed matrix;
- Repeat a few times with more permutations.

“Similarity” between rows is preserved.

***Sparse solutions to nonnegative linear systems
and applications***
A. Bhaskara et al.

To solve $Ax = b$, where A , x , b have nonnegative coefficients and $\|b\|_1 = 1$, increment x coordinatewise while keeping the “potential” $\Phi(x) = \sum_j b_j(1 + \delta)^{(Ax)_j/b_j}$ small; a small number of iterations leads to a sparse approximate solution.

***Phase recovery from a Bayesian point of view:
the variational approach***
A. Drémeau and F. Krzakala

The phase recovery problem, finding $x \in \mathbb{C}^n$ such that $y = |Dx|$, can be solved by alternating projections, convex relaxation, or variational Bayes.

***Katyusha: the first direct acceleration
of stochastic gradient methods***
Z. Allen-Zhu (2016)

Katyusha momentum combines variance reduction and

momentum.

$$\begin{aligned}x_{n+1} &\leftarrow \lambda z_n + \mu x^* + (1 - \lambda - \mu)y_n \\i &\sim U(\llbracket 1, n \rrbracket) \\ \nabla_{n+1} &\leftarrow \nabla f(x^*) + \nabla f_i(x_{n+1}) - \nabla f_i(x^*) \\ y_{n+1} &\leftarrow x_{n+1} - \beta \nabla_{n+1} \\ z_{n+1} &\leftarrow z_n - \alpha \nabla_{n+1} \\ x^* &\text{ updated from time to time}\end{aligned}$$

Incorporating Nesterov momentum into Adam
T. Dozat

***Adding gradient noise improves learning
for very deep networks***
A. Neekakantan et al. (2015)

***Exploiting the structure:
stochastic gradient methods using raw clusters***
Z. Allen-Zhu et al. (2016)

(LSH-based) approximate clustering transforms “big data” into “data”; the clusters can improve variance reduction in SVRG.

Lip reading sentences in the wild
J.S. Chung et al.

Curriculum learning.

***Machine teaching:
an inverse problem to machine learning
and an approach toward optimal education***
X. Zhu

Machine teaching is the inverse problem of machine learning (ML): not going from training data to fitted model, but manufacturing a training dataset for which the ML algorithm of interest would derive the desired model.

Unitary evolution recurrent neural networks
A. Arjovsky et al. (2016)

To avoid exploding or vanishing gradients, use (real) unitary weight matrices (all eigenvalues have modulus 1). Unitary matrices are not easy to parametrize: model them as products of

- (Complex) diagonal matrices;
- Reflexions: $R = I - 2vv^* / \|v\|^2$, $v \in \mathbb{C}^n$;
- Permutation matrices (use a single, fixed one);
- Fourier and inverse Fourier transforms.

**Full-capacity
unitary recurrent neural networks**
S. Wisdom et al. (2016)

Unitary matrices can eliminate the vanishing/exploding gradient problem in RNNs. Instead of using a parametrization of some of those matrices, consider them as points on the (Stiefel) manifold of unitary matrices.

Self-normalizing neural networks
G. Klambauer et al.

Batch/layer/weight normalization may not be needed: scaled exponential linear units (SELU)

$$f(x) = \begin{cases} \lambda x & \text{if } x \geq 0 \\ \alpha(e^x - 1) & \text{if } x < 0 \end{cases}$$

with $\lambda > 1$ (e.g., $\lambda = 1.0507$, $\alpha = 1.7581$) are self-normalizing, in the sense that if $X \sim N(0,1)$ then $Ef(X) = 0$ and $\text{Var } f(X) = 1$ and if X is close to standardized, then $f(X)$ is more so.

**Understanding the difficulty of training
deep feedforward neural networks**
X. Glorot and Y. Bengio (2010)

Xavier initialization suggests to select the random initial weights so that the activations of all layers have zero mean and unit variance.

**Modeling temporal dependencies in
high-dimensional sequences: applications to
polyphonic music generation and transcription**
N. Boulanger-Lewandowski et al. (2012)

Restricted Boltzman machines (RBM) economically model high-dimensional discrete distributions. A recurrent temporal RBM (RTRBM) is a sequence of RBMs whose parameters are a (fixed) linear function of the previous hidden state. An RNN-RBM is a sequence of RBMs whose parameters are given by a recurrent neural net (RNN). They can be used as a prior to improve the accuracy of polyphonic transcription.

WaveNet: a generative model for raw audio
A. can den Oord et al.

To generate raw audio samples (16 000 Hz), use dilated causal convolutions, gated units, residual and skip connections.

Strongly-typed recurrent neural networks
D. Balduzzi and M. Ghifary (2016)

Physicists' dimension analysis suggests RNN, LSTM, GRU variants.

**Learning scalable deep kernels
with recurrent structure**
M. Al-Shedivat et al.

Adding a Gaussian process (GP) layer to a recurrent neural net (RNN) and using the negative log-marginal likelihood as objective is problematic: the objective no longer factorizes over the data and stochastic optimization cannot be used – but semi-stochastic alternating gradient descent (full gradient for the GP parameters, stochastic gradient for the RNN) is good enough.

**Professor forcing: a new algorithm
for training recurrent networks**
A. Lamb et al. (2016)

Recurrent neural networks (RNN) generate sequences one character at a time, each conditional on the previous ones. During training, one can use:

- The previous characters of the ground truth sequence (“teacher forcing”, maximum likelihood);
- The previous outputs;
- A mixture of both;
- An adversarial approach, training another model to distinguish between true and generated sequences, and using its performance as a penalty.

**Improved semantic representations
from tree-structured
long short-term memory networks**
K.S. Tai et al.

LSTMs can be generalized from chains to trees.

**Deep recursive neural networks
